Work stress continues to interest researchers, as illustrated by studies identified in this review that focused on occupations other than health care. For example, in a 3-year study of 14,337 middle-aged men, there was no strong evidence that job demands or job strain were predictors of coronary heart disease (CHD).[21] Findings did verify, however, that a supportive work environment helped reduce CHD. The importance of work support was corroborated in a study of 1,786 lower-ranking enlisted Army soldiers where support helped decrease psychological strain from job demands.[22] A study of 472 Air Force personnel illustrated high levels of work stress in 26 percent of the respondents, with 15 percent claiming work-related emotional distress and 8 percent noting work stress negatively affected their emotional health.[23] Finally, in a sample of 25,559 male and female German workers, the combined effects of exposure to work stress and downsizing contributed to more symptoms than either experience alone.[24]

Stress in the Health Care Professions

Numerous recent studies have explored work stress among health care personnel in many countries. Investigators have assessed work stress among medical technicians,[25] radiation therapists,[26] social workers,[27] occupational therapists,[28] physicians,[29–33] and collections of health care staff across disciplines.[34–38] Most of the studies focused on nurses, but the studies were not always clear regarding which types of nursing personnel participated. Registered nurses (RNs) were the dominant focus.[39–83] Other investigations considered licensed practical nurses (LPNs) and nursing aides;[84–86] licensed nurses (e.g., RNs and LPNs);[87–90] RNs, aides, and clerical staff;[91] and generic assessments of nursing staff.[92–104]

Only four of these investigations considered the effect of stress and burnout among nurses on patient outcomes.[40, 56, 90, 99] These studies examined burnout in relation to increased mortality, failure to rescue,[40, 56] and patient dissatisfaction.[90, 99] Similarly, in an investigation of the relationship between personal stress and clinical care, 225 physicians reported 76 incidents in which they believed patient care was adversely affected by their stress.[30]

Most of the investigations explored the effects of work stress and burnout on health care personnel in acute care settings. Staff working in long-term care (LTC)[102] and nursing homes[84, 85, 100] were the focus of four studies, however. Interestingly, two reports from nursing homes found that staff experienced more stress when caring for patients with dementia.[84, 100] In addition, possible differences among types of nursing personnel were illustrated in a study of rural nursing homes where aides reported more job strain than RNs.[100]

Findings are also emerging about differences in work stress based on shift length and generational cohort. Generational differences were explored in a single-site report of 413 RNs, in which baby boomers (43 percent) and Generation Xers (41 percent) had different perceptions of work stress.[78] The investigators expanded their work to four hospitals in the Midwest (N = 694 RNs).[77] Baby boomers comprised 53 percent of the sample; their scores for stress and strain variables were significantly worse than nurses in the older and younger cohorts. The baby boomers also had significantly less social support.

Shift length, 8-hour versus 12-hour, was explored in relation to both burnout[95] and role stress.[60] In a random sample of Michigan nurses, RNs working 12-hour shifts (n = 105) reported significantly higher levels of stress than RNs working 8-hour shifts (n = 99).[60] However, when differences in experience were controlled, stress was similar in both groups. Conversely, a study from Poland illustrated that nurses working 12-hour shifts (n = 96) compared unfavorably in several aspects to nurses working 8-hour shifts (n = 30).[95] Although the type of nursing personnel involved was unclear, the nurses on 12-hour shifts experienced significantly more chronic fatigue, cognitive anxiety, and emotional exhaustion.

Gender and Family Obligations

The complexity of work stress is further illustrated in two studies that considered gender effects. The prevalence of burnout was studied in a convenience sample of hospital-based neonatologists (n = 86) and office-based pediatricians (n = 97).[32] Although the prevalence of burnout was comparable between the specialty groups, burnout was found more frequently in female physicians (79 percent) than male physicians (62 percent). In a study of female physicians, 51 working full-time and 47 working reduced hours, burnout was not related to number of hours worked per se.[29] Rather, burnout was lower if female physicians worked the number of hours they preferred (r = -0.22, P = 0.03). These studies may have particular relevance for nursing because the profession is predominately female.

Findings from studies that explored family-work conflict in relation to stress, burnout, and well-being indicated the importance of considering both work and family spheres.[25, 29, 38, 44, 45, 86, 94] An investigation conducted using a diverse sample of 342 nonprofessional employees (17 percent worked in health care; 70 percent were women) found family-work conflict was a predictor of well-being.[86] A study of a diverse group of health care personnel compared 64 cases with 64 controls.[38] Although the subjects in the case group were more likely to experience more objective stressful situations in and out of work, for both the case group and the control group, both work and nonwork stress contributed to anxiety and depressive disorders.

Work interfering with family had a direct relationship with work exhaustion in a 4-year study of medical technologists, 80 percent of whom were female.[25] Family interfering with work, however, was not studied. A study of 101 female nurses found that work interfered with family more than family interfered with work.[94] The investigators noted, however, that most of the nurses, who were in their mid-40s, were between the demands of child care and elder care. This finding is consistent with findings from a study of 170 Australian nurses: the principal determinant of stress was workload; nurses were unlikely to bring personal stress to work.[45] Conversely, there was no difference between female physicians working full-time or reduced hours in regard to work interfering with family or family interfering with work.[29] In addition, a study of family-work conflict identified personality as an important factor in whether individuals perceive situations as stressful.[44]

Personal Characteristics and Work Relationships

Personality was explored as an important variable in the burnout/work stress equation in a number of investigations.[26, 37, 41, 49, 50, 81, 82, 92] Together, these studies support findings that perceptions of job stress and burnout are not just a product of work conditions because not all

workers, exposed to the same conditions, develop burnout or perceive stress. However, the specific features of personality that affect the perception of stress or burnout remain unclear.

Neuroticism has been associated with exhaustion.[41, 92] External locus of control has demonstrated a positive relationship with burnout[92] and stress.[26] Findings are mixed for hardiness.[37, 50, 81] Evaluations of anxiety reflect a link with stress and burnout.[49, 82] Anxiety is viewed as having two components—state anxiety, the temporary component which manifests when an individual perceives threatening demands or dangers, and trait anxiety, the more stable component which may be regarded as a personality characteristic.[105] In a study of intensive care unit nurses, the investigators concluded that individuals high on state-anxiety were not only at risk for burnout, but also for making medical errors.[82] In another study, higher trait-anxiety predicted psychological distress.[49] In addition, relationships with other staff—coworkers, physicians, head nurses, other departments—were also predictors of psychological distress.

Investigators have also examined the association between interpersonal relationships and burnout and stress. The exact linkages are not yet understood. Problematic relationships among team members were shown to increase burnout.[93] Verbal abuse from physicians was noted to be stressful for staff nurses.[71] In a study of 260 RNs, conflict with physicians was found to be more psychologically damaging than conflict within the nursing profession.[59] However, a study exploring verbal abuse among 213 nursing personnel (95 percent RNs) found the most frequent source of abuse was other nurses (27 percent).[88] Families were the second most frequent source of abuse (25 percent), while physicians ranked third (22 percent).

Management Styles

Relationships between staff nurses and nurse managers are particularly important when examining stress and burnout.[49, 53, 65, 70, 89] Numeric ratings from a survey of 1,780 RNs indicated that supervisor support and quality of supervision were lowest for nurse managers.[53] Handwritten comments from 509 (28.6 percent) of the RNs clarified these ratings by noting the following problems: (a) inadequate unit leadership and the frequent turnover of nurse mangers, (b) insufficient physical presence of the supervisor on the unit, (c) failure to address problems—too much sweeping them aside or not even being aware they exist, and (d) modest awareness of numerous staffing issues.

These ideas were corroborated in a study of 537 RNs from Canada.[65] Using structural equation modeling, the investigators substantiated the importance of manager behavior on employee experiences. Similarly, in a qualitative study of 50 nurses conducted in England, managers were identified as a direct cause of stress.[89] Finally, responses from 611 RNs on 50 inpatient nursing units in four southeastern U.S. hospitals showed that group cohesion was higher and job stress lower when nurse managers used a more participative management style.[70]

In addition to illustrating a likely connection between nurse managers and staff nurse stressors, these studies also reflected the demanding role of today's nurse managers who are often responsible for multiple patient care areas. However, only two studies were identified between 1995 and 2005 in which burnout was assessed in nurse managers and nurse administrators. One study was conducted in the United States[69] and the other study in Canada.[66] Investigators for the Canadian study examined burnout in a random sample of nurses in first-line (n = 202) and middle-management (n = 84) positions.[66] Nurses in both groups reported high levels of emotional exhaustion and average job satisfaction. In the U.S. study, the investigators explored burnout among nurses (N = 78) from rural and urban hospitals in a southeastern State

who held positions in middle-management and higher.[69] Almost half the respondents (49%) reported high levels of emotional exhaustion.

Lessening Stress

Various studies were designed to evaluate ways to mitigate stress. Studies of social support and empowerment dominated these investigations. Although social support is a multifaceted construct, definitions and types of support were not typically found in these more recent investigations. However, the importance of coworker support was verified in one study.[39] In another study, a general construct labeled "organizational support" exhibited the expected negative relationship with work exhaustion.[25] Similarly, social support from supervisors or colleagues demonstrated a negative association with work stress.[31, 72, 96] Stated differently, based on another study, as nurses felt more stress, they relied more on social support.[87] A cluster analysis demonstrated that high social support was found only in the cluster with low burnout and low stress.[59] No buffering effects were discerned in the studies, but there was a direct and beneficial effect of social support on workers' psychological well-being and organizational productivity.[36] Although these findings do not clarify the mechanism for social support, they do indicate that coworkers and supervisors at all levels would be wise to consider the importance of reciprocal interpersonal exchanges that enhance security, mutual respect, and positive feelings.

All but two studies[80, 96] of nurses and workplace empowerment were conducted by teams involving Laschinger.[57, 62, 64–68] Work empowerment showed a strong, negative association with job tension and a strong positive relationship with perceived work effectiveness.[62, 65] Similarly, in other reports, structural empowerment in the workplace (e.g., opportunity, information, support, resources, power) contributed to improved psychological empowerment (e.g., meaning, confidence, autonomy, impact).[64, 67, 68] Psychological empowerment, in turn, had a strong positive effect on job satisfaction and a strong negative influence on job strain. Likewise, as perceptions of empowerment increased, staff nurses reported less emotional exhaustion and depersonalization along with a greater sense of personal accomplishment—the three components of burnout.[57] Empowerment was negatively associated with work stressors in another study as well.[96]

Because empowerment is often viewed as a characteristic of how work environments are structured, it has strong implications for nurse managers' behaviors. However, one study revealed an interpretive side to empowerment that derives from nurses' perceptions of their personal effectiveness and success.[80] Additionally, there is beginning evidence that nurse managers experience empowerment in a way that mirrors staff nurse experiences. That is, nurse manager perceptions of structural empowerment influenced their sense of psychological empowerment, which, in turn, affected the extent to which they experienced burnout.[66]

Evidence-Based Practice Implications

Based on current empirical evidence on stress and burnout in nursing, there is difficulty in making recommendations regarding how to enhance patient safety. Although findings consistently indicated that nurse burnout was negatively related to job satisfaction, only two studies explored the relationship between nurse burnout and patient satisfaction.[90, 99]

Additionally, findings are inconsistent for two studies that examined the relationship between nurse burnout, 30-day mortality, and failure to rescue for surgical patients.[40, 56] Data for one of

these studies were collected from nurses and patients throughout Pennsylvania.[40] Data for the other study were collected from nurses and patients at a single site.[56] Some of the differences can be accounted for by numerous methodological variations between the two studies. Other differences might be attributed to the strong collective bargaining unit at the single-site study that had negotiated staffing based on nurse-patient ratios that were adjusted for patient acuity.[56] Moreover, fewer nurses from the single-site study reported being either dissatisfied or very dissatisfied with their jobs, compared with the Pennsylvania study (8 percent versus 25 percent, respectively).

Practice implications are also unclear regarding the effects of work stress on nursing staff. The lack of clarity derives, in part, from the complexities of the work stress concept. In one study, for example, nurses were grouped into one of four clusters based on their level of stress, affective and physical symptoms, burnout, and unit social support.[59] In another, the nurse ratings of job strain placed them in four groups ranging from high to low strain.[68] This heterogeneity suggests that many dynamics are operational in relation to stress and burnout. The effects of shift length on stress is one of the dynamics that is not yet understood.[60, 95] Likewise, evidence about how verbal abuse[88] and generational differences[77] operate in the stress equation is just beginning to emerge. The role of personality, family-work conflict, and other features of stress require further study.

Evidence is accruing about the utility of empowerment and social support in mitigating stress. Some caution is warranted in regard to empowerment, however, because the work of one investigator dominates the field.[57, 62, 64–68] Findings related to social support indicated that interpersonal exchanges with coworkers and supervisors may enhance security, mutual respect, and positive feelings—which helped to reduce stress.[31, 39, 72, 96] Overall, however, the assessments of social support were often founded on weak conceptualization and relied upon psychometrically weak instruments to measure the concept. Moreover, the analytical models did not always consider the direct, indirect, and interactive effects of social support.

Although the evidence is sparse, the studies have practice implications for nurse managers. First, managerial behaviors were linked to stress and burnout. Managerial support[38] and participative management[70] helped to reduce stress. Similarly, burnout and work stress were reduced when administrators created work environments that provided staff with access to opportunity, information, resources, and support—the features of empowerment.[64, 65] Second, and studied even more infrequently, nurses in supervisory positions may encounter stress[69] and burnout[66] themselves. There is no existing evidence, however, that empirically illustrates how managerial stress affects staff stress or the manager's ability to behave in a way that reduces staff stress. Given the current emphasis on improving the work environment, there is an imperative to carefully investigate both aspects of the nurse administrator in relation to stress and burnout.

Despite lacking absolute clarity, there is a body of research addressing work stress that spans more than 50 years in the nursing profession. Stress is pervasive in nursing and health care. Moreover, working conditions seem to be deteriorating at the same time that a severe and protracted nursing shortage is occurring. Leaders of health care organizations can no longer ignore these findings. Just as institutional leaders need to understand their financial standing, they also need to assess how environmental stress is affecting patients and staff and take action to alter unhealthy situations.

Research Implications

To derive a better understanding of stress and burnout in the workplace, solid conceptualizations are needed that bring together the various pieces of the stress puzzle. At present, research is often conducted absent a solid theoretical and conceptual base. A more comprehensive blueprint of nurse stress and burnout in the work place needs to be developed. Empirical studies could then be conducted to investigate these very complex relationships, prospectively, over time. Once work stress is examined from a more solid theoretical and conceptual basis, then intervention studies can be initiated to assess the most useful ways to mitigate work stress.

Studies need to move beyond the tendency to use descriptive designs. There is sufficient evidence to believe that work stress is a factor among health care personnel. What is less well understood is the effect of stress on patient outcomes. Studies are needed to enhance the understanding of stress and burnout on patient safety. Studies are also needed to better understand stress beyond the acute care setting.

In addition, because nurse administrators are responsible for creating the environment in which nursing is practiced and patient care is given,[106] it is important to explore interventions that will reduce the stress and burnout experienced by nurse administrators. Findings from studies of this nature could have a threefold effect. By reducing the stressful nature of the nurse administrator's work, nurse administrators could be more satisfied in their positions. This role satisfaction, in turn, could lead to enhancing those managerial behaviors that improve the work environment for staff nurses. Finally, improved working conditions for nurse administrators might make the role more appealing and help correct the serious dearth of individuals interested in pursuing administrative positions.[107]

Conclusion

Stress and burnout are concepts that have sustained the interest of nurses and researchers for several decades. These concepts are highly relevant to the workforce in general and nursing in particular. Despite this interest and relevance, the effects of stress and burnout on patient outcomes, patient safety, and quality care are not well defined by evidence. In fact, the link between stress and burnout to patient outcomes has been explored in only four investigations. There is a great need for comprehensive studies that will examine these dynamics in a way that will yield more solid evidence on which to base practice.

Acknowledgments

Tremendous gratitude is expressed to the staff of the Armed Forces Medical Library for their considerable support of this work. They conducted the database searches and assisted in acquiring numerous papers considered in this review.

Search Strategy

Both MEDLINE® and CINAHL® databases were searched to locate literature for this review. A reference librarian conducted the searches after working with the author to specify search terms. The search terms for MEDLINE® were psychological stress, professional burnout, work stress, and occupational health. The search terms for CINAHL® were occupational stress, professional burnout, and nursing units. For both databases, the searches were limited to research articles published in the English language between 1995 and 2005.

There were 1,145 articles identified in the CINAHL® search and 392 identified by the MEDLINE® search, with some duplication in the citations identified by the two databases. All 1,537 abstracts were reviewed. Numerous abstracts were eliminated from further consideration. For example, articles about instrument development, stress in specific populations (e.g., children, adolescents, pregnant women, parents, caregivers) and occupations other than health care (e.g., the police force, fishermen, flight crews, farm workers) were omitted from this review. Likewise, dissertations, literature reviews, concept analyses, and physiologic and immunologic studies of stress in general were not included.

Once the unrelated articles were eliminated, 138 articles remained as candidates for this review. A complete copy of each of these papers was acquired and read, following which an additional 53 articles were removed from further consideration. Dominant among the reasons for excluding these papers were that they were not research based or they were short reports that were lacking essential details.

Evidence Table

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Aiken 2002[40]	Burnout	Cross-sectional (4)	Design: Level 4 Patient outcomes: 30-day mortality, failure to rescue (Level 1) Nurse outcomes: burnout	Pennsylvania; 10,134 RNs (survey data) linked with discharge data for 232,342 surgical patients from 168 hospitals. Nurses: 94% female; 40% BSN or higher; average of 14 years working as a nurse. Patients: 44% male, average age 59, general surgery (44%), orthopedic surgery (51%), vascular surgery (5%).	Staffing	After adjusting for patient and hospital characteristics: Nurse staffing effects on 30-day mortality (odds ratio [OR] = 1.07, 95% confidence interval [CI] = 1.13–1.34, $P < 0.001$) and failure to rescue (OR = 1.07, 95% CI = 1.02–1.11, $P < 0.001$) imply that decreases in mortality rates and failure to rescue could be realized by increasing RN staffing. After adjusting for nurse and hospital characteristics: Nurses who cared for more patients exhibited high emotional exhaustion (OR = 1.23, 95% CI = 1.13–1.34, $P < 0.001$).
Halm 2005[56]	Burnout	Cross-sectional (4)	Design: Level 5 Patient outcomes: mortality and failure to rescue (Level 1) Nurse outcomes: emotional exhaustion	Large Midwestern hospital; 140 RNs (survey data), discharge data for 2,709 surgical patients. Nurses: 96% female; 43% BSN or higher; average 17 years working as a nurse. Patients: 37% male, average age 56, general surgery (50%), orthopedic surgery (46%), and vascular surgery (4%).	Staffing	Absent risk adjustment and with a strong collective bargaining unit that negotiated staffing plans: No statistically significant relationships were found for nurse staffing on 30-day mortality or failure to rescue. Variables significantly related to mortality were age, circulatory diagnoses, admission through the emergency department, and more comorbidities. 25% of the nurse sample had high scores on emotional exhaustion.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Hillhouse 1997[59]	Affective and physical symptoms	Cross-sectional (4)	Design: Level 5 Nurse outcomes: affective symptoms, physical symptoms	A large university hospital; 260 nurses: 97% female, average age 34, all college educated, in current positions an average of 5 years with an average of 11 years experience as a nurse.	Data related to stress, burnout, physical and emotional symptoms were grouped using statistical techniques.	Based on cluster analysis, hospital nurses are a heterogeneous population regarding the effects of stress. Cluster 1 (low stressor/low symptom): low affective and physical symptoms, low burnout and perceived stressors, high unit social support (32%). Cluster 2 (high stressor & burnout/moderate symptom): moderate physical and affective symptoms, high burnout and stressors, low unit social support (43%). Cluster 3 (high stressor/ high symptom): high affective and physical symptoms, high burnout and perceived stressors, low unit social support (26%).
Hoffman 2003[60]	Stress	Cross-sectional (4)	Design: Level 4 Nurse outcomes: role stress	Michigan; 208 RNs randomly selected from the Michigan Nurses Association. Nurses: 92% female, average age 43, 95 (46%) had diplomas or associate degrees, 88 (42%) had a BSN, average experience on their units = 9 years. 99 worked mostly 8-hour shifts (48%), 105 (51%) worked a combination of 8-, 10-, and 12-hour shifts	Length of work shift	RNs working 12-hour shifts experienced significantly higher stress than nurses working 8-hour shifts (P = 0.04). When experience was controlled, stress was similar between the two groups.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Laschinger 2001[63]	Burnout	Cross-sectional (4)	Design: Level 5 Staff outcomes: burnout, nurse perception of care quality	Ontario, Canada; 3,016 medical surgical nurses from 135 hospitals. Nurses: average age of 44 years, average experience in nursing 19 years, 84% were diploma prepared, 69% were from small hospitals, 18% were from teaching hospitals, 13% were from community hospitals.	Magnet Hospital characteristics	Standardized path coefficients from a Structural Equation Model indicated that positive work environments were associated with lower burnout (-0.62), which were then associated with higher perceived quality (-0.42). Higher levels of autonomy, control, and collaboration were associated with higher levels of trust in management (0.56), which was associated with higher perceptions of care quality (0.34).
Laschinger, 2001[64]	Job strain	Cross-sectional (4)	Design: Level 3 Nurse outcomes: job strain	Urban tertiary care hospitals in Ontario, Canada; 404 randomly selected staff nurses: 52% female; all worked in large urban teaching hospitals; on average, 40 years old (standard deviation [SD] = 8.07), 16 years nursing experience (SD = 8.5), 8 years experience in current workplace (SD = 5.8); 58% worked full time; 15% had baccalaureate degrees, 85% were diploma graduates.	Empowerment—both structural and psychological	A proposed model was tested using structural equation modeling. Structural empowerment had a direct, positive effect on psychological empowerment (beta = 0.85); psychological empowerment had a direct negative effect on job strain (beta = -0.57).

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Laschinger 1999[65]	Empowerment, job stress	Cross-sectional (4)	Design: Level 3 Nurse outcomes: empowerment, job tension, work effectiveness	Two sites of a large, merged urban teaching hospital in Canada. Nurses: 537 staff nurses; 95% female; 84% diploma educated; 69% worked full time; on average 40 years old (SD = 6.5), 17 years nursing experience (SD = 6.9), 10 years experience in current specialty (SD = 5.5).	Leader behavior	A proposed model was tested using structural equation modeling. Path coefficients from the final model indicated that leader-empowering behaviors directly affected power and work empowerment as well as indirectly affecting work empowerment through power. Higher perceived access to empowerment was associated with lower job tension (-0.39) and increased work effectiveness (0.26) (direct effects). Perceived empowerment also indirectly influenced work effectiveness through job tension (-0.29).
Laschinger 2001[67]	Job strain	Cross-sectional (4)	Design: Level 3 Nurse outcomes: job strain, quality of work life	Urban tertiary care hospitals in Ontario, Canada; 404 randomly selected staff nurses: 52% female; on average, 40 years old (SD = 8.07), 16 years nursing experience (SD = 8.5), 8 years experience in current workplace (SD = 5.8); 58% worked full time; 15% had baccalaureate degrees, 85% were diploma graduates.	Quality of work life	Nurse ratings of job strain fell into Karasek's four job categories: high strain (37%), active (33%), passive (21%), and low strain (10%). When categories were collapsed into high strain/low strain groups, 63% of the sample fell into the low strain group. Comparisons of the high strain and low strain groups revealed significant (P = 0.0001) differences for both structural and psychological empowerment as well as organizational commitment.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Lee 1996[69]	Burnout	Cross-sectional (4)	Design: Level 3 Nurse outcomes: stress, commitment, social support	Members of a State organization of nurse executives working at 134 rural and urban hospitals in the southeastern U.S. 78 nurse administrators: female (93%); ages 31–40 (35%); positions—chief nurse officers (CNOs) (45%), assistant CNOs (19%), division or department heads (30%), nurses with executive-level roles (6%); education—doctorate (3%), master's (42%), baccalaureate (29%), associate degree (3%), diploma (26%); average administrative experience, 13 years (range 2–32), CNO tenure in current positions 2 years or less (51%).	Commitment	No significant differences were found for burnout or commitment among the four groups of nurse administrators. Phases of burnout were determined with most nurse administrators in the lowest level (37%); 13% were at the highest level. All burnout scale scores and the organization commitment score were related inversely (r = 0.472 – 0.515) and significantly (P ≤0.001). Emotional exhaustion and burnout phase decreased as the coworker trust and support increased, although 49% of respondents reported high levels of emotional exhaustion.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Leiter 1998[99]	Burnout	Cross-sectional (4)	Design: Level 3 Patient outcomes: satisfaction (Level 3)	16 inpatient units from 2 settings at an 800-bed tertiary care hospital in central Canada. Nurses: 711 with an average of 34 respondents from each inpatient unit (range 22–63), 97% female, 18% had worked for the hospital for > 20 years (2% for < 1 year); 83% RNs, 14% registered practical nurses. Patients: 605 with an average of 36 respondents from each inpatient unit (range 3–104); 55% female, most were between 66 and 75 years old (22%); length of stay was most often up to 3 days (35%).	Patient satisfaction	Patient perceptions of overall quality corresponded to nurses' relationships with their work. Patients on units where nursing staff felt more exhausted were less satisfied with their care.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Leveck 1996[70]	Stress	Cross-sectional (4)	Design: Level 3 Nurse outcomes: perceived quality of care, management style, group cohesion	50 inpatient units from 4 acute care hospitals in the southeastern U.S. Nurses: 358 RNs. Patients: retrospective audits of 525 randomly selected charts.	Management style, group cohesion	Although the average job stress score was moderately low, it was a predictor of quality care in a theoretical model tested using structural equation modeling. Units where nurses perceived participative management also perceived higher levels of group cohesion and lower levels of job stress. Lower job stress was associated with increased quality of nursing care. Indirect effects of variables on quality care, including management style, occurred through job stress. Medical-surgical nurses perceived higher job stress than nurses on other units such as intensive care.
Rowe 2005[88]	Stress and verbal abuse nurse-to-nurse	Cross-sectional (4)	Design: Level 5	500-bed teaching hospital in Philadelphia. Nurses: 213 RNs and LPNs (69% response rate, 5% were LPNs); 96% female, most were diploma graduates (33%); 53% worked full time, 85% had > 5 years experience, 88% were staff nurses.	None—descriptive	96% of the participating nurses reported they had been spoken to in a verbally aggressive manner—79% indicated verbal abuse by patients, 75% by other nurses, 74% by attending physicians, 68% by patients' families. The most frequent sources of verbal abuse were other nurses (27%), patients' families (25%), physicians (22%), and patients (17%). A few of the verbally abusive experiences (13%) were related to errors in patient care.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Santos 2003[77]	Stress, strain, coping	Cross-sectional (4)	Design: Level 5	Four Midwestern hospitals. Nurses: 694 RNs representing 3 age cohorts—1909–1945, matures (8%); 1946–1964, baby boomers (53%); 1965–1979, Generation Xers (35%).	None—descriptive	The four major problem areas within each of the three study variables—stress, strain, coping—were identified. *Stress*: physical environment, responsibility, role overload, role boundary; *Strain*: physical, psychological, vocational, interpersonal; *Coping*: self-care, recreation, rational/cognitive, social support. Significant differences were evident among the generations with baby boomers reporting more stress and worse coping than the other 2 cohorts as well as significantly more interpersonal strain.
Simoni 2004[80]	Stress	Cross-sectional (4)	Design: Level 3 Nurse outcomes: empowerment	Two hospitals in a mid-Atlantic State. Nurses (randomly selected, n = 142) RNs with an average age of 35 years (SD = 10.1), 48% had baccalaureate degrees, most had been working <5 years since becoming RNs (42%).	Empowerment	Two of the three individual styles of stress appraisal were significantly correlated with psychological empowerment: skill recognition ($r = 0.52$, $P < 0.001$), and deficiency focusing ($r = -0.24$, $P < 0.01$). Together, these two interpretive styles explained 24% of the variance in empowerment.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Vahey 2004[90]	Burnout	Cross-sectional (4)	Design: Level 3 Patient outcomes: satisfaction (Level 3)	2 units each in 20 urban hospitals across the U.S. using 1991 data. Nurses (n = 820—both RNs and LPNs): 93% male; on average, 35 years old (SD = 10), 10 years in nursing (SD = 9), 4 years on present unit (SD = 4). Patients (with AIDS) (n = 621): 88% male, average age 37 years (SD = 8).	Patient satisfaction	After adjusting for patient characteristics (age, gender, race, risk factors, and illness severity), patients on units where nurses reported higher-than-average levels of emotional exhaustion were only half as likely to be satisfied with nursing care as compared to units where nurses reported lower-than-average emotional exhaustion (OR =0.51, 95% CI = 0.30–0.87, *P* < 0.05). Patients on units where nurses reported higher-than-average personal accomplishment were twice as likely to be satisfied with their nursing care compared to units where nurses reported lower-than-average personal accomplishment (OR = 2.37, 95% CI = 1.37–4.12, *P* < 0.01). The nurses' work environment exerted both direct and indirect effects on patients through its effect on nurse burnout.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Weinberg 2000[38]	Stress	Cross-sectional (4)	Design: Level 3 Staff outcomes: psychiatric disorders	City-based hospital. Four groups of staff members (randomly selected): nurses, physicians, administrative, ancillary. Based on scores from survey responses, participants were identified who had minor psychiatric disorders (e.g., definite depressive or anxiety disorders). These 69 cases were matched to controls by occupational group, gender, and age (within 5 years). Each group had 23 nurses, 8 physicians, 23 administrative staff, and 10 ancillary staff. 52 of the 69 individuals in each group were females (75%). Mean age for cases and controls was 39 years (SD = 10).	Psychiatric disorders (especially depression or anxiety)	Cases were less likely to have a confidant and more likely to have a family or past history of psychiatric disorder as well as a severe event and severe chronic difficulty over the previous 12 months. Most chronic difficulties were outside work. There were no significant differences between cases and controls in regard to management responsibilities at work or the proportion who worked shifts. Cases had significantly more objective work problems than controls. Of 20 work problems, 6 were experienced significantly more often by cases—work role conflict, lack of manager support, physical environment problems, poor promotion prospects, job not secure, skills under used (OR = 2.19 – 3.44; p= 0.006-0.10). The greatest difference between cases and controls was lack of managerial support (*P* = 0.006). Work problems (OR = 1.4, *P* = 0.0003) and difficulties outside work (OR = 8.77, *P* = 0.0001) were contributors to stress.

Chapter 27. Temporary, Agency, and Other Contingent Workers

Ann E. K. Page

Background

The Institute of Medicine (IOM) report, *Keeping Patients Safe: Transforming the Work Environment of Nurses*,[1] determined that the use of temporary nursing staff or staff from agencies external to the health care organization to provide care threatens patient safety. Involving personnel with less knowledge of the nursing unit and larger organizational care policies—and interrupting the continuity of patient care—increases the risk to patients' safety. In its report, the IOM recommended that health care organizations avoid using nurses from external agencies.

In 2004, 2.3 percent of registered nurses (RNs) provided their services through a temporary agency, as opposed to being employed by the organization or organizations through which they delivered care.[2] This was an increase from the 1.8 percent of RNs working in their principal nursing position through a temporary employment service in 2000, which itself was a 36 percent increase over that reported in 1996, reversing a declining trend between 1988 and 1996.[3] Although this proportion continues to represent a minority of the nurse workforce, the increase mirrors workforce trends occurring globally across many industries.[4, 5] Temporary workers, contract employees from external agencies, intermittent workers, "casual" workers, and other types of workers without a standard employer-employee relationship with the organization in which they provide services are together referred to in the United States as "contingent workers."[6] In other counties, such arrangements are sometimes referred to as "precarious employment," the terminology used in the European Union, for example.

Although use of nurses from external agencies can increase the number of staff available for patient care, threats to patient safety are theorized to arise, in part, because temporary staff are less familiar with a nursing unit and a health care organization's overall structure, policies, practices, and personnel—including information systems, facility layout, critical pathways, interdependency among work components, ways of coordinating and managing its work, and other work elements.[4, 7] This can be compounded when temporary workers do not receive the same level of orientation and training from the organization in which they provide care as do the organization's employees. Studies in industries outside of health care have found that increased use of contingent workers can result in higher accident rates and other adverse effects.[4] The International Atomic Energy Agency, for example, cites use of contract personnel to replace traditionally hired employees as a symptom of incipient weakness in an organization's safety culture.[8] Health care researchers find similar results.

Research Evidence

Searching health care literature for the effects of contingent nursing staff on patient safety and other quality of care outcomes is difficult because of the various terminologies used to refer to such workers: for example, temporary, float, casual nursing, contingent employment, or precarious employment. Moreover, health care research, unlike research on the impact of

temporary employees across a variety of other industries, typically has not exclusively examined the effects of temporary workers on patient safety and care quality. Findings are typically embedded in studies of more comprehensive issues such as the effects of nurse staffing or health care organization practices.

The search strategy (see below) resulted in finding seven observational studies; of which six studies reported adverse patient outcomes associated with the use of contingent nurses[7, 9–13] (see evidence table). The seventh study, which did not find adverse patient outcomes,[14] did not measure patient outcome directly, but rather examined nurses' documentation of their own performance of activities related to patient safety and better quality of care—the lowest level of outcome measured for all seven studies. The findings of the seventh study also were confounded by the provision of specialized training in the legal ramifications of documentation to only two of the three groups under study—the groups that subsequently performed at the highest level.

Although it is possible that the findings of six of seven studies showing adverse effects of using agency nurses are a manifestation of reporting bias (i.e., multivariable studies that did not find a difference in the use of contingent nurses might not report the finding of no difference), the evidence cited in these studies does not support this possibility. Five of the seven studies examined variables in addition to staffing composition and their effects on bloodstream infection, 30-day mortality, medication errors, and violence committed by psychiatric patients. All five of these identified and reported on variables for which "no difference" in patient care or outcomes was found.

Evidence-Based Practice Implications

The IOM report identified the need for all health care organizations to have in place mechanisms to achieve "flexible" staffing in instances when the patient census, acuity, or both demand staffing at a higher level than anticipated. However, the research included in the aforementioned analysis reaffirms the importance of avoiding the use of nursing staff from external sources as a mechanism to provide such flexible staffing. The IOM recommends using internal nursing "float pools" composed of nurses employed by the health care organization. Although using floating nurses may still result in nurses being assigned to patient care units with which they are less familiar, using an organization's own float pool of employed nurses at least assures that these nurses have received the same orientation and in-house training as other nursing staff permanently assigned to specific nursing units. Float pools would also assure that, even if the floating nurses are not familiar with policies and procedures unique to individual patient care units within the organization, the nurses would be familiar with organization-wide policies and practices pertaining to patient safety, such as an organization's error reporting system, decision-support systems, and information technologies.

Research Implications

Research on temporary and agency nurses could benefit from a meta-analysis to determine how strong the effect may be between using external nurses and patient safety and outcomes. Additional research could be conducted to further build the evidence base pertaining to the effect on patient care outcomes of using contingent nurses to meet staffing demands. However, research is also needed to understand the reasons for the use of contingent workers in health care in the first place. Such research can inform policy decisions by health care organizations and

other entities affecting workforce deployment. Are contingent workers preferred by health care organizations? If so, why? To what extent is increasing use of contingent nursing staff caused by the same factors leading to increased use of contingent workers globally across myriad industries, or are there unique factors at play in nursing? Do nurses employed by temporary agencies prefer this type of employment? If so, why? Can these factors be replicated in health care organizations to bring contingent workers into standard employer–employee relationships with health care organizations? If nursing staff employed by temporary agencies do not prefer this employment, why are nurses so employed in the face of a widely cited nursing shortage?

Conclusions

Whether temporary workers or float pools are used to meet staffing shortfalls, hospital managers and leaders are challenged to ensure patient safety by matching the available skill mix of nurses to the needs of patients. The flexibility offered by temporary workers may address staffing gaps, but it is important to have effective communication, education, and orientation mechanisms to enable comprehensive, safe patient care by outside nursing staff. More research is needed on the effects of contingent nursing staff on patient safety and the reasons for the use of contingent workers.

Search Strategy

A search of MEDLINE®, CINAHL®, the Cochrane Registry of Controlled Trials, and the Cochrane data base of systematic reviews for the period January 1990–March of 2006 using the search terms (temporary OR contingent) AND (staff OR personnel OR nurs$) in all fields for human studies and English-language articles yielded 809 articles. Five of these titles or abstracts described a research study that included measures of the effects of contingent nurses on patient safety or clinical quality outcomes.[7, 9–11, 14] A repeat of this search using (float OR casual) in place of (temporary OR contingent) generated 181 references, which yielded an additional research study with these variables.[12] A similar search within PychoINFO yielded 178 references, of which one was a previously undetected research study examining use of temporary nurse staffing and patient outcomes.[13] All searches were mediated through the OVID search engine. Studies measuring only nurse outcomes (e.g., occupational injuries, job satisfaction, or features of work design) were excluded, although there is literature showing adverse outcomes in these areas as well.

Evidence Table

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Alonso-Echanove 2003[7]	Use of float nurses – agency nurses or nurses from other hospital areas who had been working in the unit under study for less than a year.	Prospective cohort	Level 3 study design. Level 1 outcome measure: central venous catheter (CVC) bloodstream infections (BSIs)	4,535 adult patients admitted for at least 24 hours in 1997–1999 to eight Intensive care units at six geographically distinct hospitals	Observational study – no intervention	Of more than 60 potential risk factors studied, portion of days cared for by a float nurse was one of only six statistically significant (*P* <.005) variables strongly associated with the development of CVC-BSIs in patients. Risk of CVC-associated BSI was 2.6 times higher for patients cared for by float nurses more than 60% of the time.
Bourbonniere 2006[11]	Use of a high proportion of contract nurses (RNs and LPNs combined) to fill nurse staffing positions. High proportion was defined as 5 percent or more of total full-time equivalent nursing positions.	Cross-sectional, time series	Level 4 study design. Level 3 or higher outcome measures; i.e., study measured health care quality deficiencies detected in nursing homes as part of their State 's annual survey and certification inspection process.	15,717 freestanding nursing homes (facilities) in urban and rural counties in the United States between 1992 and 2002.	Observational study – no intervention	Annually, facilities using 5 percent or more contract RNs and LPNs were disproportionately represented in the top quartile of nursing facilities ranked in each State according to health care deficiencies detected during annual State survey and certification inspections. For each calendar year these differences were statistically significant($P < 0.05$).
Estabrooks 2005[9]	Use of temporary or casual nurses in hospital staffing.	Cross-sectional	Level 4 study design. Level 1 outcome measure: 30-day mortality following admission	18,142 patients discharged from 49 of 109 acute care hospitals in Alberta Province, Canada	Observational study – no intervention	Hospitals with a higher proportion of casual and temporary nurses had higher rates of 30-day patient mortality (odds ratio = 1.26, 95% confidence interval of 1.09 to 1.47).

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
James 1990[13]	Use of agency (temporary) nursing staff	Retrospective cohort	Level 4 study design. Levels 1 and 2 outcome measures: any act of violence, defined as physical aggression involving physical contact directed at fellow patients, staff, self, or property.	All acts of violence occurring in a 12-bed "high dependency" ward within a 60-bed psychiatric unit in a district general hospital in London, England, during January 1986 through March 1987 (15 months).	Observational study – no intervention	A greater than three-fold increase in violent incidents over the study period was strongly associated with a decline in the number of permanent nursing staff employed by the hospital and an increase in the use of agency nurses, despite the maintenance of a constant level of nurse staffing. Study found a positive correlation between the number of violent incidents and use of agency nurses ($P = 0.0018$) and agency nursing shifts ($P = 0.0005$), and a negative correlation between the number of violent acts and levels of permanent nursing staff ($P = 0.0007$).
Robert 2000[12]	Use of nurses from an external agency or from a hospital pool compared to nurses permanently assigned to the surgical intensive care unit (SICU)	Case-control study	Level 4 study design. Level 1 outcome measure: nosocomial bloodstream infections (BSIs)	28 patients with BSIs and 99 randomly selected controls in a 20-bed SICU in a 1,000 bed, university-affiliated, inner-city, public teaching hospital. Cases were any patient hospitalized in the SICU for 3 or more days from June 1994 to June 1995 in whom a primary BSI was identified.	Observational study – no intervention	BSIs were significantly ($P < 0.004$) more frequent during the period of high use of nurses from the external agency or hospital float pool and low use of permanently assigned nursing staff. The pool nurse-to-patient ratio was significantly higher for case patients ($P < 0.001$) than for controls. Conversely, the regular nurse-to-patient ratio for the 3 days prior to infection was significantly lower for case patients than control patients) ($P < 0.001$).

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Roseman 1995[10]	Use of temporary nurses	Cross-sectional	Level 4 study design. Level 2 outcome measure: medication errors	All medication errors reported in a 140-bed acute care medical center in Alaska from 1984 to1989.	Observational study – no intervention	Number of shifts worked by temporary staff was positively (and statistically significantly) associated with medication errors (odds ratio = 1.15). Errors decreased when permanent nursing staff worked overtime (odds ratio = 0.85).
Strzalka 1996[14]	Use of nurses from external agencies, compared to internal float pool nurses and nurses hired by the organization to staff a specified nursing unit under study (unit-hired nurses)	Prospective cohort	Level 4 study design. Level 3 outcome measure: Nurses' documentation that they performed nine activities determined by the facility as related to patient safety (e.g., side rails raised, assessment of mental status, vital signs, etc.) and related to bowel management.	All agency nurses and two randomly selected comparison groups of internal float and unit-hired nurses providing care on one nursing unit in a large teaching hospital in the United States over an 8-month period.	Observational study – no intervention	Nursing groups' documentation varied from indicator to indicator, with internal float pool nurses generally documenting at the highest level and unit-hired nurses performing at the lowest, with agency nurses falling in between. Differences were often minimal and were statistically significant (at the $P < 0.05$ level) for only five of the nine documentation activities. Agency nurse reporting was significantly lower than float pool nurses on only two measurement items.

Chapter 28. The Impact of Facility Design on Patient Safety

John Reiling, Ronda G. Hughes, Mike R. Murphy

Background

Recent attention in health care has been on the actual architectural design of a hospital facility, including its technology and equipment, and its effect on patient safety. To address the problems of errors in health care and serious safety issues, fundamental changes of health care processes, culture, and the physical environment are necessary and need to be aligned, so that the caregivers and the resources that support them are set up for enabling safe care. The facility design of the hospital, with its equipment and technology, has not historically considered the impact on the quality and safety of patients, yet billions of dollars are and will be invested annually in health care facilities. This provides a unique opportunity to use current and emerging evidence to improve the physical environment in which nurses and other caregivers work, and thus improve both nurse and patient outcomes.

Human Error and Cognitive Functioning by Design

Cognitive psychologists have identified the physical environment as having a significant impact on safety and human performance.[1, 2] Understanding "the interrelationships between humans, the tools they use, and the environment in which they live and work"[3] is basic to any study of the design a health care facility and its effect on the performance of the nurses and other caregivers who interface with the facility and its fixed (e.g., oxygen and suctioning ports on the wall of a patient room) and moveable (e.g., a patient bed) equipment and technology. Humans do not always behave clumsily and humans do not always err, but they are more likely to do so when they work in a badly conceived and designed[4] health care setting.

Organizational/system factors that can potentially create the conditions conducive for errors are called latent conditions. According to Reason,[1] latent conditions are the inevitable "resident pathogens" that "may lie dormant within the system for a long time, only becoming evident when they combine with other factors to breach the system's defenses. Latent conditions can be identified and remedied before an adverse event occurs." Examples of latent conditions are: poorly designed facilities, including the location of technology and equipment; confusing procedures; training gaps; staff shortages or improper staffing patterns; and poor safety culture. A specific example of a latent condition effecting patient safety would be the impact of low lighting levels in the medication dispensing areas that are associated with some medication errors but not others.[5] These and other conditions occur at what Reason describes as the "blunt end," where administrators, the work environment, and resources determine the processes of care delivery. Latent conditions are present in all organizations and can be unintentionally created by those who are responsible for designing systems, ensuring adequate staffing, creating and enforcing policies, and so on.

The design of a facility/structure with its fixed and moveable components can have a significant impact on human performance, especially on the health and safety of employees,

patients, and families.[6] In a review of more than 600 articles, researchers found that there was a link between the physical environment (i.e., single-bed or multiple-bed patient rooms) and patient (e.g., fewer adverse events and better health care quality) and staff outcomes (e.g., reduced stress and fatigue and increased effectiveness in delivering care).[7] Efforts to improve patient and staff outcomes can target latent conditions for clinicians by using evidence-based designs to decrease distractions, standardize locations of equipment and supplies, and ensure adequate space for documentation and work areas. The research done by Reason[1] and Leape[2] describes the value of practices based on principles designed to compensate for human cognitive failings. Thus, when applied to the health care field, human factors research (i.e., an area of research that includes human performance, technology design, and human-computer interaction; this topic is covered in chapter 5, "A Human Factors Framework," by Henriksen and colleagues), which has emphasized the need for standardization, simplification, and use of protocols and checklists, can be used to improve health care outcomes.

By targeting human factors through facility design and ensuring that latent conditions and cognitive failures that lead to adverse events are minimized, patient safety will improve. This requires a multifaceted approach, including developing a strong safety culture, redesigning systems or facilities with their equipment and technology, focusing on eliminating the conditions of cognitive errors, and helping caregivers correct/stop an error before it leads to harm or mitigate it if it occurs.[1, 2]

Factors Influencing the Built Environment

With human factors in mind, there are several aspects of the built environment that should be considered. In a review of the literature by Henriksen and colleagues,[8] the following design elements were identified as critical in ensuring patient safety and quality care, based on the six quality aims of the Institute of Medicine's report, *Crossing the Quality Chasm: A New Health System for the 21st Century*:[9]

- *Patient-centeredness*, including
  - using variable-acuity rooms and single-bed rooms
  - ensuring sufficient space to accommodate family members
  - enabling access to health care information
  - having clearly marked signs to navigate the hospital
- *Safety*, including
  - applying the design and improving the availability of assistive devices to avert patient falls
  - using ventilation and filtration systems to control and prevent the spread of infections
  - using surfaces that can be easily decontaminated
  - facilitating hand washing with the availability of sinks and alcohol hand rubs
  - preventing patient and provider injury
  - addressing the sensitivities associated with the interdependencies of care, including work spaces and work processes
- *Effectiveness*, including
  - use of lighting to enable visual performance
  - use of natural lighting
  - controlling the effects of noise

- *Efficiency*, including
  - standardizing room layout, location of supplies and medical equipment
  - minimizing potential safety threats and improving patient satisfaction by minimizing patient transfers with variable-acuity rooms
- *Timeliness*, by
  - ensuring rapid response to patient needs
  - eliminating inefficiencies in the processes of care delivery
  - facilitating the clinical work of nurses
- *Equity*, by
  - ensuring the size, layout, and functions of the structure meet the diverse care needs of patients

There have been five other significant reviews of the literature relating to the physical environment and patient outcomes. Nelson and colleagues[10] identified the need to reduce noise pollution and enhance factors that can shorten a patient's length of stay (e.g., natural lighting, care in new/remodeled units, and access to music and views of nature); according to their study, patients can benefit from the skillful utilization of music and artwork. Ulrich and colleagues[7] found research that demonstrated that the design of a hospital can significantly improve patient safety by decreasing health care associated infections and medical errors. They also found that facility design can have a direct impact on patient and staff satisfaction, a patient's stress experience, and organization performance metrics. Three other reviews found that hospital design, particularly when single-bed rooms are employed, can enhance patient safety and create environments that are healthier for patients, families, and staff by preventing injury from falls, infections, and medical errors; minimizing environmental stressors associated with noise and inefficient room and unit layout; and using nature, color, light, and sound to control potential stressors.[11–13]

Nurse staffing levels. Preventable adverse events such as falls and complications have been found to be related to both the design of health care facilities and nurse staffing levels. Patient falls in acute care settings can result from slippery floors, poor placement of handrails, inappropriate door openings, furniture heights,[14] and inadequate nurse staffing.[15, 16] Infection rates have been found to be lower in patients, particularly critically ill patients, when there are higher staffing levels.[17, 18, 19] High rates of postoperative infections, especially related to wounds among patients ages 65 to 70, have been found to be associated with facilities that were overcrowded, had few private rooms, lacked individual bathrooms and toilets, had no isolation facilities, and had deficient ventilation systems.[16] Without effective ventilation systems, efforts to avoid ventilator-associated pneumonia—such as patient positioning, oral health, and airway management[20, 21]—have a greater potential of not being as beneficial. Then again, the greater risk for health care associated infections may be associated with nurses not implementing evidence-based practices,[22] such as aseptic technique or washing hands appropriately[18] to prevent infections, as well as nurse understaffing;[23–26] how much is not known. These are only some of the examples that indicate that there are fewer adverse events when appropriate nurse staffing levels are met, and operational costs are lower because the rates of adverse events are lowered.[27] Thus, adequate staffing must be addressed to enable the benefits of well-designed health care facilities.

Structural obstacles and the nature of work for nurses. Several factors have been identified as physically being in the way of the work of nurses. An assessment of the organization of nurses in medical and surgical units in hospitals in France found that the work of

nurses was dependent upon the spatial configuration of the unit. For purposes of this study, nurses' work areas were divided into four categories: the patients' rooms, the nurses' area, the corridor, and other specialized areas such as a storage room. Nurses were found to have generally followed three paths in their trips: different points of the nurses' area, trips between the patients' rooms and nurses' area, and trips between the patients' rooms. Trips were organized according to spatial and functional logic. The majority of the activities performed by nurses were found to last less than 2 minutes. On the surgical unit, nurses during one shift were found to perform 3,855 trips that lasted approximately 3 minutes and 25 seconds each; this was fewer than the 4,521 trips performed by nurses on the medical units, each lasting approximately 3 minutes and 9 seconds. The constant movement by nurses varied based on the spatial organization of the unit as well as the temporal structure of the tasks. On the surgical unit, nurses were interrupted, an average of once every 20 minutes; on the medical unit, nurses were interrupted an average of once every 12 minutes.[28]

One approach to address these obstacles and to better meet patients' needs is to not have one central nursing station. Instead, there would be several decentralized nursing work stations throughout the unit with supplies, linens, and equipment areas. Appropriately distributed supplies and equipment could reduce fatigue and improve efficiency of nurses[29] by minimizing the time associated with finding supplies and equipment and moving from one location to another. Patients could benefit from more time with nurses and increased surveillance opportunities that require nurses to visually monitor patients—a benefit enhanced further by using single-bed rooms in hospital design.[30]

Single-bed and variable-acuity rooms. Debate continues as to whether hospitals should have single-bed rooms or semiprivate rooms for patients. Research over the past 10 years has compared single to semiprivate rooms and, in so doing, has provided greater insight into cost implications, patient satisfaction, and impact on patient care and outcomes. Several reviews of the literature found that single-bed rooms were more conducive for infection control and patient care,[7, 31, 32] were associated with reduced stress and improved outcomes for patients,[33] and increased privacy and accessibility for patients and families.[34] Noise levels and catheter-related infections have been found to be lower for critically ill infants in single-bed rooms.[35] Comparatively, environmental risk factors for patients in multiple occupancy include lack of privacy[36] and higher noise levels that can affect their comfort and recovery.[37] Environmental noise and light as well as patient interruptions can cause sleep disturbance,[36] especially in intensive care unit patients.[38]

Patients and families tend to be more satisfied with single-bed rooms. In one study, patient satisfaction among low-risk maternity patients was found to be higher with single rooms because of having their privacy respected; patients felt they were in a comfortable environment and felt that they received more support and education.[39] Clinicians have also been found to prefer single rooms for maternity patients[40] and neonatal intensive care patients.[35]

The availability of single-patient rooms has been found to control the spread of infection from patients infected with methicillin-resistant Staphylococcus aureus,[41–43] gram-negative bacteremia in burn patients,[44] and respiratory and enteric infections requiring contact isolation in pediatric units.[45] Single-bed isolation rooms, intended to prevent the spread of infectious agents by using pressure differentials to contain them, are effective only if the room is tightly sealed.[46] Thus, in terms of controlling infection in isolation rooms and other patient rooms, the greater risk may be associated with nurses not implementing evidence-based practices regarding hand washing and aseptic technique to prevent infections.[18]

The design of a patient room that allows flexibility and can be adapted to meet changing acuity and care needs of patients has been found in some institutions to contribute to decreased medication errors and falls.[47, 48] A well-designed patient room has also been found to be a factor in improving care delivery processes for clinicians by providing more private patient consultations,[36] improving patient and clinician satisfaction,[48] decreasing length of stay,[29] and facilitating continuity of care during a hospital stay.[39]

Traditionally, the bed charge has been higher for single rooms and the capital investment greater. Yet research has found that single rooms and flexible/adaptable rooms for maternity care and intermediate and intensive care offered cost savings, particularly because of shorter lengths of stay and a decrease in the number of transfers within the hospital.[40, 49] Such rooms are more likely to be filled[47] and can avoid the costs of transfers when the room is acuity adaptable.[36]

Lessons From Best-Practice Designs

There are several examples of the impact of evidence-based design in acute care settings; a few will be discussed here. Research in the early 1970s found that unit efficiency was determined by the design of the unit, not room size or occupancy.[50] Research conducted since then has continued to emphasize the importance of designs. One study[51] began with a systematic evaluation of best practices in 19 intensive care units (ICUs), built between 1993 and 2003, that received a design award from the Society of Critical Care Medicine, the American Association of Critical Care Nurses, and the American Institute of Architects. The reviewer found positive characteristics of the ICUs to include single-bed rooms for improved patient care, safety, privacy, and comfort; bed locations that provided easy access for clinicians; hand-washing sinks and waste disposal in the patient rooms; and use of natural lighting. Negative characteristics were found to be renovation projects that posed health and safety hazards during the construction; mixed-service units with safety and staffing problems; overall layout—and layout of work areas for staff—that lacked a common design solution; and family space that was often located outside the unit and provided the family with limited access.

The Pebble Project, supported by the Center for Health Design and funded by the Robert Wood Johnson Foundation, includes several hospitals across the country. As part of this project, evidence-based designs are used and empirical evidence is assessed to measure outcomes such as safety (visit the Center for Health Design's Web site at www.healthdesign.org). Findings from the Pebble Project are expected to advance the evidence base by increasing our knowledge of design features that can ensure a safe healing environment where the best quality of care can be provided. The project is intended to have a ripple effect and influence other health care facilities nationwide.[52]

There are several examples of hospitals involved in the Pebble Project, such as Children's Hospital in San Diego, which opened a long-term, convalescent hospital designed to promote the care needs for permanently disabled children. The design included out-of-sight wheelchair storage in patients' rooms, private spaces outside the patient rooms for parents to hold their children, and an improved ventilation system to decrease respiratory infections. The Methodist Hospital in Indianapolis opened a 56-bed cardiovascular critical care unit where patients are admitted directly to their rooms from the emergency room, admitting, physicians' offices, or the Lifeline helicopter. Patient rooms are private and patients are in control of the temperature and light. Each room also has an interior window that can become opaque to increase privacy. The design also enabled nurses to observe patients better, resulting in half as many patient falls, and the need for patient transfers has decreased substantially from 200 per month to an average of 20

per month. Bronson Methodist Hospital in Michigan opened a new facility with private patient rooms and increased patient access to nature (e.g., indoor gardens, natural light, and landscape views) and decreased patient stress using of positive distractions such as music, water sounds, artwork, and daylight. The Barbara Ann Karmanos Cancer Institute renovated several hospital areas to be patient-centered and to provide a more pleasant environment, where patient rooms were made larger and an emphasis was placed on lighting and acoustics. In doing so, administrators and clinicians have seen a decrease in the use of pain medication and medication errors on these units. Thus, by incorporating private rooms into their designs, these four hospitals and patients they have served have experienced successful outcomes in their new and renovated facilities.[53]

Research Evidence

There were 10 original articles that met the inclusion criteria for this review. Four articles described investigations with nurses in relation to the work and built environment, five were about patient's perspectives, and two were about specific built environment projects; one study investigated both staff and patient perceptions of the built environment.

Nurses' Perspective

Four studies assessed hospital nurses' perspectives on factors associated with the built environment using cross-sectional surveys. Two surveys intended to assess the work environment and challenges prior to moving forward with specific changes.[54, 55] When asked about performance obstacles, nurses reported: work environments; distractions from families; hectic and crowded work environments; delays in getting medications from the pharmacy; amount of time spent teaching families; equipment not being available; patient rooms not well stocked; insufficient workspace for completing paperwork; time spent seeking supplies or patients' charts; receiving many phone calls from families; delays in seeing new medical orders; and misplaced equipment.[54] When asked about what physical changes were problematic in the layout of the current unit, including patients' rooms, pediatric nurses reported that they were not satisfied with: the size of residents' closets, showers, and activity room; the actual size, aesthetics, and location of the break room and dining room; the available space for medical equipment; the available space for charting; and the outdoor recreation area. Not only did nurses share similar concerns with parents, the facility aesthetics and work environment were found to be associated with higher satisfaction and better coworker relationships among nurses.[55]

The other two surveys assessed the perceptions of nurses about single versus multiple bed rooms. A very small sample of nurse managers and unit directors (n = 7) in best-practice ICUs reported the benefits of single-bed rooms as enhanced patient safety, ensured privacy for patients, increased access to patient status information, and more space for family members.[56] In the other survey, administrative and nursing staff (n = 77) reported that they favored single-occupancy rooms because of their flexibility, being more appropriate for patient examination, improved quality of patient monitoring and scope of patient surveillance, and improved patient comfort level and patient recovery rate. Helpful characteristics of single-occupancy rooms were reported as: the more favorable layout of the room, including the availability of extra space in the room making arrangement of furniture easier and providing storage for clean and dirty supplies in the room; better privacy for patients and more space for family members; and better lighting

and temperature control and lower noise levels. A little over half of the respondents believed that health care acquired infections were low or very low in single-occupancy rooms, but that there was no difference in the number of patient falls or the need for pain-reducing or sleep-inducing medications between the two types of rooms. Conversely, helpful characteristics of double-occupancy rooms included proximity to the nursing station. However, being able to see patients for monitoring purposes was reported as problematic for both single and multiple occupancy rooms.[57]

Patients' Perspective and Impact

Five of the identified studies assessed the perspective of patients who received care in a purposefully built environment within hospitals. Two studies used focus groups to assess the patients' perspective, one with hospital inpatients,[58] and the other with patients and family members in ambulatory care, acute care, and long-term care settings.[59] A consistent theme among these studies was the preference for an environment that offered quality and comfortable personal space, rather than an environment that addressed only medical needs, but none were without some aspect that was not favorable.

Three studies assessed the perspectives of patients and family members in the United States and the United Kingdom. Patients and family members in the United States, across various settings, reported wanting a health care environment that facilitates connections to clinicians; fosters a sense of well-being; and is not dissociated from the world outside the hospital, outpatient setting, or long-term care setting.[59] Patients in the United Kingdom, hospitalized patients in various units (n = 51) reported feeling a loss of independence and control while hospitalized, but felt safer and at home when they had the TV close by, and were able to walk around. For these patients, the most important factors about the built environment were privacy, a homely environment, considerations for disabilities, and being able to see outside and get outside.[58] Patients in another study in the United Kingdom reported a relationship between the environment and internal areas of the hospital and how that made them feel comfortable, able to keep a sense of normalcy, and as having a positive affect on their feelings of well-being. Patients further reported that they felt that it was important to have good signage, controllable lighting and temperature, privacy, reduced noise levels, access to the natural environment, safety and security in internal and external areas, internal and external children's play areas, accommodations for visitors, shops and personal services, good 24-7 catering facilities, and good landscape designs with seating and garden areas.[60]

Patient perceptions were assessed after implementation of a built environment in a hospital. In one study, there were fewer patients who left against medical advice, aggression levels in patients decreased, and levels of benzodiazepine dosing decreased compared to measured occurrences before the new unit opened. It is not known if there was any assessment of patients' perceptions.[61] Parents (n = 40) in a children's hospital reported more satisfaction with the structure and facility aesthetics**,** but were not satisfied with space for showers/baths, the amount of closet space in the patient room, lack of sufficient private areas to be with their child or for outdoor recreation, location of the nurses station, and the low level of natural lighting.[55]

Acuity-Adaptable Rooms

One study investigated the impact of an evidence-based design of 56 new acuity-adaptable rooms for a combined coronary critical care and step-down unit.[62] Researchers found that two

different levels of acute care (intensive care and step-down care) could effectively be merged together into a single patient room by making the room acuity adaptable to accommodate the changing needs of patients. Once in the new single-bed acuity-adaptable unit, researchers found: a large reduction in clinician handoffs and transfers; a 70 percent reduction in medication errors; a reduction in patient falls; improvements in patient satisfaction; decreases in budgeted nursing hours per patient day; and increases in available nursing time for direct care without additional cost. Yet, clinicians felt more isolated by the increased size of the unit and with decentralized nursing stations; then again, the "isolation" gave nurses greater opportunity for autonomous decisionmaking.

Designed ICU

The implementation of a new neonatal intensive care unit, designed to have a more efficient floor plan, provide space for supportive family-centered care, and to use of natural light, used was assessed using multiple methods.[63] On this new unit, the majority of nurses were positive about the design features. Nurses reported the new unit as enabling efficiency, in part attributable to being able to move about the unit at a greater velocity, enabling them to spend more time with the infants and less time needed to walk about the unit in the course of their work. The nurses also reported that the new unit was more comforting, clean and quieter, and the new lighting was thought to have a positive impact on the patients. Additionally, nurses reported that they felt that families were utilizing the majority of space designated to them.

Addressing the Problem: A Case Study

One new 80-bed community hospital in Wisconsin has been designed to improve patient safety through research-based design. Following the report of the Institute of Medicine (IOM), *To Err Is Human: Designing a Safer Health System*,[64] the management and medical staff at St. Joseph's initially believed that adverse events applied to other institutions and not their own. When it became apparent that St. Joseph's, too, had preventable adverse events, top management authorized the design of a facility with the equipment and technology to lower or eliminate preventable adverse events—a design that could possibly be used as an example by other health care organizations that were building new facilities, remodeling, or expanding existing facilities.

The process began in April 2002, when leadership from SynergyHealth St. Joseph's Hospital met with national leaders representing health care administration, health services research, hospital quality improvement and accreditation, hospital architecture, systems engineering, medicine, nursing, and pharmacy.[65] Using personal experience, human factors principles, health care research, and research from other industries, it was agreed that a National Learning Lab, would be used to develop recommendations for facility design, define and create a roadmap for safety by design, including safe design principles, make recommendations for changes in care processes, and enhance safety culture for hospitals through facility design focused on patient safety. The specific safety design principles, intended to specifically address both latent conditions and active failures, included the following:

1. Automate where possible.
2. Design to prevent adverse events (e.g., patient falls, operative/postoperative complications and infections, and deaths associated with restraint use).
3. Design for scalability, adaptability, and flexibility.

4. Place accessibility of information in close proximity to the patient.
5. Improve visibility of patients to staff.
6. Involve patients in their care.
7. Minimize fatigue of staff.
8. Minimize patient transfers/handoffs.
9. Reduce noise.
10. Standardize.

These principles were substantiated by using failure mode and effects analysis throughout the design process, involving patients/families, and instituting an organizational culture of safety, these principles would enable designs that would support the anticipation, identification, and prevention of adverse events.[65]

Designing for Nursing Care

The first step for the National Learning Lab was an educational program about human error and its causes associated with latent conditions and active failures. The goal of this education was to gain commitment to the need for nurses to be active in the design phase. Then representatives of nursing were elected to a facility design committee. Design teams of nurses were also formed to assure formal input into the design. Mock-ups were also an important feature and prompted more input from the nurses. Many rooms were mocked up, and the medical-surgical room was modified multiple times by the involvement of nurses reviewing every detail to assure a safe design. Nurses' involvement in equipment and technology planning started immediately with the mock-ups. The interplay between the facility (with its equipment and technology) and nurses and patients creates safe or unsafe interactions, and the result is affected in large part by the facility design.

Once the National Learning Lab was over, St. Joseph's Hospital began the important process of implementing the Lab's recommendations. For St. Joseph's to implement the National Learning Lab's recommendations, senior leadership knew they needed to involve nurses in the facility design process because of nursing's essential role in caring for patients, and because nurses interface with all the systems of a hospital at the "sharp end," including equipment, technology, facilities, and patients—more so then any other care provider in a hospital. Not discounting the role of physicians, other clinicians, and health care staff, nurses provide care 24 hours a day, 7 days a week. As such, nurses providing care are most aware of the best way to design a patient room (for example) so the room design minimizes the potential for human error and harm to patients. St. Joseph's organized the design process to maximize the involvement of nurses.

Single-Patient Room

In many instances, including the need for patient isolation measures, double or multiple-occupancy rooms were viewed as not being conducive to patient safety and quality care. The floor plan shown in Figure 1 illustrates how a series of standardized single-patient rooms were laid out on both sides of a hallway in St. Joseph's Hospital. This perspective allows various features of the room to be seen in relation to each other. There are two entrances to the room, one from the hallway (along the lower edge of the picture), and one from the alcove on the right. In that alcove, also entered from the hallway, a desk, computer, and chair are provided for use by

staff. The alcove also contains a standardized storage area, so staff can find everything they need for the care of the patient adjacent to the patient room.

The interior of a single-patient room incorporates many of the recommendations relating to latent conditions and active failures in the design for safety (see Figure 2). The family area of the room is in the right corner of the room, by the window, and includes a couch/pull-out bed, chair, desk with Internet connection, and good natural lighting. The treatment area of the room is on the left side of the bed, with room all around the bed for patient care. It is intentional, also, that the patient is on the nurses' and other caregivers' right as that person enters the room from either door, so care can be more efficiently provided. Note that the bathroom is at the head of the patient's bed, allowing the patient to get to and from the bathroom without impediments, holding onto a rail all the way if necessary. At the head of the bed is the headwall with connections for various gases such as oxygen; on the wall to the left of the bed is a pull-down table the caregiver can use when it is needed. Although it is not shown in the illustration, there will also be a portable cart in each room, with a computer on it. Last but not least, in the lower right-hand corner of the room, between the two doorways, easily visible to the patient, there is a sink—an ever-present and convenient reminder to nurses, all staff, and visitors to wash their hands.

Figure 1. Floor Layout of Single-Patient Rooms in St. Joseph's Hospital

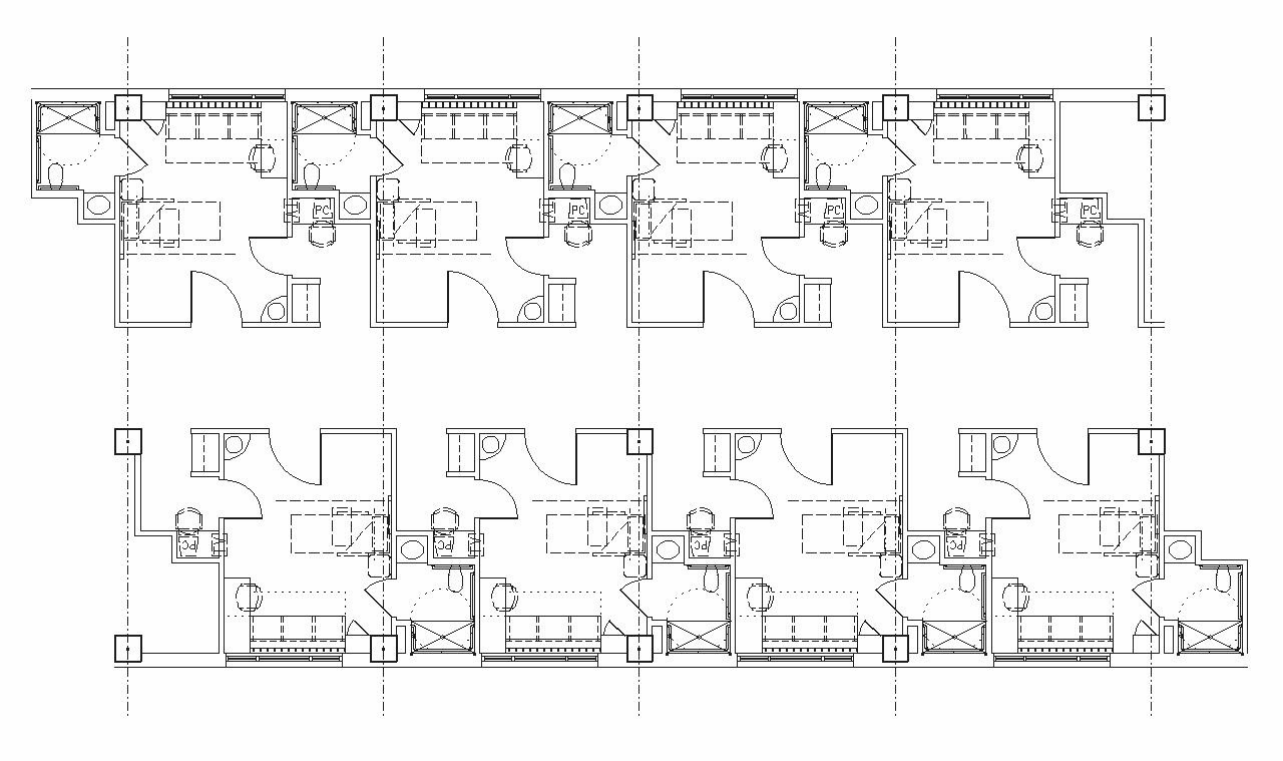

Figure 2. Single-Patient Room in St. Joseph's Hospital

Applying Knowledge of Active Failures and Latent Conditions to Room Design

The design process for St. Joseph's Hospital focused on safety, employing broad participation, including nurses, physicians, board members, administration, National Learning Lab participants, expert consultants, other health systems, health care writers, and design teams. The patient room was selected as a good example of how the design plan for the hospital came together in one location. To show how the room design was reached, each of the applicable latent conditions and active failures will be discussed, to explain how they relate to the plan for a single-patient room.

Noise reduction: Noise interferes with communication, creates distractions, affects cognitive performance and concentration, and contributes to stress and fatigue.[66] Particularly sensitive are mental activities involving working memory.[67] Noise can also adversely impact healing, alter quality of sleep, and reduce overall perceived patient satisfaction, yet the evidence at present is equivocal.[68] Since a standardized patient room has a material effect on noise, the bed in each single room in St. Joseph's is in the same location as the next room. In the traditional patient room style, called back-to-back, patient beds are on the same wall. Back-to-back plans create major transfer noise between rooms, and their use of the same oxygen, compressed room air, and

suction intensifies the transfer noise and vibration. In a truly standardized room, this does not occur. In addition, the walls between rooms are separated and insulated with airspace, minimizing transfer noise. This was designed into the structure early in the building design. In addition, vibration noise between floors and within a floor was minimized through design. The mechanical, electrical, and plumbing systems were designed to use the optimum materials for minimizing noise. This included using vibration isolation/dampening devices wherever vibration could be a factor.

The flooring in the patient room is rubber, second to carpet in sound reduction qualities. The reason carpet was not chosen (it was mocked up and tested) is because spills and mishaps needed to be cleaned up immediately. Carpet requires housekeeping to bring a carpet cleaner, which could take time and also could be embarrassing for the patient. Carpet was chosen, however, for the alcoves and hallways, with a low-nap, special carpet for hospital application. Special ceiling tiles that absorb noise better than regular ceiling tiles were chosen. Triple glazed windows were specified to minimize outside noises. No overhead paging system is used (except for public emergencies such as a tornado warning), and nurse call systems use minimal tone with vibrating features. As specific equipment and technologies were needed, manufacturers of that piece of equipment or technology were contacted and asked how they reduced noise in their products. That became one important criterion for selecting which company's equipment to use.

Scalability, adaptability, flexibility: Many design and construction concepts can be applied to achieve a scalable (e.g., the ability to expand or remodel easily) or adaptable (e.g., the ability to adapt space for different or evolving services) health care facility. At St. Joseph's, all rooms have higher-than-normal ceilings to allow changes to be incorporated in the future. Space around the bed is sized so procedures (e.g., colonoscopies) could be performed in the room in the future.

Visibility of patients to staff: The importance of being able to see patients is inherent to nursing care, a concept that was recognized early by Florence Nightingale, who advocated the design of open, long hospital wards to see all patients. The design of units and patient rooms should allow caregivers to be in visual proximity to patients; a pod structure can allow close proximity and enable quality care by improving efficiency and effectiveness. At St. Joseph's, each alcove door has a glass window with a blind so nurses can work in the alcoves and see the patient or check on the patient. The nurse can also check on the patient in the evening without opening the door and waking the patient. Each room is wired for cameras for observation. All materials, such as medication, linens, IV poles, and a rough-in for icemakers, are delivered to the alcove to allow nurses to spend more time with the patient. The chart will initially be in the room, but shortly after the new hospital opens, it will be replaced by electronic medical records with a workspace so nurses and other caregivers can spend more time with the patient. Furthermore, visibility also means lighting to see the patient. Natural light is maximized by large windows in every patient room. Light sources after hours are as close to natural light as can be achieved cost effectively. Canned lights are located over the patient for assessment. A total of 15 lights are located in every room, including the bathroom and alcoves.

Involving patients in their care: The IOM[9] found that many patients have expressed frustration with their inability to participate in decisionmaking, to obtain information they need, to be heard, and to participate in systems of care that are responsive to their needs. The availability of information for patients increases their knowledge regarding their illness and treatment options, and being informed gives patients the opportunity to participate in shared decisionmaking with clinicians and may help patients better articulate their individual views and preferences.[69–71] This reflects several dimensions of patient-centered care, including respect for

patients' values, preferences, and expressed needs, as well as providing information, communication, and education.[72]

At St. Joseph's, the patient room is designed with a treatment section near the door and a family section near the window. A couch folds outs into a bed; a desk with an Internet connection encourages family members or friends to stay with patients. This is intended to help patients to be more active with their care and better able to protect themselves from errors. A portable computer on a cart (same one used by staff) is located in each room so patients can have appropriate access to their chart.

Standardization: Standardization has been documented as an important human factors-based design strategy [4, 64] that can help lessen the number of errors. Standardization reduces reliance on short-term memory and allows those unfamiliar with a specific process or design to use it safely.[64] With a focus on improving the human-system interface by designing better processes and systems, standardization of patient rooms, treatment areas, equipment, and procedures can substantially reduce errors.[64]

There were many design elements that incorporated standardization as a physical attribute. The patient rooms in St. Joseph's may be the first patient rooms in the country to be standardized. The headwalls are standardized throughout the facility; a seven-drawer configuration was designed into every patient room or alcove to provide consistency of supply locations and to simplify the restocking of those supplies. This provides staff with a known constant, regardless of where they may be caring for a patient throughout the facility due to floating, a patient resuscitation, or some other emergent situation. The electronic medical record, use of bar-coding, computerized provider order entry, and other technologies will be standardized eventually, assisting in the development of standardized protocols and order sets. The facility materials distribution and routine nurse functions can also be standardized to match the facility.

Equipment is not fully standardized yet, but that is the goal, since fully standardized equipment provides the highest level of safety. The complexity and variety in equipment vendors and models is immense, and this complexity creates more errors. This weakness—the lack of equipment standardization—was pointed out continually in using failure and effects mode analysis. So St. Joseph's is evolving toward equipment standardization. The hospital was able to purchase limited new patient monitoring equipment, and took care to assure that new and existing equipment were from the same vendor to give the user a similar feel and functionality, regardless of which equipment they were using. The hospital will continue to utilize this process to guarantee long-term equipment standardization within the facility.

Automation where possible: The IOM identified health information technology solutions as a necessary component to improving patient safety.[9] As discussed in the chapter on health information technology, technologies such as electronic medical records can improve communication and information dissemination between providers.

At St. Joseph's, electronic medical records, bar-coding, physician order entry, a pneumatic tube system, two computers in every room (one in the alcove and one on a cart in the room), a sophisticated nurse call system, new patient beds, and patients lifts for every room are examples of automation. These applications are intended to allow caregivers to give care more efficiently and rely less on short-term memory. Many design features and technology applications have affected multiple latent conditions. This was one of the important criteria used at the matrix exercise to determine which design features to include. Technology applications were deemed to be a critical part of allowing St. Joseph's to design for safety.

Immediate accessibility of information, close to the point of service: In order to provide patients with the most accurate diagnosis and treatment possible, clinicians need to have complete, real-time information about the patient, care needs, and treatment options. Technologies such as the Internet, electronic medical records, and clinical decision-support systems can accomplish this. At St. Joseph's, electronic medical records were seen as the most useful way of making information accessible quickly at the point of service. When the hospital opened, the patient chart was 100 percent paper based. In traditional hospital environments, the patient chart changes location without regard to patient activities. Early mornings, a physician may come around and take the chart to a quiet dictation area to write notes and orders. The chart is often left there until another care provider requires the chart. Or, the chart may be left with the unit secretary to input/transcribe orders.

A transitional plan was developed to meet this guiding principle: When the hospital opened, a mandate was incorporated into the physician and staff orientation that the chart on the medical/surgical unit never leaves the alcove unless the patient leaves. This was surprisingly effective and compliance was unusually high. When an order is written, the physician uses a wall-mounted button labeled "New Order" or "Stat Order" to alert the unit clerk. The unit clerk then transcribes the order and does any necessary computer order entry in the alcove. The chart never leaves the alcove. Anecdotally, the physicians find this process useful to them. They can make rounds more efficiently, since they never have to look for a chart to write their notes or orders. They never have to "batch" their rounding and then look for all of the charts to document. Verbal orders are also reduced. For obvious reasons, this process will cease to be relevant when the electronic medical record is implemented.

Minimizing fatigue: Fatigue has been identified as a contributing factor to human error.[73, 74] While the effects of fatigue on patient safety is not known, fatigue has been found to have a negative impact on alertness, mood, and psychomotor and cognitive performance, which can have an impact on patient safety.[74–76] Some of the effects of long work hours and increasing workload can be mitigated by minimizing the distances staff must travel between patient rooms, and by using health information technology at the bedside to reduce reliance on short-term memory and thought processes. Other considerations in the design of St. Joseph's to minimize fatigue are carpeting and rubber flooring, a chair in the alcove, single rooms, keeping all materials in the alcove so nurses have to take fewer steps, less reliance on short-term memory, less noise, natural light, and strong lighting sources.

Minimizing patient transfers/handoffs: Transferring patients from one unit, room, or floor to another puts both the patient and staff at risk of harm, and it is disruptive to both patients and clinicians. Often these transfers involve handoffs, which, as described in another chapter in this book, also place the patient and clinician at risk for errors. Minimizing patient transfers and handoffs has design implications. Private single rooms with appropriate space around the beds, lifts, and other safety mechanisms allow more procedures to be performed in the room. This is similar to the model in obstetrics with Labor Delivery Recovery Post-Partum (LDRP) rooms, where the mother delivers the child and the child can remain with the mother in the same room for the entire stay. Another example is the physical therapy gym located on the med-surg unit—the patient never leaves the unit to obtain therapy, and their nurse is always in close proximity should a change in patient condition occur. Electronic medical records are another important tool. Bar-coding helps with continually and accurately identifying the patient.

Addressing the Root Causes of Precarious Events

The approaches used by St. Joseph's to address root causes for other types of at risk areas are described as follows:

Operative/postoperative complications and infections: Among the design features that will contribute to the reduction in operative/postoperative complications and infections are private rooms; a sink at the entrance to the medical/surgical patient rooms, which you must pass going in either door (to encourage hand washing); internal window blinds (to reduce accumulation of dust); a housewide air filtration system that includes central HEPA filters; ultraviolet lights in all clinical areas; airflow systems in which clean air passes the patient and is recycled and filtered again; and a radiant heat panel above or below every patient window to eliminate condensation. These are all features that minimize infection. Air supply and return grates that need cleaning have been upgraded to stainless steel so cleaning is more effective. However, the most important design element is the location of the sink, since lack of hand washing is the number one reason for hospital-acquired infections.

Inpatient suicides: Data from the Joint Commission indicate that out of the approximately 1,500 to 1,800 suicides that occur annually in hospitals, about 50 percent of those occur in medical/surgical units. The two most common methods are jumping and hanging. In a medical/surgical room, there are many things patients can use to hang themselves, such as bathroom curtain rods, showerheads, television brackets, or lights. Thus, St. Joseph's decided to use breakaway shower curtain rods and minimize other hanging risks by choosing lights and brackets that met the design needs of the room but would be less likely to be used for a suicide attempt. To minimize jumping, windows cannot be opened, and they are triple-paned, making them much harder to break through. If a suicide-risk patient is identified, that patient is transferred to the mental health unit, but increased visibility in all patient rooms helps staff keep a closer watch, which helps minimize the risk of suicides.

Death of patients in restraints, patient falls: St. Joseph's, like most hospitals, has minimized restraints. The new beds ordered for the hospital have eliminated many of the risks of deaths due to restraints. With less and less restraints, however, the risk of falls rises. Most patients fall at night or while walking with a nurse or other caregiver. Design elements that help reduce falls include fixed night lights in every room, beds that drop down to sixteen inches above the floor, locating the bathroom at the head of the bed with railings to the stool and shower, and utilizing bathroom lights that automatically turn on when anyone enters the bathroom. Besides the above-mentioned strategies, a bed-exit system is being explored using infrared technology. If a patient is identified as he is trying to get out of bed, then lights could turn on, an emergency call to the pager could occur, or a voice could ask the patient to wait for a caregiver. Such a system is in design at St. Joseph's.

Correct tube—correct connector—correct hole placement events, oxygen cylinder hazards: All connectors are a different size for different gases and color-coded. Storage and identification of portable gases employ the same identification program. All gases are in standardized locations to further minimize the risk of a gas-connecting error.

Wrong-site surgery: Operating room suites were standardized, using proper lighting and cable access to digital images and photographs of the surgery site.

Medication and transfusion-related adverse events: Bar-coding, unit doses at point of service, electronic medical records, and physician order entry are critical elements for medication

error reduction. Private rooms with alcoves that include medical records allow nurses to concentrate on one patient and document those efforts, before moving on to the next patient.

Bringing It All Together at St. Joseph's Community Hospital

The use of failure mode and effects analysis, patient focus groups, mock-ups with employee evaluation, and checklist safety design principles (latent conditions and active failures) helped St. Joseph's create the safest room they could envision. The patient room evolved over months of design. Over 27 different designs or refinements were made on the patient room. This room is not the only way a patient room can be designed for safety, but it is believed to be a good way, and it exhibits efficient, thoughtful features that meet National Learning Lab expectations.

The 2002 National Learning Lab had a powerful effect on St. Joseph's and is beginning to influence hospital facility development nationally. St. Joseph's Hospital implemented the recommendations of the Learning Lab, designing around latent conditions and active failures, and enhancing or creating a safety culture through facility design with its technology and equipment. The importance of nursing leadership in the whole process cannot be overstated. Without the commitment, knowledge, and perseverance of the nursing leadership, along with the chief executive officer, board, medical staff, architects, and the rest of the design teams, a safe design would not have occurred.

The effort of St. Joseph's is just the tip of the iceberg of the potential for improving safety of patients in hospitals as a result of facility development. The impact of the National Learning Lab recommendations on processes also offers an immense opportunity to improve the safety of patients in hospitals. The work of St. Joseph's should serve as a model for those health care leaders who share the vision that facilities, including equipment and technology, focused on safety will improve the health and well-being of the patients whom they serve.

The building of the new hospital was completed in 2005, and investigators are currently evaluating the impact of their designs on the frequency of adverse events and patient outcomes. Using innovative architectural and design features to enhance patient safety together with institutionalizing a nonpunitive safety culture can potentially have a greater impact than design features alone. Over the past few years, the National Learning Lab changed St. Joseph's Hospital and has begun to influence hospitals and health care throughout the country.

Leaders and clinicians at St. Joseph's found that the project, with its many safety enhancements, resulted in capital expenditures under budget—an important consideration in the business case. The National Learning Lab's process of identifying and addressing latent conditions was correlated with the Toyota Lean Principles. Standardization, visibility, continuous flow, value stream, minimizing handoffs/transfers will be created as a result of a safely designed facility. This should lead to less human error and potential harm and more efficient operations (process). Yet, one of the major difficulties of translating this efficiency and better outcomes into improved net income is the basic misalignment of financial incentives. Both the fee-for-service and the DRG (diagnosis-related group) introduce perverse incentives. Hospital revenues can actually be reduced as a result of improved safety, and savings can accrue to the insurance companies and not the institutions creating the improvements. Although there is some evidence of changes to improve these misaligned incentives, more dramatic changes are needed to encourage safe process redesign.

Practice Implications

The evidence base is growing in support of evidence-based design for renovations and new building. The new field of evidence-based design has emerged at a time when there is a health care construction boom.[77] There are many factors in the workplace that impact care delivery and work satisfaction, and they should be incorporated into designs. Based on the Gurses and Carayon study,[54] care processes will need to be modified to address inefficiencies caused by distractions (e.g., by family members), overly busy working conditions, delays in getting access to required resources (e.g., medications, patient medical records, supplies, and medical equipment), delays in seeing new medical orders, and misplaced equipment.[54]

Nurses need to be involved and have an active role in evaluating, planning, and testing the layout of patient units and patient rooms to ensure a healing and comfortable environment for both patients and clinicians. Lessons learned should be shared with others to enable improvements across the country, not just on one facility. Current laws and regulations will need to be modified to support new hospital standards and building codes.[10] As single-bed patient rooms are now considered the minimum standard for maternity/postpartum and intensive care units in general hospitals,[78] nurses will need to be involved in planning for transitions and assessing environmental and structural features that will improve the quality of care afforded patient.

Research Implications

The impact of the built environment will most likely be magnified by concurrent efforts to change organization culture and functionality as well as processes of care delivery, but future research would need to so demonstrate. Since the majority of the research on the impact of the built environment has been conducted in specific units in hospital settings, it will be important to investigate whether similar effects can be realized in general medical-surgical units and outpatient settings, including clinics and offices.

In a 2004 report commissioned by the Agency for Healthcare Research and Quality, *The Hospital Built Environment: What Role Might Funders of Health Services Research Play*,[10] the following gaps in the literature were identified: What are the effects of the built environment on the quality of communication and information sharing between clinicians, patients, and families? What is the relationship between environmental factors and the working conditions for clinicians? What are the best mechanisms and designs for facilitating effective hand washing? What is the effect of elements in the built environment that reduce staff fatigue, distractions, and stress? And what is the role of the built environment in decreasing infection rates across patient types? Nurses can have a critical role in addressing these and other research gaps. In this relatively new and exciting area of research in health care, nurses need to and should be actively involved throughout the research and quality improvement processes involving the design of the work environment space.

Conclusions

In the next few years, hospital leaders will be involved in new hospital construction projects to meet the changing marketplace demands associated with the growing demand of an aging population. Many clinicians, architects, and hospital administrators believe that the hospital built

environment can benefit the satisfaction of health care providers as well as patient satisfaction and outcomes. There is some evidence that the built environment may influence patient and family perceptions of the quality of and satisfaction with care received during a hospitalization. There is also some evidence that nurse satisfaction with the built environment was related to general well-being and job satisfaction, two factors that are critical because of their impact on patient care.

The evidence-base is emerging to support the business case that designing for safety and quality can improve patient outcomes and safety, promote healing, increase patient satisfaction, and reduce costs. It is thought that the cost of building or remodeling projects based on design evidence conducive to patient safety can result in organizational savings over time, without adversely impacting revenues.[8] Investigators with the Center for Health Design have been assessing hospitals involved in the Pebbles Project, and have found that the financial incentive for investing in evidence-based design using therapeutic design elements such as single-bed rooms and decentralized nursing stations added close to $12 million in costs to hospital reconstruction—but those costs would be recouped within one year of being operational.[79]

Those building new or remodeling current facilities should consider beginning with transitioning to a culture of safety, then using a safe design as a matter of focusing on maximizing the safety features without expending additional capital resources. While relatively new, evidence is growing in objective assessments of the impact of built environments, particularly around the issue of infection control. Some safety features will cost more than traditionally designed facilities (e.g., HEPA filters and ultraviolet lighting to improve air quality) while other safety features will cost less than a traditionally designed facility, most notably standardization. In all, most of the safety features of a built environment involve a reordering of functions in most "traditionally" designed facilities, minimally affecting capital costs, to improve the quality of care and patient outcomes.

Search Strategy

PubMed® was searched to locate studies and related literature on the built environment. Most of the articles identified in the literature search were primarily descriptive. Search terms included "built," "environment," "hospital design and construction," "interior design and furnishings," "patients' rooms," and "health care." Excluded from the review were articles published before 1999, non-English language articles, expert opinions, case reports, and letters. Three hundred abstracts were obtained. To be considered evidence in this review, the research had to involve nurses or patients in clinical settings, reported findings related to patient safety, and not be specific only to health information technology.

Evidence Table

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Chaudhury 2006[57]	Single-occupancy rooms in acute care	Cross-sectional study	Survey of nurses about patient care, management, and infection control issues (Level 4).	77 administrative and staff nurses in 3 hospitals in Washington and 1 in Oregon	None	Nurses favor single-occupancy rooms because of their flexibility, being more appropriate for patient examination, quality of patient monitoring, improved patient comfort level, improved patient recovery rate, and scope of patient surveillance. 57 percent believed that health care acquired infections were low or very low in single-occupancy rooms. There was no difference in the number of patient falls, need for pain-reducing or sleep-inducing medications between the two types of rooms. Helpful characteristics of single-occupancy rooms were layout of the room; availability of space in the room; the arrangement of furniture; privacy; space for family members; storage for clean and dirty supplies; and the location of the sink, bathroom, door, and window; lighting; temperature control; and lower noise levels. Helpful characteristics of double-occupancy rooms were proximity to nursing station; visibility of patients for monitoring purposes; and the location of the sink, bathroom, door, and window.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Douglas 2005[60]	Built environment Patient-centered care	Cross-sectional study	Multiple methods, including 50 personal interviews, autophotographic study with 35 patients, novice-expert cohort of patients and clinicians, and a survey of past patients (Level 4).		None	Patients viewed the environment and internal areas of the hospital that made them feel comfortable and able to keep a sense of normalcy as having a positive effect on their feelings of well-being. Novices and experts considered the following important: good signage; controllable lighting and temperature; privacy; reduced noise levels; access to the natural environment; safety and security in internal and external areas; internal and external children's play areas; accommodations for visitors; shops and personal services; good 24-7 catering facilities; and good landscape designs with seating and garden areas. Patients reported the general atmosphere (e.g., feel of the environment, feeling safe and at home, having the TV close by, and being able to walk around) as important. Patients felt a loss of independence and control.
Douglas 2004[58]	Built environment	Cross-sectional study	Face-to-face interviews with hospital inpatients (Level 4).	21 patients in surgery, medicine, care of the elderly, and maternity in 1 hospital in the UK	None	Patients reported the general atmosphere (e.g., feel of the environment, feeling safe and at home, having the TV close by, and being able to walk around) as important. Patients interviewed felt a loss of independence and control Most important factors about the built environment were privacy, a homely environment, considerations for disabilities, being able to see outside, and to get outside.
Feeney 2007[61]	Built environment	Cross-sectional study	Assess the impact of a new, purpose-built acute unit on patients' behaviors and care needs (Level 4).	1 psychiatric unit in a hospital in Ireland	Implementation of a purpose-built acute psychiatric unit in a hospital in Ireland	After the new unit opened, there were fewer patients that left against medical advice, aggression levels in patients decreased, and levels of benzodiazepine dosing decreased.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Fowler 1999[59]	Built environment	Cross-sectional study	Conducted 9 focus groups with patients (Level 4).	Patients in ambulatory, acute care, and long-term care settings	None	Patients and family members look for an environment that facilitates a connection to staff and caregivers, is conducive to a sense of well-being, and facilitates a connection to the outside world.
Gurses 2007[54]	Effects of physical environment	Cross-sectional study	Survey of nurses in intensive care units (ICUs) (Level 4).	272 nurses in 17 ICUs in 7 hospitals in Wisconsin	None	Reported performance obstacles included noisy work environment, distractions from families, hectic and crowded work environments, delay in getting medications from pharmacy, amount of time teaching families, equipment not being available, patient rooms not well stocked, insufficient workspace for completing paperwork, time spent seeking supplies or patient's charts, receiving many phone calls from families, delay in seeing new medical orders, and misplaced equipment.
Hendrich 2004[62]	Acuity-adaptable rooms	Pretest, post-test	Implementation of new acuity-adaptable rooms (Level 3).	A coronary critical care unit and its step-down medical unit at 1 hospital in Indiana	Evidence-based design of 56 new acuity-adaptable rooms for the combined coronary critical care and step-down unit.	After the move, there was a large reduction in clinician handoffs and transfers; a 70 percent reduction in medication errors; a reduction in patient falls; improvements in patient satisfaction; decrease in budgeted nursing hours per patient day; increased available nursing time for direct care without additional cost.
Rashid 2007[56]	Effects of physical environment	Cross-sectional study	Development of a survey instrument about underlying effects of environmental features on staff perception of patient comfort, patient safety, patient privacy, family integration, and working conditions (Level 4).	Nurse managers/directors in 7 adult ICUs built between 1993 and 2003	None	Respondents reported that private patient rooms enabled patient safety; ensured privacy of patients; access to patient status information and space for family was important; and flexible patient charting locations and adequate work surface/space were important.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Shepley 2002[63]	Built environment	Pretest, post-test design	A multi-method approach using behavioral mapping; interviews; questionnaires; and calibrated measures of walking, noise, and temperature (Level 3).	21 nurses were observed, 10 completed the questionnaire, and 8 nurses were interviewed in a neonatal ICU in 1 hospital.	Implementation of a new neonatal ICU, where the new design focused on the development of a more efficient floor plan, the provision of space for supportive family-centered care, and the use of natural light	On the new unit, nurses were found to spend most of their time in active baby care, followed by walking, conversations, passive baby care, and charting. More time was spent taking care of the babies on the new unit than on the old unit. Those responding to the questionnaires perceived the new unit as comforting and clean but less secure than the old unit. Family-centered care was perceived as supportive of babies and their families, though its ratings were lower for the supportiveness of nurses and physicians. The unit was rated as generally being efficient and the new lighting was thought to have a positive impact on the patients. Those who were interviewed felt that families were utilizing the majority of space designated to them. They felt the design was efficient, lighting was improved, and noise levels were lower.
Varni 2004[55]	Built environment	Cross-sectional study	Development of a measurement instrument about the built environment (Level 4).	Parents and staff in a children's convalescent hospital	None	Parent satisfaction with the structure and facility aesthetics was associated with higher satisfaction with care. Staff satisfaction with the facility aesthetics and work environment was associated with higher satisfaction and coworker relationships.

Chapter 29. Turbulence

Bonnie M. Jennings

Background

The health care environment was once regarded as safe and secure[1] for patients and staff. Turmoil and change have pervaded the U.S. health care system since the 1980s, contributing to a state of chaos and instability.[1] Today's health care work environment can therefore be characterized as turbulent—it is in a state of unrest, disturbance, agitation, or commotion.[2]

There are many sources of turbulence in 21st century health care. They can be grouped into five categories:

- Hectic conditions in hospitals;
- The rapid growth of large health care corporations, which has altered organizational structures and dynamics;
- Constantly changing health policies, such as those related to insurance—what is covered, what is paid for out-of-pocket, how Medicare Part D really works;
- World events that have placed new demands on health care workers, such as concerns related to bioterrorism; and
- An aging population that is seeking care for chronic conditions from a health care system designed for acute care.

Although turbulence from all of these categories works to create challenges for health care workers, it is turbulence on hospital units that has the most immediate effect on the nurses' work environment. Staff nurses are striving to meet complex patient needs that require rapid decisionmaking, despite there being fewer resources and more interruptions and distractions.

The focus of this review is predominantly on studies that explored turbulence at the level of the patient care unit. Although publications were located that addressed turbulence in health care, no systematic conceptualizations were found delineating or describing the features of turbulence. Moreover, there were indications of slippage between the terms *turbulence* and *uncertainty*. Nevertheless, *turbulence* seems to capture key components of the dynamic and complex work environment that add to the challenge of providing quality care and keeping patients safe.

Research Evidence

Perhaps because turbulence remains to be clarified conceptually, a number of studies relied on qualitative methods. Although these investigations do not meet the criteria for inclusion according to most evidence hierarchies, they provide a rich description of turbulence. The 11 qualitative studies that were identified through database searches examined the work environment from the perspective of various health care personnel—Registered Nurses (RNs),[3–11] physicians,[12] and physical therapists.[13]

Although these studies varied in the rigor of their analytic approaches, five themes appeared across them. In general, turbulence was viewed as a *loss of control*[6, 11, 13] due to simultaneous demands; new, difficult, or unfamiliar work; heavy patient loads; and excessive responsibility.[6] Staff experienced the loss of control as a sense of chaos that infiltrated both their professional

and personal lives.[13] As the environment became more turbulent, *noise* escalated.[3, 6] *Problems with equipment and supplies* (e.g., malfunctioning, missing, calling for cumbersome processes to acquire) were also addressed as elements of turbulence.[3, 5, 11] Aspects of *workload*, particularly variability associated with patient turnover—due to admissions, discharges, and transfers—were mentioned as well.[4, 7, 11, 13]

Turbulence and Communication: The Qualitative Evidence

The dominant discovery from qualitative investigations concerned how turbulence altered various aspects of *communication*, leading to breakdowns, distractions, interruptions, loss of information during handoffs,[3-6, 8-10] and impaired decisionmaking.[3, 4, 10, 12] Although these studies did not always explore patient outcomes, they offer initial evidence to suggest that turbulence may upset certain aspects of communication, thereby compromising patient safety.

Findings from three qualitative investigations can be used to illustrate how turbulence might contribute to heavy communication loads and interruptions. In the first study,[5] eight experienced acute care nurses were observed and interviewed. The investigators in this study coined the term "stacking" to characterize a care management strategy in which nurses kept track of patient care that remained to be done. Evidence of cognitive stacking was also found in the second study,[10] where both ethnography and human factors engineering techniques were used to analyze the work of seven RNs on medical and surgical units. Based on 43 hours of observation, the investigators found that, on average, nurses had a cognitive load of 11 activities; the maximum load averaged 16. These numbers become highly meaningful when viewed in relation to a classic paper from psychology that identified seven, plus or minus two, informational concepts as the limit for information processing.[14] The cognitive stacking experienced by these medical-surgical nurses often exceeded seven.

In the third study,[9] communication related to nurse call systems was studied in two hospitals. Data were gathered from 41 nurses through observations and focus groups. The call systems were viewed by RNs as a source of unnecessary interruptions: 70 percent of the patient calls in one hospital and 80 percent in the other were for issues that did not require the skills of an RN. Interruptions were also common in the previously mentioned study of medical-surgical RNs, comprising an average of 7 percent of their work time.[10] Forty-seven percent of the interruptions happened during patient-related interventions, with 22 percent of these occurring in the medication room during medication preparation.

Turbulence and Medication Errors

The likely connection between turbulence and medication errors was also found in interview data from eight novice RNs who recounted their experiences with near-miss (n = 2 cases) or adverse events (n = 6 cases).[4] All six adverse events and one of the near misses were related to medication administration. Factors in the environment that may have contributed to these errors included a sense of time pressure, inadequate handoffs, impaired decisionmaking, or awkward workflow patterns—all of which could pertain to turbulence.

The quantitative studies can be categorized according to three ideas: medication errors, patient turnover, and communication. Medication errors were explored in three studies that examined features of turbulence.[15-17] In one study,[15] the investigators discovered that the work environment was more likely to be hectic and staff were more likely to be distracted in the 30

minutes preceding medical errors, 91 percent of which related to medication administration. In another study,[16] two protocols were designed to reduce distractions during medication administration. Although there were fewer distractions with one protocol (64 distractions) than the other (180 distractions), both protocols were effective in minimizing disruptions as compared to the control group (484 distractions). The differences among the three groups were statistically significant ($P = .0001$). Interruptions were the most common source of distractions across all three groups. Finally, in an intervention study designed to reduce patient transfers between coronary care and step-down units,[17] the medication errors index was reduced by 70 percent. Transfers were characterized as a "hiccup" in care delivery that could allow error to be introduced. Moreover, transfers take time that could be better spent in caring for patients (see Table 1).

Patient Turnover

The second grouping of quantitative studies considered census and staffing variability or patient turnover related to admissions, discharges, and transfers, as well as observation patients.[17-23] The census variability from patient turnover demonstrates the need to replace midnight census as an indicator of patient volume; it also contributes to turbulence in the environment. The previously mentioned intervention study,[17] for example, reduced patient turnover from transfers by 90 percent through using acuity-adaptable rooms for coronary patients.

The importance of patient turnover is further illustrated in work by Houser,[24] who used structural equation modeling to assess features of the complex work environment on patient outcomes. Although workload, measured by length of stay and midnight census, demonstrated a negative relationship with patient outcomes, it was not a statistically significant predictor of outcomes. Adding patient turnover to the workload measure may have yielded different findings.

Patient turnover was used in combination with other variables in an additional two studies. The first[19] illustrates the slippage between turbulence and uncertainty. The investigators measured objective uncertainty—at times referred to as environmental turbulence—using patient turnover divided by midnight census. Although objective uncertainty was predictive of emotional exhaustion ($P < 0.01$) among staff nurses, the relationship was negative. The investigators suggest this unexpected finding may reflect that patient census variability possibly mediates the emotional effects of environmental turbulence because of the relief offered by occasional decreases in patient turnover.

In the second study,[21] path analysis was used to test a model to predict environmental and personal characteristics affecting nurse performance. Similar to objective uncertainty, the measure of turbulence included patient turnover. Although turbulence did not demonstrate direct effects on nursing performance, it did have a direct negative relationship with interpersonal relations and communication skills that was statistically significant ($p \leq 0.01$). These findings begin to illustrate that more turbulent environments may exert undesirable effects on communication with patients, families, and other staff.

Turbulence and Communication: The Quantitative Evidence

Turbulence and communication were explored in other studies as well. Communication mechanisms were examined at one academic health science center based on three types of unit level practice environments—complex, unpredictable and rapidly changing, or stable.[25] Patient

care communication mechanisms used by the RNs were similar regardless of the degree of stability in the practice environment. The investigators suggested that quality could be better sustained if nurses learned to adjust their communication according to demands in the practice setting.

Communication was quantified and described in two studies. In observing eight emergency department (ED) nurses and physicians for about 20 hours across all shifts, 831 distinct communication events were identified.[26] On average, each of the eight clinicians spent 89 percent of their time communicating; they experienced 42 communication events per hour. Interruptions characterized one-third of the communication events, with each clinician experiencing an average of 15 interruptions per hour.

In the second study,[27] communication patterns were evaluated between the operating room (OR) charge nurses and other OR staff members at four hospitals—two university and two community. The OR suites ranged in size from 4 to 18 rooms. Observations and a data collection tool were completed on 17 nonconsecutive days, for a total of 2,074 communication episodes observed over about 100 hours. Communication episodes per hour ranged from 32 to 74, with more communication episodes associated with the larger OR suites. Charge nurses most often communicated with OR nurses (39 percent). The most common purpose of communication related to equipment coordination. Most communication occurred face-to-face (69 percent), with only 7 percent of the exchanges occurring via intercom. The duration of the communication ranged from 10 seconds to 10 minutes, with a mean of 40 seconds and a median of 20 seconds. Despite the overall brevity of most communication, the investigators did not assess interruptions.

The findings from this collection of qualitative and quantitative investigations have strong implications for practice (see Table 1). Turbulence can be said to emanate from two major sources—workload and communication. Reducing workload and improving communication, with particular attention to minimizing interruptions, could have dramatic effects on stabilizing the practice setting.

Table 1: Summary of Research Evidence Related to Turbulence—Key Findings Center on Communication and Workload Issues

Communication	• Breakdowns • Distractions • Interruptions • Inadequate handoffs (e.g., loss of information) • Impaired decisionmaking • Overload of information (cognitive stacking) • Noise • Interpersonal relations
Workload	• Excessive responsibility • Heavy patient loads • Patient turnover (admissions, discharges, transfers) • Simultaneous demands • New, difficult, unfamiliar work • Time pressure • Equipment and supply issues

Evidence-Based Practice Implications

Common sense suggests that turbulence could interfere with care delivery in several ways. However, the practice implications related to turbulence are only beginning to surface. There is a paucity of studies examining turbulence, fewer still that include patient outcomes, and only three that met criteria for inclusion in the evidence table (see Evidence Table). Even these studies must be considered with caution. None of the studies, for example, was designed to allow causality to be inferred.[17]

However, messages that can be used in practice can be constructed by combining the findings from studies in the evidence table with those using qualitative methods and the quantitative investigations that did not focus on patient outcomes. First, it appears that mitigating turbulence has a positive return in regard to patient safety. In particular, efforts to reduce environmental turbulence may be a major remedy for reducing medication errors. Second, intriguing and potentially fruitful areas for future exploration include cognitive stacking and cognitive shifts, interruptions and other distractions such as noise, and the overall effect of turbulence on communication in general. Finally, features of workload, such as patient turnover and time pressure, are also important avenues for future investigations. Data indicate that each of these elements is connected to patient safety in important ways.

Needed: A Conceptual Framework

Turbulence is an emerging concept that appears to have important ramifications for patient safety. Empirical work is limited, however, by the absence of a model that specifies the components of turbulence. Developing and testing a theoretical model of turbulence would therefore make an important contribution to guiding future research. Exploring similarities and differences between turbulence and uncertainty would also advance conceptual and theoretical clarity. Additional qualitative work may be required to achieve this goal.

Although common sense suggests that chaos is not compatible with patient safety, the understanding based on research findings is limited. Findings from a few studies are beginning to indicate there is a connection between environmental turbulence and medication errors.[4, 10, 15-17] The relationship of turbulence to other clinical outcomes and patient safety indicators remains to be illuminated. More rigorous designs would facilitate a better understanding of the effects of turbulence on patient outcomes. Instrument development would also make a contribution, if a psychometrically sound measure of turbulence could be developed once there is greater conceptual clarity.

Concurrently, although some individuals may regard intervention studies as a bit premature, evidence is accumulating in support of the belief that features of workload and communication have undesirable effects on patient safety. A challenge to researchers, therefore, is to design easy-to-introduce ways to reduce environmental turbulence. Questions and avenues of pursuit might include establishing a metric of a safe patient load, developing an intervention to mitigate the undesirable effects of patient turnover, introducing ways to minimize interruptions, developing processes and procedures to improve handoffs, and determining how to reduce cognitive overload.

Additional possibilities include working with architects and engineers to construct patient care units for the future. These units would take into consideration the needs of both patients and

staff. The overall goal would be to reduce turbulence for the purpose of creating a safer, more secure environment for both patients and staff.

Lastly, there is currently a gap in examining turbulence in long-term care, outpatient settings, and the home. Along with advancing the understanding of turbulence in each of these care settings, it would be useful to explore turbulence across the care continuum as it applies to patient safety and quality care.

Conclusion

Turbulence is a concept that appropriately characterizes contemporary conditions surrounding nurses' work. Because this concept is more recent in its application to health care, the literature about it in relation to quality care and patient safety is sparser. Nevertheless, as indicated in Table 1, ideas related to turbulence cluster nicely within two themes—communication and workload. Focusing efforts on improving communication and managing workload could offer much needed help to the practicing nurse who is often found working in a highly turbulent environment.

Search Strategy

Literature for this review was identified with the help of a reference librarian. Both MEDLINE® and CINAHL® databases were searched from 1995 to 2005 with the goal of being as inclusive as possible. The search terms were slightly different for each database because of differences in MeSH® headings. The terms included: turbulence, work interruptions, attention/or distractions, uncertainty, variability, unpredictability, workload or work overload, loss of control, and work environment. Citations were limited to research reports published in the English language.

The MEDLINE search identified 158 possible citations and the CINAHL search identified 1,324 possible citations. The abstracts for each of the 1,482 studies were reviewed. Based upon information in the abstracts, all but 119 publications were eliminated from consideration. Reasons for excluding papers were that they were not related to nurses in particular, health care staff in general, quality, or patient safety. For example, some studies identified initially pertained to memory assessments, environmental factors related to racial disparities, statistical tests, and studies of particular patient populations. The remaining 119 articles were reviewed in their entirety, 94 of which were eliminated from further consideration because they were not pertinent to turbulence per se (i.e., they were related to other concepts such as stress or leadership), or because they were simply short reports lacking in details.

Acknowledgments

Tremendous gratitude is expressed to the staff of the Armed Forces Medical Library, Falls Church, VA, for their considerable support of this work. They conducted the database searches and assisted in acquiring numerous papers considered in this review.

Evidence Table

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Grayson 2005[15]	Work conditions	Case control	Patient outcomes (Level 4), medical errors (medication and procedural) (Level 1)	11 acute care hospitals, 112 of 300 nursing personnel (RNs, licensed practice nurses, nursing assistants, patient care technicians) involved in a recent medical error that resulted in minimal or no harm to the patient.	None per se: working conditions were described at 3 points in time and attributes of the work environment were explored to determine the prevalence of potential triggers for errors.	Preliminary results for the first 112 interviews indicate: 91% of the errors related to medication administration. Participants were more likely to report a hectic working environment in the 30 minutes prior to making an error compared to the rest of the shift (OR = 2.6; 95% CI = 1.3-5.4) and more likely to feel distracted (OR = 4.1; 95% CI—1.9-10).
Hendrich 2004[17]	Patient transfers	Pretest, post-test	Design: Level 3, Patient outcomes, sentinel events (medication errors and falls) (Level 1), patient satisfaction and financial outcomes	Two, 28 bed floors in an acute care hospital, Patient transfers.	Acuity-adaptable rooms to provide progressive and critical care in the same setting.	During the two years before the change, the coronary care and step-down units averaged more than 200 intra-unit transfers each month; after the acuity-adaptable rooms were introduced, transfers were reduced by 90%, the medication error index was reduced by 70%, the fall index was reduced from an annual rate of about 6 to 2, and patient dissatisfaction declined.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Pape 2003[16]	Distractions	Non-randomized trial	Design: Quasi-experimental. The dependent variable was the number of distractions experienced by the nurse	A medical-surgical unit with an average patient census of 30, in a 520-bed acute care hospital, Nurses (n = 24)—46% (n = 11) licensed practical nurses, 17% (n = 4) of the RNs had BSNs	Two protocols were tested. Both provided the nurses checklists to guide their medication procedures. In addition, for the focused protocol, staff members were asked not to interrupt the nurse during medication administration. For the Medsafe protocol, in addition to the checklist and staff instructions, the nurses wore a special vest when administering medications. The control group received their medications under usual conditions. Each group (control, focused, Medsafe) was tested for 8 cycles yielding 24 high-volume medication cycles (the unit of analysis started with the beginning of medication administration and ended when the administered medications were documented).	The control group experienced 484 distractions (M = 60.5, SD 12.9), there were 180 distractions with the focused protocol (M = 22.5; SD = 8.5), and 64 distractions with the Medsafe protocol (M = 8, SD = 4.5). Statistically significant differences were found between the control group and each of the protocols (p = 0.001) and between the two protocols (p = 0.014) indicating that fewer distractions occurred when protocols were used as compared to the control group although the fewest distractions occurred with the Medsafe protocol. Across all groups, the most common distraction was interruptions by personnel (n = 267, M = 11.13), followed by hearing conversations by others (n = 215, M = 8.96). Loud noise was a less frequent distraction (n = 34, M = 1.42).

Chapter 30. Nursing Workload and Patient Safety—A Human Factors Engineering Perspective

Pascale Carayon, Ayse P. Gurses

Background

The heavy workload of hospital nurses is a major problem for the American health care system. Nurses are experiencing higher workloads than ever before due to four main reasons: (1) increased demand for nurses, (2) inadequate supply of nurses, (3) reduced staffing and increased overtime, and (4) reduction in patient length of stay.

First, the demand for nurses is increasing as a result of population aging. Between 2000 and 2020, the United States population is expected to grow by 18 percent (31 million), but the over-65 population, with more health care needs, is expected to grow by 54 percent (19 million).[1, 2] Second, the supply of nurses is not adequate to meet the current demand, and the shortage is projected to grow more severe as future demand increases and nursing schools are not able to keep up with the increasing educational demand.[3, 4] When a nursing shortage occurs, the workload increases for those who remain on the job.[5] Third, in response to increasing health care costs since the 1990s, hospitals reduced their nursing staffs and implemented mandatory overtime policies to meet unexpectedly high demands, which significantly increased nursing workloads. Fourth, increasing cost pressure forced health care organizations to reduce patient length of stay. As a result, hospital nurses today take care of patients who are sicker than in the past; therefore, their work is more intensive.[6]

There are several important consequences of high nursing workload. Research shows that a heavy nursing workload adversely affects patient safety.[7] Furthermore, it negatively affects nursing job satisfaction and, as a result, contributes to high turnover and the nursing shortage.[8] In addition to the higher patient acuity, work system factors and expectations also contribute to the nurses' workload: nurses are expected to perform nonprofessional tasks such as delivering and retrieving food trays; housekeeping duties; transporting patients; and ordering, coordinating, or performing ancillary services.[9] A 1998–1999 survey of more than 43,000 nurses in five countries found that 17 percent to 39 percent of respondents planned to leave their job within a year because of job demands.[9] Heavy nursing workload increases burnout and job dissatisfaction, which in turn contributes to high nurse turnover.[10] This chapter focuses on the impact of nursing workload on patient safety. We first present different concepts and models of nursing workload, then discuss the impact of workload on patients and on nursing staff, presenting various mechanisms of the relationship between nursing workload and patient safety. Finally, we describe a human factors engineering approach on how work systems can be redesigned to reduce nursing workload or to minimize the negative impact of a heavy nursing workload.

Concepts and Models of Nursing Workload

Nursing workload measures can be categorized into four levels: (1) unit level, (2) job level, (3) patient level, and (4) situation level.[11] These measures can be organized into a hierarchy. The situation- and patient-level workloads are embedded in the job-level workload, and the job-level

workload is embedded in the unit-level workload. In a clinical unit, for example, numerous nursing tasks need to be performed by a group of nurses during a specific shift (unit-level workload). The type and amount of workload of nurses is partly determined by the type of unit and specialty (e.g., intensive care unit [ICU] nurse versus general floor nurse), which is the job-level workload. When performing their job, nurses encounter various situations and patients, which are determinants of the situation- and patient-level workloads.

Workload at the Unit Level

The most commonly used unit-level workload measure is the nurse-patient ratio. The nurse-patient ratio can be used to compare units and their patient outcomes in relation to nursing staffing. Previous research provides strong evidence that high nursing workloads at the unit level have a negative impact on patient outcomes.[7, 12, 13] These studies' suggestions regarding improving patient care are limited to increasing the number of nurses in a unit or decreasing the number of patients assigned to each nurse. However, it may not be possible to follow these suggestions due to costs and the nursing shortage. The major weakness of this type of research is that it conceptualizes nursing workload at a macro level, ignoring the contextual and organizational characteristics of a particular health care setting (e.g., physical layout, information technology available) that may significantly affect workload. Research should examine the impact on nursing workload of work factors in the health care microsystems.

Workload at the Job Level

According to this conceptualization, the level of workload depends on the type of nursing job or specialty (ICU nurse versus operating room nurse). For instance, Schaufeli and LeBlanc[14] used a job-level measure of workload to investigate the impact of workload on burnout and performance among ICU nurses. Previous research linked job-level workload (a working condition) to various nursing outcomes, such as stress[15, 16] and job dissatisfaction.[17] Workload measures at the job level are appropriate to use when comparing workload levels of nurses with different specialties or job titles (ICU nurses versus ward nurses).[18] However, workload is a complex, multidimensional construct, and there are several contextual factors in a nursing work environment (e.g., performance obstacles and facilitators) other than job title that may affect nursing workload.[19] In other words, two medical ICU nurses may experience different levels of workload due to the different contextual factors that exist in each ICU. The workload at the job-level conceptualization fails to explain the difference in the workloads of these two nurses.

Workload at the Patient Level

This conceptualization assumes that the main determinant of nursing workload is the clinical condition of the patient. Several patient-level workload measures have been developed based on the therapeutic variables related to the patient's condition (e.g., Therapeutic Intervention Scoring System)[15, 20, 21] and have been extensively discussed in the nursing literature. However, recent studies show that factors other than the patient's clinical condition (e.g., ineffective communication, supplies not well-stocked) may significantly affect nursing workload. As with the previous two workload measures, patient-level workload measures have not been designed to measure the impact of these contextual factors on nursing workload.

Situation-Level Workload

To remedy the shortcomings of the three levels of measures explained above and complement them, we have suggested using another way to conceptualize and measure nursing workload based on the existing literature on workload in human factors engineering: situation-level workload.[11] In addition to the number of patients assigned to a nurse and the patient's clinical condition, situation-level workload can explain the workload experienced by a nurse due to the design of the health care microsystem. In a previous study, we found that various characteristics of an ICU microsystem (performance obstacles and facilitators)—such as a poor physical work environment, supplies not well stocked, many family needs, and ineffective communication among multidisciplinary team members—significantly affect situation-level workload.[22] For example, sometimes several members of the same family may call a nurse separately and ask very similar questions regarding the same patient's condition. Answering all these different calls and repeating the same information about the patient's status to different members of the family is a performance obstacle that significantly increases the (situation-level) workload of nurse.

It is important to note that the impact of this performance obstacle on nursing workload would not be apparent if we used a unit-level or patient-level workload measure. Compared to workload at the job level, situation-level workload is temporally bound: it explains the impact of a specific performance obstacle or facilitator on nursing workload over a well-defined and relatively short period of time (e.g., 12-hour shift), rather than using the overall experience of the nurse in a given microsystem. Situation-level workload is multidimensional, that is, different types of performance obstacles and facilitators affect different types of workload. Whereas the distance between the patients' rooms assigned to a nurse affects physical workload, the condition of the work environment (noisy versus quiet, hectic versus calm) affects the overall effort spent by the nurse to perform her job.[23] No prior study investigated the impact of the microsystem characteristics on situation-level nursing workload.[19] In summary, by studying workload at the situation level, researchers can identify the characteristics of a microsystem that affects workload. This information is vital for reducing nursing workload by redesigning the microsystem. In the last section of this chapter, a human factors engineering approach based on the situation-level workload is described.

Research Evidence

Impact of Nursing Workload on Patients

A heavy nursing workload seems to be related to suboptimal patient care[10, 24] and may lead to reduced patient satisfaction.[25] A 2004 report by the Agency for Healthcare Research and Quality (AHRQ) describes several AHRQ-funded studies on the relationship between hospital nurse staffing and quality of care (e.g., urinary tract infection, hospital-acquired pneumonia) and patient safety outcomes (e.g., failure to rescue).[26]

Much of the research investigating the impact of nursing workload on patient safety focused on linking nursing staffing levels with patient outcomes. There is strong evidence in the literature that nurse staffing levels significantly affect several nursing-sensitive patient outcomes.[13, 26, 27]

Several studies found a significant relation between lower nurse staffing levels and higher rates of pneumonia.[28-30] For example, a multisite study in California found that an increase of 1 hour worked by registered nurses (RNs) per patient day correlated with an 8.9 percent decrease in the odds of pneumonia among surgical patients.[28] Another study found a significant relationship between full-time-equivalent RNs per adjusted inpatient day and rate of pneumonia: the rate of pneumonia was higher with fewer nurses.[31] However, other studies have not confirmed these findings;[31, 32] for example, the evidence regarding the impact of nurse staffing levels on pneumonia is conflicting. As workload is affected by more than just staffing levels, a deeper understanding of nursing workload is required to better assess the impact of workload on patient outcomes. Later, a human factors engineering approach to nursing workload that can provide this deeper understanding of nursing workload and its causes will be described, allowing for the development and implementation of solutions aimed at reducing or dealing with workload.

Nursing staffing levels have been shown to have a significant impact on nosocomial infections. For example, Needleman and colleagues[13] found that among medical patients, a higher number of hours of care per day provided by RNs was related to lower urinary tract infection rates. A retrospective cohort study in a neonatal ICU revealed that the incidence of *E cloacae* infection in the unit was significantly higher when there was understaffing of nurses.[33] A prospective study in a pediatric cardiac ICU found a significant relation between the monthly nosocomial infection rate in the unit and the nursing hours per patient day ratio: there were more nosocomial infections when the number of nursing hours per patient day was lower.[34]

Although not as strong, some evidence exists regarding the impact of nurse staffing levels on failure to rescue (death within 30 days among patients who had complications) and mortality. A study using administrative data from 799 hospitals in 11 States revealed that a higher number of hours of RN care per day was associated with lower failure to rescue rates.[13] In a study of 168 nonfederal adult general hospitals in Pennsylvania, Aiken and colleagues[10] found that each additional patient per nurse was associated with a 7 percent increase in the likelihood of mortality within 30 days of admission and in the likelihood of failure to rescue. An earlier study found that hospitals that had more RNs per admission had lower mortality rates.[35]

There were four studies that found a relationship between nurse staffing and patient outcomes. One study found that having a nurse-patient ratio of less than 1:2 during evening shifts was associated with a 20 percent increase in length of stay in patients who had abdominal aortic surgery in Maryland hospitals between 1994 and 1996.[36] Researchers conducted studies in 1992 and 1994 using hospital cost reports and discharge data in New York and California, finding that more nursing work hours were associated with reduced length of stay.[37] Additionally, a critical incident study of Australian ICUs revealed that insufficient nursing staff was linked to drug administration or documentation problems, inadequate patient supervision, incorrect ventilator or equipment setup, and self-extubation.[38]

A majority of the studies on nursing workload and patient safety used nurse-patient ratio as the measure of nursing workload. According to research on workload in human factors engineering (see section above), it is well known that workload is a complex construct, more complex than the measure of nurse-patient ratio.[11] It is unlikely that the multidimensional, multifaceted structure of workload can be captured by one unique, representative measure. Therefore, the belief is that researchers who use the nurse-patient ratio as a measure of workload offer a limited contribution to understanding the impact of nursing workload and designing solutions for reducing or mitigating nursing workload. One reason for the extensive use of the

nurse-patient ratio may be that this measure is easy to use and is readily available in existing databases. But tools used by human factors researchers can comprehensively assess workload, facilitate the identification of the sources of excessive workload, and provide direction for corrective interventions.[11]

How Does Nursing Workload Impact Patient Safety?

According to the Systems Engineering Initiative for Patient Safety (SEIPS) model of work system and patient safety,[39, 40] structural/organizational characteristics of health care work systems, such as nursing workload, can affect quality of care and patient safety. In this section, a description of how nursing workload can affect patient safety will be offered (see Table 1). The first five mechanisms describe the impact of a heavy workload experienced by one nurse on that particular nurse. The last mechanism describes the systemic and organizational impact of a heavy workload experienced by a nurse's coworkers and team members.

Table 1: Relationship Between Nursing Workload and Patient Safety

Mechanisms	Description	Examples
Time	Nurses who have a heavy workload may not have sufficient time to perform tasks safely, apply safe practices, or monitor patients, and may reduce their communication with physicians and other providers.	No or little time to double-check medications
Motivation	Nurses who have a heavy workload may be dissatisfied with their job, thus affecting their motivation for high-quality performance.	No or little motivation and commitment to high levels of performance High workload creating frustration and contributing to the development of negative attitude toward one's job.
Stress and burnout	Nurses who have a heavy workload may experience stress and burnout, which can have a negative impact on their performance.	Reduced physical and cognitive resources available for nurses to perform adequately
Errors in decisionmaking (attention)	High cognitive workload (one dimension of nursing workload) can contribute to errors, such as slips and lapses or mistakes.	Forgetting to administer medications
Violations or work-arounds	High workload conditions may make it more difficult for nurses to follow rules and guidelines, thus compromising the quality and safety of patient care.	Inadequate hand washing
Systemic/organizational impact	The heavy workload of a nurse, nurse manager, or another provider could affect the safety of care provided by another nurse.	A charge nurse may not be available to help other nurses with their patients when needed.

Nursing workload and lack of time. Nursing workload definitely affects the time that a nurse can allot to various tasks. Under a heavy workload, nurses may not have sufficient time to perform tasks that can have a direct effect on patient safety. A heavy nursing workload can influence the care provider's decision to perform various procedures.[41] A heavy workload may also reduce the time spent by nurses collaborating and communicating with physicians, therefore affecting the quality of nurse-physician collaboration.[42] A heavy workload can lead to poor nurse-patient communication.[43, 44]

Nursing workload and deteriorated motivation. Several studies have shown the relationship between nurses' working conditions, such as high workload, and job dissatisfaction.[10, 45, 46] Job dissatisfaction of nurses can lead to low morale, absenteeism, turnover, and poor job performance, and potentially threaten patient care quality and organizational effectiveness.[47] Researchers have found positive associations between job satisfaction and job performance,[48] and patient satisfaction and quality of care.[49]

Impact of workload on nursing stress and burnout. High workload is a key job stressor of nurses in a variety of care settings, such as ICUs.[15, 16, 50] A heavy nursing workload can lead to distress (e.g., cynicism, anger, and emotional exhaustion)[51] and burnout.[10] Nurses experiencing stress and burnout may not be able to perform efficiently and effectively because their physical and cognitive resources may be reduced; this suboptimal performance may affect patient care and its safety.

Nursing workload and errors. Workload can be a factor contributing to errors.[52, 53] Errors have been classified as (1) slips and lapses or execution errors, and (2) mistakes or knowledge errors.[52] High workload in the form of time pressure may reduce the attention devoted by a nurse to safety-critical tasks, thus creating conditions for errors and unsafe patient care.

Nursing workload and violations or work-arounds. Violations are defined as deliberate deviations from those practices (i.e., written rules, policies, instructions, or procedures) believed necessary to maintain safe or secure operations.[54] The literature on violations emphasizes the role of the social and organizational context, where behavior is governed by operating procedures, codes of practice, rules, and regulations.[54, 55] This approach emphasizes factors in the work system that can contribute to violations. The health care field has begun to explore caregivers' violations of protocols.[56] A survey describing medical practice was administered to 315 nurses, doctors, and midwives and 350 members of the general public in the United Kingdom. The study examined two factors manipulated within nine scenarios of surgery, anesthetics, and obstetrics. The first factor, behavior, was described as an improvisation (no rule available), a violation of clinical protocol, or compliance with a clinical protocol. The second factor, patient outcome, was described as good, bad, or poor. Samples of health care providers and the general public were asked to evaluate the nine scenarios with regard to the inappropriateness of the behavior, the likelihood that they would take further action (i.e., reporting by health care provider and complaining by the public), and responsibility for the outcome (e.g., the health care professional, the patient, the protocol itself, the hospital). Results showed that violations of protocols and bad outcomes were judged most harshly. Whether outcomes were good or bad, violations were evaluated more negatively. The authors of the study warned against overreliance on procedures (or protocols) as a form of organizational defense against accidents or claims. Procedures may stifle innovation and make people less able to function in novel situations.

Alper and colleagues[57] conducted a survey of 120 nurses (59 percent response rate) in three units of a pediatric hospitals to assess self-reports of violations in the medication administration process. Between 8 percent and 30 percent of the nurses reported violations in routine situations, and between 32 percent and 53 percent of the nurses reported violations in emergency situations. The most frequent violations or work-arounds occurred in matching the medication to the medication administration record and checking the patient's identification.

Further research is needed to understand the work system factors that lead to violations. Violations occur more frequently when nurses are under time pressure or high workload because of emergency situations. Under high workload, nurses may not have time to follow rules and

guidelines for safe care, especially if following the rules and guidelines necessitate additional time, such as hand washing.

Systemic, organizational impact of nursing workload. This final mechanism of the relationship between nursing workload and patient safety is based on the systemic, organizational impact of nursing workload: a heavy workload experienced by a nurse not only affects this nurse, but can also affect other nurses and health care providers in the nurse's work system. Understaffing may reduce time nurses have to help other nurses. This lack of time may also result in inadequate training or supervision of new nurses.

Practice and Research Implications

We propose a human factors engineering approach to nursing workload and patient safety, which is based on the SEIPS model of work system and patient safety.[58, 59] This approach is based on the key principle of human factors engineering, i.e., work system design.[60, 61] According to the work system model, several elements of the work system can affect nurses and their performance, safety, and well-being.[58] These work system elements are causes or factors contributing to nursing workload. The first step of the proposed approach is therefore to understand how the work system of nurses can contribute to their workload. Human factors engineers have developed and used various methods to assess each element of the work system model and the interaction between the elements,[62] such as observations of the work situation;[62, 63] direct measurement of the work environment and workstation; and interviews, focus groups, and survey of workers.[40, 64] Once the human factors engineers have identified the elements and characteristics of the nurses' work system that contribute to workload, they can redesign the work system to reduce the workload.

In a previous study,[23] the causes of situational workload experienced by nurses in 17 ICUs in Wisconsin were identified, demonstrating that there were differences in the factors that lead to a heavy nursing workload in different ICUs. For example, compared to their colleagues in other participating ICUs, a higher number of nurses of a 24-bed medical surgical ICU reported the following factors that led to high workload: difficulty finding a place to sit down and do paperwork, distance between patients' rooms, poor condition of the equipment, spending a lot of time searching for patients' charts, and a crowded and disorganized work environment. Since this ICU was larger than the other ICUs in the study and many specialties were involved in the care of patients in this ICU, it was not surprising to see such work system factors as a crowded and disorganized work environment, and spending a lot of time searching for patients' charts (e.g., different specialties searching for the chart during the day).

Once the work system factors contributing to nursing workload have been identified, interventions aimed at reducing or mitigating the workload can be designed. The work system redesign interventions should follow the two basic principles of the Balance Theory of Carayon and Smith: (1) eliminating the source of the excessive workload, or (2) compensating or balancing out the workload.[60, 61] According to the Balance Theory, redesigning the work system should aim at eliminating the negative aspects of work; however, this is not always feasible or practical. The Balance Theory, therefore, proposes an alternative approach aimed at compensating for or balancing out the negative aspects of work. For instance, "making available to nurses resources and social support to assist them in accomplishing their duties"[50, 51] can be conceptualized as a compensating mechanism: different types of support (e.g., informational

support, practical support, affective support) can be provided to help nurses deal with negative aspects of their work, such as workload.

Another key concept of the human factors engineering approach to nursing workload is the work *system*: any change in one element of the work system can affect other elements of the work system in negative and/or positive ways.[60, 61] For instance, work hour limits for physicians have affected nurse schedules. Nurses are often required to work increased overtime to compensate for reduced physician hours.[65] This is an example of how changing one element in the work system of physicians can negatively affect the work system of nurses. Table 2 summarizes the research implications of the proposed human factors engineering approach to nursing workload and patient safety.

Table 2: Research Implications on Nursing Workload and Patient Safety

Research Implications	Objectives
Measurement of situational workload	Test and evaluate various methods for measuring nursing workload at the situational level.
Identification of work system factors that contribute to situational workload	Identify the work system factors that contribute to nurses' situational workload under various conditions and in various care settings.
Evaluation of the impact of situational workload on outcomes	Evaluate the impact of situational workload on various outcomes, such as nurses' job satisfaction and stress, nurses' perceptions of quality and safety of care, and patient outcomes. Conduct this research in various care settings and organizational settings.
Development of strategies for reducing situational workload	Develop, implement, and evaluate interventions for reducing situational workload and its negative impact on nurses and patients.
Evaluation of barriers to improving nurses' work system and reducing situational workload	Identify the organizational and structural barriers to effective changes in nurses' work system and the challenges in reducing situational workload.

Conclusion

Nursing workload is affected by staffing levels and the patients' conditions, but also by the design of the nurses' work system. In this chapter, a description of different levels of workload, including situational workload, was offered, and a proposal for a human factors engineering approach aimed at reducing workload or at mitigating or balancing the impact of workload on nurses and patient care was suggested.

Evidence Table. Nurse workload and patient safety

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Key Finding(s)
Aiken 2002[10]	Hospital nurse staffing	Cross-sectional study	Risk-adjusted patient mortality, failure to rescue, job dissatisfaction, job-related burnout	Linked data from 10,184 nurses surveyed, 232,342 surgical patients discharged from the hospital between 04/01/1998 and 11/30/1999, and administrative data from 168 hospitals in Pennsylvania	In hospitals with high patient-to-nurse ratios, patients experience higher 30-day mortality and failure-to-rescue rates, and nurses are more likely to report burnout and job dissatisfaction.
Anderson & Maloney 1998[25]	Nurse workload and patient satisfaction	Cross-sectional study	Patient satisfaction	Survey data from 188 patients in a 250-bed Army medical treatment facility	Patient satisfaction was negatively correlated with average daily census, and positively correlated with the number of nursing care hours required and the number of registered nurses available.
Archibald 1997[34]	Nurse staffing levels and patient census in ICU	Cross-sectional study	Rate of nosocomial infections per 1000 patient days	One pediatric cardiac intensive care unit; 782 admissions during one year	Higher patient census was related to higher rates of nosocomial infections. There was an inverse correlation between the monthly nosocomial infection rates and the nurse/patient ratio.
Beckmann 1998[38]	Nursing staffing issues in incidents reported by ICU staff	Noncomparative study	Incidents associated with nursing staff shortage reported to the Australian Incident Monitoring Study-ICU (AIMS-ICU) project	89 nursing staff shortage incidents and 373 incidents involving nursing staff shortage contributing factors	Incidents involving nursing staff shortage contributed primarily to problems in unit management (65%) and patient management (48%).

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Key Finding(s)
Keijsers 1995[24]	Burnout (emotional exhaustion and depersonalization)	Cross-sectional study	Standardized mortality ratio for each of the 20 participating ICUs; perceived personal performance; perceived ICU performance	576 nurses from 20 ICUs	High burnout of ICU nurses is related to poor perceived unit performance and poor perceived personal performance. Nurses in well-performing ICUs (as measured by the standardized mortality ratio) reported higher burnout than nurses in poor-performing units.
Lichtig 1999[37]	Nurse staffing	Cross-sectional study	Adverse patient outcomes (pressure ulcers, pneumonia, UTIs, postoperative infections), length of stay	Hospital cost reports and patient discharge data from hospitals in the States of California and New York	Higher nurse staffing and higher proportion of RNs were related to lower length of stay. Lower rates of adverse outcomes were related to a higher proportion of RNs.
Manheim 1992[35]	Regional variation in hospital mortality	Cross-sectional study	Severity-adjusted Medicare hospital mortality rate	3,796 hospitals in nine US Census regions	The percentage of RNs per adjusted admission was a negative predictor of mortality rates.
Needleman 2002[13]	Hours of nursing care per patient	Cross-sectional study	Rates of urinary tract infections, rates of failure-to-rescue, in-hospital death, rate of adverse outcomes	Administrative data from 1997 for 799 hospitals in 11 States	A higher proportion of hours of nursing care was related to better quality of care outcomes, such as lower rates of urinary tract infections among surgical patients and lower rates of pneumonia, shock or cardiac arrest and “failure-to-rescue” among medical patients. There was no association between hours of nursing care per patient and the in-hospital death rate and the rate of adverse outcomes.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Key Finding(s)
Pronovost 1999[36]	Organizational characteristics of ICUs	Observational study with patient data collected retrospectively and ICU data collected prospectively	In-hospital mortality and hospital and ICU length of stay	All Maryland hospitals that performed abdominal aortic surgery from 1994 to 1996	Having an ICU nurse:patient ratio of less than 1:2 was associated with increased resource use.

Chapter 31. Organizational Workflow and Its Impact on Work Quality

Carol Cain, Saira Haque

Background

What Is Workflow?

Workflow, loosely defined, is the set of tasks—grouped chronologically into processes—and the set of people or resources needed for those tasks, that are necessary to accomplish a given goal. An organization's workflow is comprised of the set of processes it needs to accomplish, the set of people or other resources available to perform those processes, and the interactions among them. Consider the following scenario:

> On a slow Friday afternoon in the emergency room, as one nurse prepares to go off shift, the clerk looks up from the desk and asks, "By the way, since you're passing by housekeeping on your way out, would you remind them that room 12 still needs to be cleaned?"
>
> "No problem," replies the nurse, and indeed, on a slow Friday afternoon, it is no problem. The informal methods and processes that the hospital has developed over the years to keep the enterprise humming work well, in general, and can work very well in optimal times. It's no trouble to remind housekeeping to come up; it's no trouble to run a special specimen down to the lab, and certainly no trouble to catch the attending physician during rounds to get a quick signature. Even if these small adjustments are forgotten, in due time the regular hospital schedule will bring the right people to clean the room, to pick up the lab specimen, to document the encounter.

These same methods that an organization uses to get work done, however, can begin to show stress under trying circumstances. When the ward is full and it takes 12 hours for a room to be readied for the next patient, that impact is felt throughout the organization. When the number of small interruptions outweighs the amount of planned work done in a given hour, that impact is felt in slower progress, lower job satisfaction, and potentially lower quality of care. In many situations, it is very clear to all what needs to get done. Where organizations differ is in how they do it. The examination of how an organization accomplishes its tasks often concerns the organizations' workflow.

In health care, as in other industries, some workflows are designed, while others arise organically and evolve. The systems and methods by which organizations accomplish specific goals differ dramatically. Some organizational workflows seem more straightforward than others. Most often, when workflow processes are looked at in isolation, the processes appear quite logical (and even efficient) in acting to accomplish the end goal. It is in the interaction among the processes that complexities arise. Some of these interactions hide conflicts in the priorities of different roles in an organization, for example, what the nursing team is accountable to versus the physician team and its schedule. Organizations also adapt workflows to suit the

evolving environment. Over time, reflecting on organizational workflows may show that some processes are no longer necessary, or can be updated and optimized.

Why Is It Important to Nurses?

Health care has often faced the pressure to design, or redesign, its workflows to be more efficient and effective. In many cases, the trigger for examining workflow is in response to changes in how things are done. Today, the need to think about workflow design is more pressing due to several factors, including:

- The introduction of new technologies and treatment methodologies into clinical care
- The challenge of coordinating care for the chronically ill
- The participation of a growing array of professionals in a patient's care team, and new definitions in their roles
- Cost and efficiency pressures to improve patient flow
- Initiatives to ensure patient safety
- Implementation of changes to make the care team more patient-focused

One important reason that workflow is of pressing concern for today's clinicians is the introduction of new health care information technology (health IT) into clinical practice. Health IT promises many benefits for improving quality and efficiency. However, the introduction of health IT can be very disruptive to existing workflows in an organization. Health IT systems often implicitly assume a workflow structure in the way their screens and steps are organized. Organizations that are thoughtful about workflow design are more likely to be successful in adapting to health IT.[1]

In contrast to industries such as manufacturing, health care is a service industry that relies heavily on good information. In closely following and taking care of patients, nurses are guardians of a rich source of information. This valuable information can be lost when poor workflows impede communication and coordination or increase interruptions.[2] Characteristics of a poorly functioning work process include unnecessary pauses and rework, delays, established workarounds, gaps where steps are often omitted, and a process that participants feel is illogical.

The design of good organizational workflow is not simply about improving efficiency. Workflow processes are maps that direct the care team how to accomplish a goal. A good workflow will help accomplish those goals in a timely manner, leading to care that is delivered more consistently, reliably, safely, and in compliance with standards of practice. An excellent workflow process can accommodate variations that inevitably arise in health care through interaction with other workflow processes, as well as environmental factors such as workload, staff schedules, and patient load.

Research Evidence

Health services researchers have explored workflow issues from several angles, including mapping processes from other industries into health care. Literature about workflow can be found in several different domains, such as quality improvement, technology implementation, and process improvements. One common thread throughout the literature is the importance of interdisciplinary involvement in all aspects of workflow analysis and implementation.

Reviewing the evidence to date, targeted studies of particular interventions and technologies amply show that good workflow design has significant (expected and unexpected) impacts on

care delivery.[3] The literature also demonstrates a relative lack of sophistication in studies of the field: whether researchers are initially concerned with the problem or whether it arises organically from the results; whether the researchers have a theoretical framework to interpret their findings; whether there is consistency in the outcomes of interest; whether the target(s) of study are structural, cultural, and/or functional; and whether the researchers are able to generalize from the findings in one setting to another. Many studies demonstrated significant benefit from careful consideration of workflow, but few studies provided easily adaptable tools and methods for immediate, consistent implementation.

Effect on Efficiency

Workflow analysis has often been used with the goal of improving efficiency. In response to financial pressure and incentives driving provider organizations, minimizing slack time has become important. Some of the studies discussed below demonstrated the power of analyzing and changing workflow to improve efficiency.

Workflow analysis can be used to redesign existing processes. A classic study of this type is Cendan and Good's[4] analysis of the routine tasks of the various members of the operating room (OR) team. They found that there was a wide variability in functions based on clinical and organizational factors. They designed a new workflow based on the analysis and conducted a pilot study. Part of their recommended solution involved defining functions in a more consistent fashion. They were able to improve turnover and improve the mean number of cases handled in a day. A significant factor in their success was their consideration of workflow from both the physician and the nursing perspectives.

Efficiency can also be improved by carrying out processes in parallel, rather than improving the efficiency of existing steps.[5] Friedman and colleagues[6] compared the impact of administering anesthesia in the induction room versus in the OR for hernia repair patients. They found that the OR time used by the surgeon decreased without significant impacts on patient satisfaction or outcomes.[6] Harders and colleagues[7] employed a combination of approaches. They used parallel processing and process redesign to improve workflow in a tertiary care center with multiple OR suites. This combination of approaches allowed for a reduction in nonoperative time. Similarly, in a study of trauma teams, Driscoll and Vincent[8] modified task allocation so that standard tasks performed during a trauma code were conducted in parallel rather than sequentially.

In each of these approaches, role definition played a critical role in the success of the efforts. Each study found that nursing routines often included nonclinical tasks, such as tracking down missing information or supplies.[9] By defining roles and essential processes, it was possible to use ancillary staff for these tasks. In order for the redesign to be successful, nursing involvement was important from the beginning. An interdisciplinary approach provided the basis for the workflow analysis and redesign; this was cited as a success factor in multiple studies.[4, 6, 7]

Common Issues

Workflow issues often arise in studies of technology. One well-studied domain area is barcode medication administration (BCMA).[10] BCMA is a technology that has been shown to improve care quality by reducing reliance on memory, increasing access to information, and increasing compliance with best practice. However, very simple inconveniences—such as the need to access a patients' wrist for the barcode strip—have led to workflow workarounds, such

as scanning barcodes off a key ring rather than the patient. In this case, the nurses' adaptation to make their work more efficient circumvents some of the intended benefits of the defined process.

More complex interactions have also been observed. Because many BCMA systems require that the physician enter an order before the nurse can have access to the medication, some nurses have, in critical situations, "borrowed" medication from one patient on the ward to give to another until the medication for the second patient appears in the system. As a result, the nurse cannot readily document the administration of the order until the order has been entered by the physician. In some situations, a shadow system of informal paper documentation supplements, duplicates, or confuses the documentation captured in an electronic system.

When technology does not adequately support the goals of the care team, it often causes workaround workflows. These alternate workflows are a cause for concern because these informal, evolutionary systems rely on the clinicians' memories, and bypass decision-support safeguards that the system may provide. Studies have documented other negative effects,[11] such as degraded coordination between nurses and physicians, nurses dropping activities during busy periods, and decreased ability to deviate from routine sequences.

Information Transfer

Health care organizations provide valuable services that rely on large amounts of high quality information. Information transfer is complicated because caring for one patient can involve many providers and information sources. Thus, many errors occur at handoff or transition points.[12] Dykes and colleagues[13] found that many hospitals in the United States have dual paper and electronic records, leading to redundancies and inefficiencies in information. Other information tools include proprietary paper forms, the phone, the electronic record system, the whiteboard, the pager, and schedules.[14] In addition, informal meetings and verbal orders frequently also serve as information transfer devices.[15]

One attempt to address this complexity is an electronic portal that provides access to systems through one interface.[16] Though this can mitigate the problem, it cannot fully address the communication needs of a care team.

A common class of problems with information transfer and handoffs includes degradation of information.[17] If methods of transfer are informal and not documented, patient information may not be passed on when staff members leave a unit. In addition, the lines of responsibility and expectations are not always clear.[17] Incorporating formalized information transfer tools and protocols into workflow processes may help. Another problem complicating information transfer is interruptions. These interruptions often cause a break in workflow, which can impact what information is documented and passed on.[18, 19]

Intra-Professional Information Transfer

Nursing work is often fragmented and rushed, due to external pressures and the dynamic environement.[20] However, nurses serve as critical integrators and coordinators of care. Health IT tools, which can help nurses better manage and transfer information and make the information more widely available have the potential to improve practice.[21] Intraprofessional handoffs may occur within or across departments. In either case, communication and coordination is improved by having a structured documentation format.[22]

Lamond[23] reviewed the content of nursing intershift reports and found that more information was documented in the patient notes than was given in the report. The report information tended to be more overall assessments of patient care, which was not necessarily documented. Thus, it is not clear if the detailed information was transferred in subsequent reports. Perrott[24] found that customizing data fields and having nurses involved from the beginning enhanced nursing handoffs in the intensive care unit (ICU).

By understanding nursing workflow, barriers and facilitators for information transfer can be discussed and improved upon.[25] If handoff mechanisms are informal, then they might not be documented in a workflow analysis.[26] Health IT systems should not replace these handoffs, but could be used to augment the process.[27] However, when the processes are not well understood, the technology may not be used and may even be a burden.

Inter-Professional Information Transfer

Inconsistent or incomplete information during patient care transfers is a commonly cited communication difficulty.[28] This problem is exacerbated by systems and processes with duplicate or outdated information. There is a great deal of information available, but it is not always available in a streamlined or organized fashion.[29]

Clinical providers trained in different disciplines are socialized and trained differently, so they do not necessarily know what the others need.[29] Thus, when designing and implementing information technology across departments, it is important to have an interdisciplinary team involved throughout the process.[22] Physicians and nurses do not generally have the same employer and often have varying loyalties and end goals.[4] Thus, it is important to consider many perspectives when designing handoff and communication practices.

One way to look at interprofessional collaboration is to look at information needs. Reddy and colleagues[30] reviewed information needs of various providers in the ICU. They found that some roles, including nurses, served as information sources for other providers. Thus, it is important to consider the workflow implications of changing information sources. When a face-to-face communication with a nurse is replaced by an electronic report, what is lost and gained? Electronic access provides the benefits of ready access to large quantities of source data, potentially supplemented with decision support. What may be lost are functions of information synthesis, summarization, and coordination. In a survey of chief nursing officers, Dykes and colleagues[13] emphasized the role of nurses as coordinators and communicators.

Riley and Manias[31] looked at physician–nurse communication in an OR setting. They found that nurses often had informal knowledge of physicians and their habits, which they used to control practices. This knowledge was not necessarily codified formally, so new nurses would have difficulty in estimating workflow. Health care organizations have engaged in efforts to standardize inter-professional communication, for example through requiring the use of SBAR for situational briefing.[32]

It is not always necessary to have a separate process for interprofessional communication. Indeed, other efforts can be repurposed for interprofessional communication. For example, Cunliffe[33] described a nursing discharge summary process which was repurposed to provide a nurse–general practitioner communication device. A nursing discharge summary provided detailed information about nursing and social care for the patient after they left the hospital. In addition, sending this to the general practitioner (GP) provided a mechanism for communication so that the GP would be well-informed about the patient's care. Similarly, a resident sign-out

system could also be accessed by other professionals.[34] However, communication lines tend to be separate and dependent on professionals, so it is not clear how much intraprofessional access occurs. Patterson and colleagues[35] studied handoff strategies in other industries and outlined some common strategies for effective handoffs. Often, documentation was a supplement to the handoff, rather than the sole mechanism for information transfer.

Health Information Technology

Health IT, used well, can improve efficiency and organizational workflow. In health care, redundant information is often created and stored. As a result, care providers spend a great deal of time reconciling information from various sources. Integrating health IT with the workflow of various departments can help to reduce this redundancy.[22] However, if workflow is not considered and the technology is not thoughtfully implemented, the benefits cannot truly be achieved. To use technology most effectively, its potential impact to transform care delivery must be realized.[36]

While it is important to consider workflow when implementing health IT, it does not mean that health IT should leave processes intact. Health IT can bring about positive process change and better workflow. Because IT can consolidate and display information, it can be used as an opportunity to improve upon teamwork and communications.[37] Understanding existing clinical workflow prior to implementation provides a baseline to redesign systems and develop better processes.[38] Scharmhorst, Johnson, and Li[39] emphasized the importance of understanding the system prior to implementing technology, to ensure that technology streamlines nursing workflow, rather than making it more complicated. In a study of mobile cabinets with barcode scanning for medications, Braswell and Duggar[40] found that, by analyzing workflow ahead of time, both pharmacy and nursing staff reported improvements to existing work processes after implementation. Workflow concerns can lead to failure to adopt new technologies. A study of electronic prescribing systems standards finds that many of the electronic standards are adequate but provider adoption is low because the systems do not fit into workflow.[41] The evaluators recommend that the standards and systems be revised to accommodate the large role of nurses in electronic prescribing in the office setting.

Focus on Computerized Provider Order Entry

Computerized Provider Order Entry (CPOE) is an easily measurable, frequently implemented, and often intrusive instance of health IT, and has been studied often in the literature. CPOE is commonly associated with its impact on physician practice. However, there are workflow implications in CPOE implementation for the entire care team, including physicians and nurses.[42] For example, if physicians refuse to use the CPOE system, it creates adverse impacts on nursing workflow.[3, 28] Sometimes, nurses become the de facto order entry personnel, in addition to their nursing duties. These workarounds also have effects downstream. Delays in order entry can hold up medication delivery. The introduction of CPOE technology may surface informal practices that may not be in compliance with prescribing scopes of practice. Thus, nurses are a key success factor in CPOE implementation.[43] Because nurses often are primarily responsible for communication and coordination of care, understanding nursing workflows with respect to order entry is critical.[44]

Payne[45] found that implementing CPOE had a profound impact on work patterns, communication methods and roles. In analyzing workflow around electronic prescribing, the range of tasks completed by the nonprescribers was outlined.[46] After outlining the work processes and information flows, they were able to adapt the system to accommodate the necessary tasks. Similarly, Wright and colleagues[47] found that physician-nurse communications were impacted by the CPOE implementation. Paper-based order entry often relies on visual cues, such as a folded piece of paper. If the loss of context and visual cues is not accounted for in the CPOE implementation, then the nursing workflow is adversely impacted because of the uncertainty around orders.

Piasecki and colleagues[48] conducted a workflow analysis to look at the benefits of implementing CPOE in an emergency department setting. These researchers developed a return-on-investment tool to measure the outcomes of the implementation and found that many of the savings did not make a direct impact on the bottom line of the organization. This was, in part, because the changes in workflow were not fully understood until after implementation.

Though guidelines for analyzing workflow are few, the common factor was consideration of all affected roles in the organization, not only those involved with entering data into the IT system. Breslin and colleagues[49] found that having an interdisciplinary team was important in the success of a Vocera implementation. This team included clinical and nonclinical staff. By being inclusive, they learned about workflow from a variety of perspectives and were able to implement their tool in a fashion that would improve upon existing practices.

Ongoing Work in Nursing Workflow Research

Research into the workflows of nurses has long roots in studies of how nurses spend their time and how nursing teams should be staffed.[50-52] Nurse researchers embarking on observational research of nursing work can take advantage of previously developed tools for work task analysis and time motion study.[53-55]

With the introduction of new technologies, the research frontier includes studies of how nursing work is affected, with the aim of ensuring quality time at the bedside. An ongoing large multi-site time-motion study of nurse workflow[56] includes the involvement of frontline nurses in the design and improvement of their work spaces and technologies. It represents one way that lessons learned from past research can be brought to bear on future workflow design, with the intent of mitigating the pain of learning workflow and technology weaknesses through implemented experience.

Practice Implications

The research findings for these studies of operational workflows have practice implications for nurses and researchers. Throughout the literature, the importance of bringing multiple parties to the table was emphasized. Because organizational workflows often cross the lines of professional disciplines, workflow design from any single perspective runs the risk of sub-optimizing against other constraints, priorities, and schedules.

Conscious workflow design has been shown to improve the efficiency of existing work processes or enable parallelization of work. In designing such systems, researchers emphasize the importance of clearly defining roles and responsibilities, preferably with multi-disciplinary input. Designing workflow is of critical importance to all roles in a health care organization,

because the effects of decisions by an expert in one role may have downstream effects on others. A workflow optimized to serve one role, such as the nurse, can be onerous or seem irrational to another. Because each professional role deals with fairly complex, role-specific work processes, it is often difficult for experts in one role to understand and envision how proposals will affect other roles, even with the best intentions. Research on information transfer in organizational settings demonstrates that adaptations to poor workflows can lead to increased interruptions, workarounds, and informal or ill-defined communication. To improve the reliability of workflows accomplishing their desired goals, and to reduce the risk to patient safety, researchers recommend structured communications and clear agreements about roles and responsibilities in a hand-off.

Health IT systems surface many of the long-standing issues around workflow. The implementation of health IT systems can, at first glance, seem like a superficial intrusion into the way things are done. For some, it feels like the addition of another documentation step in the process of regular clinical care. This step can be disruptive and a burden, but it does not dramatically change the way work is done. Yet there are many downstream effects on communication and coordination within an organization. Analyzing workflow beforehand can help prevent some of these unintended consequences. Technology does not necessarily improve institutional efficiencies, but can bring opportunities for improvement to light.[42] Sittig and colleagues[38] found that while considering that technology was important, it was also important to consider organizational and workflow factors prior to implementation, or the benefits may not be realized. In order to realize good outcomes, interdisciplinary consideration of process and technology factors was important.[57]

In many organizations, the adoption of health IT is motivated by the desire to accomplish goals that are difficult without a structured electronic system. These goals include reducing medication errors through barcoding; improving clinical decisionmaking through decision support, such as alerts and reminders; measuring clinical quality performance; proactively reaching out to patients for population health management; or simply the ability to analyze clinical information, for example, by charting a patients' blood pressure based on nursing notes. These additional expectations of a health IT system mean that the organization can expect dramatic changes in workflow—the health IT implementation is a vehicle to trigger larger improvement activities.

It is important to realize that health IT systems have a built-in sense of how things are done, in fact, have an inherent workflow that may or may not map to the organizations' workflow. Consider the case of CPOE. Let's describe the workflow process as a series of tasks, linked chronologically, that require organizational resources. The logical model within a health IT system usually goes something like this:

1. The provider enters an order.
2. The pharmacist verifies the order.
3. The order is delivered to the point of care.
4. The nurse administers the order.

There are two things to note about this perfectly reasonable assumption about how things are done. The first is that the workflow is very linear. It will be very important to understand what happens if that linearity is disrupted somehow. For example, if the pharmacist fails to verify the order, will the system prevent the order from being "released" until this step is accomplished? Flexibility within a linear workflow is very important to the smooth operation of a complex service organization like a health care institution. Practitioners have a responsibility to check that

a health IT system reacts gracefully to a change in workflow, lest patient care be compromised. The second thing to note is that the workflow within the system only reflects one of the ways health care is delivered in an organization. In many critical care settings, for example, medications must be administered quickly, before any interaction with a CPOE system. Practitioners should also ask whether the health IT systems they are implementing reflect all of the main workflow processes within their organization.

When a new health IT system or a new technology fails to accommodate the real workflows of an organization, interacting with the technology becomes a greater burden on the organization than is required. In essence, there is "the way the world works" and then "the way the computer thinks the world works," and it is the constant responsibility of system users to reconcile the two world views. In fact, implementing health IT systems within organizations poses such a challenge that the Office of the National Coordinator for Health IT has estimated that as many as 30 percent of all implementations fail.[58] Thoughtfully constructing the workflow inherent to the technology can smooth technology acceptance.[59, 60]

Before implementing information technology in a health care environment, it is important to have an understanding of processes and information flows. In addition, it is important to consider various roles in the different departments, and to consider ideas from multiple sources.[22] Each department and role may have a different perspective of the encounter and its necessary elements.[36, 61] In addition, many organizations have a variety of tacit assumptions and information exchanges which might not be documented in a traditional analysis. Thus, it is important to consider multiple sources of data in order to develop a more complete understanding of workflow and processes.[36]

In the United States, hospitals are generally organized by functions. Because of that, workflow is also organized around these functions. Information systems were developed around these functions and were designed to meet the needs of a particular department. However, patient care takes place through a broader perspective. Thus, these functions need to be integrated.[20] In conducting a workflow assessment, it is important to consider how workflow currently functions and how it might change to improve patient care and reduce errors throughout the system.[20, 62] In addition, this kind of analysis can help find flaws in the process for which information technology can be leveraged.[20]

The truth is that many care teams do well even when workflow processes are designed poorly. Health care practitioners understand the clinical needs of patients. Health care workers often go to heroic lengths to make sure that the right thing gets done. When a problem arises, most clinicians would not hesitate to pick up the phone, run the errand, or do what is necessary to insure good care. Yet clinician resources are not unlimited. When nurses, like all people, get tired, they may become forgetful When they are rushed, they may not remember to do everything necessary.[63] These issues may be exacerbated by a health IT system that seems not to understand what the clinicians want to do—sometimes because the workflows in the health IT system do not match those in the real organization. In the seminal work on clinical error, the health care community acknowledged that most errors are the result of systematic deficiencies.[64] Good workflow processes are an aid to practitioners to insure that the system behaves to support high quality care. Nurse informaticists can work with their counterparts to apply some of the principles found in the literature to practice.

Research Implications

Workflow design is a difficult endeavor because of the complexity of most health care organizations and the division of labor into expert roles. Health care organizations are service organizations that are very flexible and interdependent in response to dynamic patient needs. For many work processes, the established workflow evolved over time in response to the kind of tasks and resources available, and were not explicitly considered or designed. Changes to organizational workflow are an opportunity to think through how the care team can provide good patient care reliably under a variety of circumstances.

Research on workflow issues can be very rewarding because of its closeness to real-world operational challenges. Study participants often experience a high level of frustration with their current situation, and are eager to have assistance in thinking through complex organizational effects. The research often starts with a theoretical model that helps define the problem space, such as conceptualizing the structure, process, and outcomes[65] or the tasks, actors, and information.[66] The model can be made operational through computer modeling, and used to represent particular problems.

In support of workflow design activities, computer simulation tools have been developed to help decisionmakers map their organizational roles and understand the impact of different workflow choices.[67-69] Models of workflow processes show the trajectories of the care providers, patients, and information. By representing workflow in a manner which is easily accessible to others, managers and researchers can identify where issues are likely to arise and develop tools to prevent them. Modeling workflow also usefully defines roles and delineates how the care team understands its job functions and work processes

For health IT, workflow design is especially difficult because many of the assumptions about workflow are implicit. The designers of IT systems benefit from conversations with their users to understand how clinical care is provided in the organization. Without the input of users, it is tempting to apply the same workflows to different organizations. Many issues can be easily resolved through small changes in user interface or clinical decision support rules—changes that are very difficult to predict in advance. Although some issues can be resolved through customizing the health IT system, others are more intractable. The health IT system may simply reveal latent problems with the old workflow. As more organizations embark on large-scale health IT implementations, a scalable method for incorporating workflow considerations is urgently needed, so that new health IT systems do not cause harm.[70] When issues have been surfaced, through conversations, observation, modeling, and other methods, researchers have the opportunity to bring to bear established quality improvement methods to workflow design. Studies to date have relied on ad-hoc methods to effect improvement after studying workflow, and there are opportunities to apply structured methods to assist an organization in responding to workflow discoveries.

Many of the research articles reviewed involved a descriptive case study. Some studies utilized a grounded theory approach. Few articles utilized a conceptual framework to frame the results. While research on service organizations has been applied to health care organizations, much work remains to be done in delineating how health care work differs from other industries, in particular to understand whether results from inquiries in other fields, such as manufacturing, can be generalized to health care. In addition, there is a need for research to demonstrate a link between performance indicators and workflow.[71] Nurse researchers have an opportunity to take the research that has been done to date and apply it on a broader scale. Much of the work that has

been done outlines specific implementation efforts or describes a single department. By taking a systems approach to organizational workflow, coordination of patient care throughout the trajectory of their stay can be improved.

Search Strategy

The search for workflow issues in delivering high quality nursing care is complicated because workflow, by its nature, touches on many organizational issues and roles. Literature that identifies specific problems in patient safety may allude to their greater systemic workflow causes or effects. Even literature that specifically considers workflow may limit the analysis to one organizational role. Thus, our literature search did not attempt to be a comprehensive search of literature published on workflow, but rather a scan of areas in the medical and nursing literature where relevant publications are likely to appear. There is also a longer history of research literature in other fields, notably industrial engineering and management.

We looked at MEDLINE® and CINAHL® articles published in English. Because workflow is not a standardized term in either database, we searched it as a keyword in its various permutations. We did the same with handoffs, as we knew that this was a common study topic where workflow issues surface. In addition, we did searches using combinations of related terms in each database. The terms we used were in categories dealing with continuity of care, care teams, information needs, information systems, and patient safety. We found that the keyword search yielded more consistent information than the standardized terms, in part because the terms were developed with specific purposes in mind. Studies of workflow are still fairly new, and it is hoped that as the field matures, it will be easier to identify a unique body of work.

Evidence Table

Source	Issue Related to Practice	Design Type	Study Design and Outcome Measures	Study Setting and Population	Study Intervention	Key Findings
Adams 2000[72]	IT; workflow	Changing practice project and Published Guidelines	Case studies	Case management	Teaching hospitals	IT brings about new workflows and information recording; can be helpful for the case manager; case managers may need to transform their workflows
Ammenwerth 2003[73]	User acceptance	Pretest and post-test	Questionnaire: 3 months before system implementation, 3 months after, 9 months after	Nurses on four wards of a hospital in Germany	Questionnaire	Previous acceptance of the nursing process and the previous amount of self confidence are two important factors influencing acceptance of a new computer based documentation system; consider fit between nursing workflow and functionality of system; some wards adapted system to their needs and others did not; some felt that it shows what they do all day
Bahlman 2005[60]	Workflow; OR; Information transfer; Implementation	Pretest and Post-test	Reviewed workflow processes for redesign	OR	Changed workflow processes	Needed to review workflow processes first; figured out ideal systems and tried to have technology match them
Banet 2006[44]	Workflow; ED; Information transfer; implementation	Pretest and Post-test	Looked at implementation of CPOE in ER and nurse perceptions	ER staff	CPOE implementation	Nurse perception of effective use of design is needed for successful implementation of information system changes; introducing CPOE into workflow is complicated; documentation time might not change
Bigelow 2006[75]	Workflow; Standards	Pretest and Post-test	Case study	Hospital system	Placed standards in an accessible document repository	New format allows for changes in workflow because standards can be looked up from multiple locations. reducing time spent searching for information

Source	Issue Related to Practice	Design Type	Study Design and Outcome Measures	Study Setting and Population	Study Intervention	Key Findings
Bowcutt 2003[29]	Interprofessional communication; Information transfer	Unpublished research	Roundtable discussion	NA	NA	Systems can enhance workflows, but they need to meet user needs; there's more information to sort through; data is not streamlined enough; if physicians don't want to do CPOE, the nurse suffers; clinical staff need to know that their documentation impacts others' workflow
Braswell 2006[40]	Implementation	Pretest and Post-test	Reviewed workflow and time spent before and after implementation	Nursing unit	Added mobile cabinets with barscanning for medications	Better teamwork with pharmacy; improvement on workflow; better documentation because of bar scanning
Breslin 2004[49]	Implementation	Case–control study, Pretest and post-test study	Observation; Documented communication workflows; Looked at phone calls; Survey	Staff within units in a hospital in Baltimore	Implemented Vocera and compared units with and without it	Having the technology saved time; less overhead paging, more efficient workflow; time savings
Bricon-Souf 1999[68]	Workflow; Modeling	Noncomparative study	Modeled flow of actors and information	ICU	NA	Development of a workflow model needs to include actors and information; flexibility and adaptability of model are important because processes are complex
Brixey 2005[18]	Workflow; Interruptions	Noncomparative study	Observation; Ethnography	RNs at a level 1 trauma center	NA	Understanding context around interruptions is good for understanding workflow; good to know causes and implications of interruptions
Brixey 2006[19]	Workflow; Interruptions	Noncomparative study	Observation; Ethnography	RNs and MDs at a level 1 trauma center	NA	Categorized activities and interruptions for doctors and nurses; layout can cause break in workflow; unavailable supplies or information can cause interruptions; technologies can contribute to more interruptions

Source	Issue Related to Practice	Design Type	Study Design and Outcome Measures	Study Setting and Population	Study Intervention	Key Findings
Browne 2004[76]	Workflow; Process redesign	Noncomparative study	Description	Hospital	Integrated fall alert so that other areas can see it; feedback was positive	Redesigned fall prevention process and included it in clinical information system; developed evidence based tool; tailored interventions to specific patient risks; integrated fall risk information into system
Burke 2005[12]	Medication administration; Information transfer	Unpublished research	Discussion of medication administration	NA	NA	Many medication errors occur at patient care transition points; nurses are very important at these points
Campbell 2006[3]	Safety	Unpublished research	Discussion of unintended consequences	NA	NA	Think about broader issues of safety; many medical errors aren't reported
Campbell 2006[77]	Safety	Quality improvement	Observation, interviews, conference.	5 medical centers with different CPOE products	Identify, describe and categorize unintended consequences of CPOE implementation	More/new work for clinicians; unfavorable workflow issues; demands for systems changes; people continued to use paper systems; communication patterns and practices changed
Cendan 2006[4]	Change; Workflow; OR	Pretest and Post-test	Analyzed and improved workflow	OR staff of a tertiary care center	Workflow diagrams were redrawn; critical moments were identified	Turnover improved and the mean number of cases improved; looked at interdisciplinary patterns
Chan 2006[78]	Workflow; Efficiency	Pretest and Post-test	Interviews	Nursing staff	Changed nursing delivery model	Some nursing work is formulated in a task-oriented assembly-line approach; allocate work assignments based on skills; some routine activities are not formalized
Christakis 2003[79]	Continuity; Information transfer	Cross-sectional study	Survey	Parents of patients at a pediatric clinic who received care at multiple sites	Cross-sectional survey of patients' families compared to organizational measures	Importance of continuity of care to promote coordination; greater objective measure of coordination was associated with improved perceptions of care coordination; consistent provider contact is associated with improved care coordination

Source	Issue Related to Practice	Design Type	Study Design and Outcome Measures	Study Setting and Population	Study Intervention	Key Findings
Clegg 2006[80]	Workflow, Efficiency; information transfer; Interprofessional communication	Pretest and Post-test	Implementation of a single assessment process for elderly patients	Elderly population in the UK	Implemented the new process and changed workflow to enhance information transfer	Improved documentation helped with sharing information; changed workflow helped to make this information available to those who needed it, reducing redundant questioning of patient
Cronin 2004[81]	Workflow, Efficiency	Noncomparative study	Description	Hospital	NA	Described challenges of incorporating IT into workflow
Cunliffe 2003[33]	Discharge; Communication; Coordination	Noncomparative study	Description of rationale and processes for developing a nursing discharge summary	Hospital in UK	Developed a standardized, structured formal discharge summary	Communication and coordination help with discharge planning; could be applied to other aspects of care; information tools can be used for multiple purposes
Driscoll 1992[8]	Coordination; Team structure	Pretest and Post-test	Observation, Survey	Trauma teams in Hospitals	Organizational changes were made during resuscitations - task allocation and horizontal team organization	When the structure of trauma team changed, complexity and distribution of individual tasks came to light; hard to get team members to work simultaneously; old habits occasionally recurred
Dykes 2006[13]	Information technology; Interprofessional communication	Pretest and Post-test	Survey, Interviews	Health care professionals in acute settings	Survey by HIMSS nursing informatics task force	95% of respondents had dual paper and electronic systems; nurses communicate and coordinate about care both formally and informally; IT does not reduce clinical thinking
Egan 2006[16]	Information transfer	Noncomparative study	Reviewed a dashboard of relevant patient information	ICU and OR staff	Determined who looks at what information and at what stage of the process	A dashboard with the data nurses need could help synthesize information, across hospitals and within departments; information availability can transform workflow; real-time data flowing from disparate devices into a single interactive display

Source	Issue Related to Practice	Design Type	Study Design and Outcome Measures	Study Setting and Population	Study Intervention	Key Findings
Elder 1998[82]	Nurse role	Unpublished research	Discussion	NA	NA	Need to clarify role of nurse, which has moved from task oriented process to outcome oriented - the focus isn't just on following orders but on the entire illness and being a manager of care
Friedman 2006[6]	Change; Workflow; OR	Case–control study	Reviewed time and workflow of group with standard versus parallel processing	Patients undergoing hernia repairs under local anesthesia	Case group has anesthesia in the OR at the start of surgery; control group had local anesthesia in the induction room during turnover time	Time decreased in case group; patient satisfaction similar; outcomes didn't change; OR time used by the surgeon decreased by 1/3; roles were redefined and team cohesiveness improved
Ghosh 2006[43]	CPOE; Implementation; Interprofessional communication	Noncomparative study	Interviews, focus groups	Chief Nursing Officers	How nurses impact and are impacted by CPOE	Nurses are a primary success factor in CPOE implementation; they have a critical role in communication, coordination and knowledge sharing; understanding communication processes is key to CPOE implementation
Guite 2006[22]	Change; Workflow; Implementation	Pretest and Post-test	Ethnography, interviews, process modeling	Level 1 trauma center	Documented each step of the current process with detailed flow diagrams; looked for opportunities for improvement and implemented a new process	Use IT to help redesign process; found considerable duplicate documentation; people have to spend time reconciling info; Consider a standardized language for shared data elements; need to integrate with workflow of various departments
Gurses 2006[14]	Information transfer; Coordination	Noncomparative study	Ethnography	Case managers at a level 1 trauma center	Information tools and processes	Information tools: bed management bundle, phone, EMR, whiteboard, text pager, schedule

Source	Issue Related to Practice	Design Type	Study Design and Outcome Measures	Study Setting and Population	Study Intervention	Key Findings
Gulliford 2006[83]	Continuity; Information transfer	Unpublished research	Discussion	NA	NA	Integration, coordination and sharing of information across providers is important; need to think about patient and provider perspective; continuity has a relational, management and informational component over time
Harders 2006[7]	Change; Workflow; OR	Pretest and Post-test	Analyzed current and new workflow	OR in tertiary care	Redesigned workflow	Reduction in nonoperative time; roles were redesigned; need to think about entire process with all team members
Johnson 2006[46]	Prescribing	Noncomparative study	Modeled development of electronic prescribing	ED	Implementation of an electronic prescribing model	Activity diagrams employ flowcharting techniques to model workflows, information exchange and business processes; Large range of tasks completed by non-prescribers, so they need to be considered in implementation
Joint Commission 2005[84]	Handoffs	Unpublished research	Discussion of JCAHO expectations of handoffs			Handoffs aren't just between departments, can also be within a given department; need to discuss barriers and facilitators for communication and obtain team involvement
King 2004[85]	IT; Workflow	Unpublished research	Discussion	NA	NA	Challenge to develop systems to satisfy multiple caregivers; think through information needs and activities across departments
Kinney 2007[62]	IT; Workflow	Unpublished research	Discussion	NA	NA	Need to understand workflow of current system before implementing IT or technology created new problems and unearths existing ones
Kirkley 2003[59]	Workflow	Noncomparative study	Description	Nursing	NA	IT can help streamline processes; implement IT as part of a larger effort to reorganize workflow and processes; Understanding goals; system should think like a nurse thinks

Source	Issue Related to Practice	Design Type	Study Design and Outcome Measures	Study Setting and Population	Study Intervention	Key Findings
Lamond 2000[23]	Information transfer; Shift change	Changing practice	Content analysis of medical notes, nursing documentation and shift reports	Medical and surgical units in hospitals	Looked at types and amount of information, order of information in shift report	More information was in patient notes than what was given in shift report; some information more often communicated in shift report than in patient notes; Evaluations and judgments are part of the report; Global information about how people are doing are more often found in the shift report than in other documentation
LaPenotiere 2004[61]	Workflow; Process redesign	Changing practice	Triage process design	Triage; ED	ED expansion built to fit desired processes.	Workflow changes described
Lium 2006[86]	Workflow	Cross-sectional study	Survey	Hospital	Frequency of EMR use	Nurses reported more EMR use when they changed their routine; clinicians need to figure out how to include the system in everyday work
Lykowski 2004[57]	CPOE; Workflow	Noncomparative study	Description of CPOE implementation process	Hospital		Multidisciplinary team involvement and incorporating process and technology led to good outcomes
Malhotra 2007[69]	Workflow; Modeling; ICU	Noncomparative study	Interviews and observations to document process and information flows in ICU	ICU in U.S.	Completed models at various levels	Communication, coordination, information needed; developed a model of workflows in an ICU
Manias 2001[87]	Rounds; Roles	Noncomparative study	Ethnographic study of 6 RNs; Participant observation, journals, interviews, focus groups	Critical care unit of a hospital in Australia	Description of process	Doctors use nurses to supplement information and provide extra details about patients; nurses discussed nursing knowledge during shift change

Source	Issue Related to Practice	Design Type	Study Design and Outcome Measures	Study Setting and Population	Study Intervention	Key Findings
McKnight 2002[28]	Information transfer; Interprofessional communication	Cross-sectional study	Surveys, focus groups	Hospital	Semi-structured survey about perceptions of information needs and communication difficulties; focus groups with physician and nurses	Information needs and communications difficulties are common and can lead to errors; problems cited were difficulty in finding information, finding inaccurate or outdated information, limited time, not knowing the system; difficulty in identifying and contacting other health care providers; limited time to lookup information; nurses mentioned patient education materials; physicians talked about paging, inconsistent communication at transfer of patient care; need feedback on order status, face to face communication where mistrust or disagreement on care plans; lack of communication leads to errors or near-misses; people want to improve their own efficiency without thinking of system efficiency
Meadows 2002[88]	Workflow; Efficiency; Staffing	Unpublished research	Discussion			Think about how to be more efficient by using technology to help redesign workflow and communications
Meadows 2003[89]	Information transfer, Interprofessional communication	Unpublished research	Discussion			Use of technology to improve teamwork and communication; Don't mimic current workflows with IT but use it to transform workflow across disciplines
Mekhjian 2002[42]	CPOE; Workflow; Implementation	Case–control study	Rapid system evaluation; time and motion study; comparison of data between areas with differential implementation of systems	Inpatient units; academic medical center;	Implemented CPOE on some units	Process breakdowns such as patient safety issues, workflow interruptions and inefficiencies; Technology may not necessarily improve institutional efficiency; incorporate safeguards for errors and interruptions; cultural change needs to be considered

Source	Issue Related to Practice	Design Type	Study Design and Outcome Measures	Study Setting and Population	Study Intervention	Key Findings
Patterson 2004[35]	Handoffs	Unpublished research	Discussion	Various industries	NA	Can learn lessons about handoffs from other industries (NASA, power plants, railroad and ambulance dispatch centers); many strategies are informal, as in health care
Pape 2003[90]	Workflow; Evidence based practice; Information transfer	Noncomparative study	Reviewed nursing practices	Nursing unit	Description of practices and implementation of evidence-based practices	IT can change in how people make decisions; discussion of how to incorporate evidence based practice and counter "cookbook medicine" arguments; how to find practices, and identify them, and implement
Patterson 2005[26]	Interprofessional communication; Information transfer	Noncomparative study	Observed handoffs; Interviews across different industries	Various industries	Description of handoff practices	Found 21 strategies for effective handoffs; provide supporting documentation in addition to the handoff; Systems highlighted can potentially be used to facilitate these strategies
Payne 1999[45]	CPOE; Implementation; Interprofessional communication	Noncomparative study	Description of first three months post implementation	Hospital	CPOE implementation	Implementing CPOE changed work patterns, communication, roles
Perrott 2004[24]	Workflow; Medication	Noncomparative study	Ethnography, Document review, Interviews	ICU nurses	Nursing handovers in an ICU	Customization of data sets; nursing education; nurse involvement in installation (from vendor and organization) were all success factors
Philpin 2006[15]	Information transfer; ICU; Interprofessional communication	Unpublished research	Discussion of nursing role	NA	NA	Nurses work with a number of other occupation groups; constant flow of other people moving in and out; discovered separate charts for observations and recording of nursing work; different providers have different documentation requirements, which may differ from organizational requirements

Source	Issue Related to Practice	Design Type	Study Design and Outcome Measures	Study Setting and Population	Study Intervention	Key Findings
Piasecki 2005[48]	CPOE	Changing practice	Review workflow to determine time and FTE savings before and after CPOE implementation	Emergency Department	CPOE implementation	Worked with business school to develop a ROI tool to measure outcomes of technology implementation; analyzed workflow before and after implementation and found savings in time and money
Plsek 1999[36]	Change; Workflow	Unpublished research	Focus groups	Clinical and support staff of a multispeciality clinic	NA	Use a high-level flow chart to show a typical visit, but need to consider different perspectives; need to mentally escape from traditional rules of workflow; can use technology to help with workflow and change how things are done
Powell 2006[17]	Information transfer; Handoffs; Interprofessional communication	Unpublished research	Discussion about improving handoffs			Problems identified: accountability of transition, transfer of information, responsibility when communicating to receiving provider - need to set expectations with sending and receiving groups; use advanced practice nurses as coordinators across sites
Price 2000[91]	Workflow; Safety	Literature review	Discussion	NA	NA	Problem based learning is done in the classroom, but should be done on the floor as part of workflow; need to think about issues of patient safety and competing demands on time

Source	Issue Related to Practice	Design Type	Study Design and Outcome Measures	Study Setting and Population	Study Intervention	Key Findings
Reddy 2002[30]	Information needs; Information transfer	Noncomparative study	Ethnography to understand information needs of physicians, nurses, students, pharmacists etc	SICU	Observed rounds; looked to see who asked questions, the kind of questions asked, resource used to answer question	Nurses and pharmacists served as information sources rather than information seekers; human sources were used more than electronic or paper sources as the first source of information; orders but not rationale is documented; need to understand clinical workflows and organizational workflows (keeping the place running); build systems to support work activities
Riley 2006[31]	Interprofessional communication; Information transfer	Noncomparative study	Observational fieldwork; Individual and group interviews using 11 nurse informants; Journaling	OR nurses	Evaluated how they dealt with each other and physicians with respect to time and identified practices	Practices found: questioning judgment and timing, controlling speed, estimating surgeons' use of time, coping with different perceptions of time; knowledge of individual surgeons was a source of power for nurses
Sandberg 2005[5]	Process redesign; OR	Cross-sectional study	Analyzed current workflow; changed and evaluated new workflow	OR Staff	Redesigned OR	Changed the process to include parallel activities and reorganized the space; improved throughput in the redesigned OR
Sandberg 2006[92]	Change; Workflow, OR	Pretest and Post-test	Looked at recovery room flow sheets, time, and nursing effort required	Ambulatory laparascopic chole-cystectomy patients	Implementation of a pathway	PACU nurses indicated that their workload increased, but the data did not support that conclusion; data looked at interventions such as pain meds and iv fluids - but is not necessarily an accurate capture of nursing workload
Scharnhorst 2003[39]	Implementation; Workflow	Noncomparative study	Workflow analysis and usability testing	Nursing staff	Implementation of handhelds	Collecting nursing data can help to define and articulate the role of nurses in health care; handhelds can help with reduction of redundancies

Source	Issue Related to Practice	Design Type	Study Design and Outcome Measures	Study Setting and Population	Study Intervention	Key Findings
Shefter 2006[93]	Workflow; Implementation	Unpublished research	Discussion	Case management	Introduction of workflow tools	Workflow technology tools can help or hinder case management; integrate patient level and organizational level data to help with workflow; information tools (databases, records) and workflow tools can help with linkages; need to consider not just training but ongoing support
Sittig 2006[38]	CPOE; Medication; Implementation	Noncomparative study	Discussion of CPOE implementation	NA	NA	Need to consider related organizational and workflow factors (not just technology); CPOE and IT efforts can alter workflow processes; we could share experiences in an M&M format; use opportunity to develop better systems
Spear 2005[20]	Change; Workflow	Noncomparative study	Multiple case studies to demonstrate best practices	Hospitals	NA	Hospital care is organized around functions, but there is not a reliable way to integrate these functions; can achieve excellence by having an environment where work is designed to reveal problems soon, are addressed quickly, solutions are quickly disseminated and people are taught to experiment at all levels of the organization; nurses spend a lot of time tracking down materials, services and information versus providing care
Stahl 2006[94]	Change; Workflow, OR	Noncomparative study	Redesigned systems before making a new OR	OR Suite	Redesigned processes emphasizing parallel processing; added staff	Increased patient throughput; added an additional nurse; considered multiple disciplines and roles
Strople 2006[27]	Information transfer	Noncomparative study	Reviewed shift report content, format and media	Nursing staff at hospitals	Analyzed content	Use of electronic systems as an adjunct to the shift report can contribute to patient care

Source	Issue Related to Practice	Design Type	Study Design and Outcome Measures	Study Setting and Population	Study Intervention	Key Findings
Van Eaton 2004[34]	Information transfer	Changing practice	Evaluation, analysis and prioritization of existing system content; Planned for a new system using a model, focus groups, modifying and implementing system	Resident run inpatient and consult services at two teaching hospitals (31 residents)	Developed and implemented system	Most residents used paper patient list to manage work so they had to recopy it; combined data from hospital information systems with resident entered details; popular and widely used; combined data needed for processes such as rounding and sign-out at the end of the day
Waring 2006[9]	Workflow; OR; Information transfer; Interprofessional communications	Noncomparative study	Ethnography, Interviews	OR in the UK; Teaching hospital	Analyzed routines and patterns of work; did some interviews; looked at different roles	Nursing staff often spent time coordinating supplies, missing items, figuring out where the patient goes next; each department seemed to be its own hub with spokes going out to other departments; each department is dependent on the work of others, yet they don't each necessarily understand the big picture; inter-departmental breakdowns; delays with schedule between surgery and floors; nurses often did transfer work themselves, which led to more delays; nurses "pitch in" and do work that other roles do not
Wright 2006[95]	CPOE	Noncomparative study	Reviewed processes and communications	Hospitals	CPOE implementation	CPOE impacts MD-nurse communications; found in implementation that significant workflow changes would be required; loss of visual cues or physical presence to give contextual information about orders; paper reports are not accurate; people know about order processes in their own departments but not how it works elsewhere or downstream impacts

* IT = information technology; EHR = electronic health record; EMR = electronic medical record; OR = operating room; ED = emergency department; CPOE = computerized provider order entry; ICU = intensive care unit; RN = registered nurse; MD = physician; HIMSS = Health Information and Management Systems Society.

Chapter 32. Professional Communication

Jean Ann Seago

Background

Instructing nurses on communication is a bit like instructing birds on flying. All nurses have been taught communication skills as a basic part of a prelicensure nursing program and then retaught communication skills in postlicensure programs, continuing education programs, workshops, and meetings. Some nurses would be insulted that anyone would even raise the issue of communication since raising the issue implies that they are deficient in one of the most basic aspects of nursing care. However, the problem with good communication is that it is, ironically, easy to talk about but hard to put into practice. In the literature, there are numerous articles that provide opinion, both expert and otherwise, about communication,[1–7] but there is very little evidence about communication practices that have demonstrated an impact upon patient outcomes. The purposes of this chapter are to discuss evidence of professional communication practices or strategies that have been tested empirically and have a relationship with patient outcomes or patient safety, and to provide communication tools that might help practicing nurses maintain and improve patient outcomes and patient safety.

This chapter will focus on communication strategies in hospitals and those related to communication between nurses and physicians. Studies related to communication between physicians and patients or nurses and patients were included if they were determined to be sufficiently methodologically rigorous and had a direct relationship with patient outcomes or patient safety. There is a large body of research on communication in other health care settings and among other professionals, which was not included in this chapter.

Historical Context

The history of communication between doctors and nurses is well documented. A series of publications begun in 1967 describing the “doctor-nurse game” provides insight into the way nurses have historically made treatment recommendations to doctors without appearing to do so, the way doctors have historically asked nurses for recommendations without appearing to do so, and how both participants strive to avoid open disagreement.[8–27] Although some nurses have argued that much has changed—and improved—in the relationships between doctors and nurses since that initial 1967 article, there is little evidence, although much wishful thinking, to support that view.[28–31] Additionally, over the years, the literature has contained descriptions of verbal abuse of nurses by physicians,[32–35] disruptive physician behavior,[36, 37] and advice on how nurses can better “handle” physicians.[38–41] So, in spite of much discussion, communication between doctors and nurses often remains contentious and obscure.

Theoretical Foundations

Many professional groups study communication among humans, and a wide range of theories guides the work. For the purpose of this review, a sample of theories used to describe or study

nurse-physician communication will be presented in brief. Habermas' critical theory has been used to identify successful nurse-physician collaborative strategies, including a willingness to move beyond basic information exchange and to challenge distortions and assumptions in the relationships.[42] Theories of Foucault and other poststructuralists that have guided concept analysis of collaboration and explored the notion that the relationship between power and knowledge (knowledge and power are not fixed, meaning not stable, and the idea that there is a hidden or "real" discourse) help explain the relationships between nurses and doctors.[43, 44] Various perspectives from the field of organizational behavior, including the structural (behavior is rational) perspective, the human resource (human needs and motivation) perspective, the political (competition for resources) perspective, and the cultural (organizational culture and climate) perspective, have been used to guide activities to improve nurse-physician communication.[45]

Feminists and scientists have used oppressed-group behavior theory to explain much of nurses' work and its structure in hospitals, including nurse-physician relationships.[34, 46–54] Many scientists and writers have evoked the issue of gender as it relates to the work of nurses and the relationship between nurses and doctors. Early literature related to gender tends to emphasize nurse image, and later work focuses more on nurse job satisfaction; job retention; and differences in decisionmaking, attitudes, perceptions, and ethical or moral dilemmas.[55–73] Mark and colleagues argue for theory development related to nurse staffing and patient outcomes, maintaining that one of the important and unexplored areas is the "why" of the nurse-physician relationships and the hypothesis that "enhanced" nurse-physician communication would "result in early recognition and intervention of potentially hazardous patient situations"[74] (p. 13).

With the recent emphasis on patient safety, hospital error, and adverse events, some hospital executives have embraced human factors science and training ideas taken from the aviation industry (Crew Resource Management)[75] to try to address the issue of patient safety and the lack of collaboration or teamwork in hospital settings. One of the most intriguing recent ideas is the use of the leader-member exchange theory[76–88] to describe the interactions between nurses and doctors in hospitals. Hughes and colleagues[89, 90] used leader-member exchange theory to create a nurse-physician exchange relationship scale and discussed the relationship between nurses and doctors in terms of a supervisor-employee relationship. The physician can be thought of as being the leader or supervisor of patient care, and the nurse can be thought of as being one of the members or employees providing care. This conceptualization will undoubtedly be challenged by nurses and nurse leaders who advocate for nurse autonomy or nurse independence, but Hughes and colleagues make a compelling argument for viewing the hospital nurse-physician relationship through this theoretical lens. There exists a long and varied history between nurses and doctors, making it difficult to use only one theory to explain all the subtleties of the relationships or to hold the key to improving those relationships.

Significance—Why Do We Care About Nurse-Physician Communication?

Over the years, there have been repeated cries and admonitions for improving nurse-physician communication and questioning why it is so difficult to achieve.[1, 63, 91, 92] Some research has shown that the lack of interpersonal and communication skills of physicians and nurses is associated with errors, inefficiencies in the delivery of care, and frustration.[93] There is evidence, though conflicting, that links better collaboration with better patient outcomes,

specifically reduced medication errors,[45, 94] reduced risk of inpatient mortality,[95–98] improved patient satisfaction,[99] and some support for efficiency measures such as shorter hospital length of stay.[100–103] However, several major reviews and studies found no relationship between nurse-physician collaboration and patient outcomes such as mortality or self-reported health status.[100, 102, 103] Physician satisfaction is generally not related to perceived increased collaboration; most frequently the evidence links perceived increased collaboration with nurse satisfaction.[4, 36, 104, 105] Additionally, nurses and physicians view the level of collaboration very differently, with nurses typically perceiving less collaboration and poorer communication than physicians.[70, 106–108] So, even though the descriptive evidence for improved patient outcomes and improved hospital efficiency is conflicting, it does not clearly negate the premise that better communication and collaboration could have an impact on patient outcomes.

In the nursing literature, nurse-physician communication is discussed or studied using terms such as empowerment, autonomy, collaboration, coordination, teamwork, transitioning, organizational culture, climate, and relationships. Assessment of the descriptive studies listed in the evidence table and references from other studies provide results, information, and opinion about nurse-physician communication, but they are not interventional studies. Some of the more compelling descriptive studies are included in the evidence table but do not meet the rigor required of randomized controlled trials. The setting of much of the descriptive or interventional work is intensive care units, emergency departments, or operating rooms and is often focused on nurse change-of-shift report;[109–112] physician/resident handoff/sign-off;[113–115] nurse-physician interaction, both routine and emergent;[91, 116–118] foreign language use by physicians and nurses;[119–124] and communication with patients.[125–131]

One of the recurring themes in the literature is the difference in perceptions between nurse and physician.[36, 69, 70, 106–108, 132–134] Nurses are typically less satisfied than physicians with the communication or interaction patterns and express the need for their opinions to be heard by physicians.[133] Areas of particular difference involve those of ethical decisionmaking and the moral dilemmas confronted by nurses related to these decisions.[135–137] There is also a body of literature on the differences between patient and provider (both nurses and physicians) in perceptions of care, quality, or comfort.[138–143] Although these papers provide important descriptions and information about nurse, physician, and patient communication, they are only briefly mentioned to provide context for this chapter. The focus of the chapter is on communication between physicians and nurses and whether there is a relationship with patient safety or other patient outcomes.

Research Evidence

There is no shortage of manuscripts in the literature that advocate, based only on opinion, for one or another method of building teamwork, collaboration, or communication, including recognizing corporate culture,[144] quality improvement,[145] continuous assessment and regular communication,[146] and reducing conflict.[147] Other publications detail the experience of one institution or unit in improving communication or teamwork using strategies such as the Comprehensive Unit-Based Safety Program developed at Hopkins,[148] Surgical Morning Meetings[149] using daily goals in an intensive care unit,[150] or interdisciplinary rounds.[151] These individual experience descriptions typically report varying outcomes or lack measured outcomes.

Evidence for Interventions That Improve Positive Communication—What Works?

This review found no randomized controlled trials (RCTs) that investigated communication interventions between nurses and physicians that had a patient outcome as a measure of interest. The RCTs included in the evidence table tested whether various communication training sessions for physicians improved communication with patients.[152–157] The evidence indicates that communication training is effective in improving physician attitudes, beliefs, and communication ability. There is also evidence that an intervention called peer leader education[155] can result in fewer symptom days, lower oral steroid rates, and reduced cost for children with asthma. In general, longer training programs (2–3 days) had greater positive effects, and the effects were longer lasting. Two RCTs tested the effect of training patients about care using information or technology and found slight improvement in patient perceptions of care.[158, 159]

Four systematic literature reviews were found that evaluated aspects of communication. One review of 14 studies measured the effect of communication training on physicians, using self-rating of the training effects, but provided no evidence of a relationship between the training and patient compliance or health status, and ambiguous effects on patient psychosocial health.[160] The second review of 26 studies concluded that various interventions had no effect on patient expectations, had conflicting lung-function outcomes, improved systolic blood pressure with any interaction, and decreased pain with improved patient-practitioner interaction.[161] The third review of 89 studies found no patient outcome changes (health status, disease incidence, cure rates, mortality rates, complication rates) with implementation of interprofessional education versus single-discipline education.[162] The fourth review, covering two studies, concluded that after communication training, team development meetings, or weekly rounds, there was no difference in patient mortality rates; but staff satisfaction increased, and there were conflicting results on length of stay.[100]

The literature search provided three nonrandomized controlled trials (NRCTs) with control groups related to interventions aimed at improving effective communication.[163–165] One study described a communication training intervention, a second added personnel (nurse practitioners and hospitalists) and multidisciplinary rounds to the environment, and the third used weekly meetings to discuss role relationships. The first study improved hospital employee work satisfaction and perception of opportunities and decreased information overload.[163] The second study improved physician perception of collaboration between nurses and doctors, but produced no change in nurse perception of collaboration.[164] The third study decreased consumers' belief in shared responsibility for care versus a physician-dominated responsibility for care, and increased consumers' belief that powerful individuals influence a consumer's health status.[165]

Included in the evidence tables are seven quality improvement projects without a control or comparison group. These projects are included as examples of the numerous studies in the literature that essentially describe the experience of one or two institutions in implementing an organizational change to improve doctor-nurse collaboration or communication. Dechairo-Marino and colleagues[166] report on a teamwork training program that produced no differences in self-reported collaboration or satisfaction; McFerran and colleagues[167] describe implementation of a structured communication technique known as Situation-Background-Assessment-Recommendation (SBAR), changing policies, debriefing, and multidisciplinary reports in four Kaiser Permanente sites. No long-term measures are reported, and only the short-term expectations for the "communication initiative" were met. Leonard and colleagues[168] report on

another Kaiser study of various groups in the organization trained in SBAR, assertion checklists, and briefings. Reported outcomes associated with the intervention include reduced wrong-site surgery, decreased nurse turnover, and improved employee satisfaction; however, no specifics on the measurement of these outcomes are provided. Lassen and colleagues[169] describe development and education of a collaborative practice (primarily physician specialists) decisionmaking protocol that was associated with a decrease in rule out sepsis diagnosis, use of antibiotics, patient days, costs, and readmissions in one neonatal intensive care unit (NICU).

Dutton and colleagues[170] reported that daily discharge multidisciplinary rounds were related to decreased length of stay in the emergency department and emergency department closures in one trauma center. Copnell and colleagues[134] reported no difference in perception of doctor-nurse collaboration after introduction of a nurse practitioner in two NICUs. Boyle[4] reported an increase in perceived doctor-nurse communication skills, nurse leadership skills, and problem-solving, and a decrease in nurse stress after a six-module training session called Collaborative Communication Intervention. The designs of these quality projects were too weak to allow any sort of conclusions to be drawn.

Practice Implications

There is insufficient empirical evidence to recommend any specific communication strategy or technology device to improve doctor-nurse communication. However, there is mixed or weak evidence to support using some of the techniques described in the cited literature. It is likely that focusing an organization on any strategy and persisting in that focus will be associated with, at least temporarily, a change in doctor-nurse communication patterns (e.g., Hawthorne effect). Given the paucity of available evidence, the following suggestions are offered for possible consideration in efforts to improve professional communication:

- Carefully evaluate various strategies for doctor-nurse communication using measurable outcomes that are important to your organization; plan to use a strategy that meets the needs and culture of your organization.
- Select a strategy, focus training, and provide organizational support and sufficient resources toward improving doctor-nurse communication.
- Slowly implement the change using sufficient resources and sufficient time.
- Do not implement multiple changes simultaneously.
- Persist in that strategy for an extended period of time (years, not weeks or months).
- Critically and rigorously evaluate the strategy using patient outcomes and worker satisfaction.
- After allowing sufficient thought and time for implementation and evaluation, be willing to publicly eliminate the strategy if it does not improve the outcomes.

Hospitals have used many communication tools such as written and verbal orders, reports, rounds, and team meetings. As the United States shifted to the "business model" for hospitals, organizations have tried to change culture or climate, create transformational leaders and knowledge workers, implement continuous quality improvement or total quality management, form quality circles, and train the one-minute manager. Some hospitals have used and are currently using technology ranging from pencil and paper, medication rooms and carts, orange vests for the medication nurse so she will have fewer interruptions, Pyxis or other automatic medication dispensers, landline telephones, fax machines, beepers, e-mail, personal digital

assistants (PDAs), cellular telephones, wireless devices, direct information transfer, and Web access.

Other recent technology includes mobile communication systems such as Vocera, electronic medical records, computerized physician order entry, and bar-coding for medication administration. A number of organizations are also trying SBAR, organizational support structures such as Rapid Response Teams or techniques such as customer relationship management from business or crew resource management from aviation. Other organizations are trying systems such as Situation-Trajectory-Intent-Concern-Calibrate (STICC) using the Hands-on Automated Nursing Data System Method from the University of Illinois at Chicago and funded by AHRQ, or Gerontology Interdisciplinary Team Training from the Hartford Foundation and the American Geriatrics Society. Few, if any, of these methods or devices have been empirically tested. Without careful consideration and evaluation, efforts to improve communication problems that exist in present-day hospitals may lead to implementation of strategies that will be ineffective.

Research Implications

Based on the literature review, future research is needed to assess the following:

- What should be the communication competencies of physicians and nurses; and should these competencies be assessed periodically?
- How can health information technologies be used to ensure effective communication between physicians and nurses, across settings and among the various care delivery models?
- What is the impact of effective communication strategies on hospitalized patient outcomes and medical errors?
- What is the impact of effective communication strategies on nurse and physician job satisfaction, and how does provider satisfaction relate to patient outcomes?
- How can communication skills training for practicing physicians and nurses have a career-long impact on their communication skills?

Conclusion

Within health care, there have been and will continue to be many approaches to professional communication. Unfortunately, the body of evidence is very limited, and the research findings to support professional communication and the relationship with patient safety and quality are not available at this time. There were limited studies that tested specific interventions aimed at changing nurse-physician communication, and there is some evidence that focusing on a doctor-nurse communication may have a positive effect. Health care organizations and providers will be challenged as they seek to improve the effectiveness of professional communication, given all the subtleties of the nurse-physician relationships.

Search Strategy

Search strategies employed included the use of the electronic databases PubMed®, CINAHL®, the Cochrane Collection, and relevant AHRQ reports. Keywords included physician, nurse, relationships, communication, coordination, collaboration, autonomy, teamwork, MD,

RN, patient, outcome, safety, and adverse event. Reference lists of select publications were investigated for potential manuscripts, and literature related to relevant measurement instruments was sought.

Evidence Table

Source	Communication Targets	Design Type	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Randomized Controlled Trials						
Ellison 2004[159]	Patients	Design Type 2 (RCT) (Level 2) questionnaire	Patient satisfaction (Level 3)	1 hospital 85 patients	Standard care plus1 day telerounding; standard care substituting 1 day with robotic telerounding	Improvement in telerounding patients of examination thoroughness, quality of discussion, postoperative care coordination, availability of MD; in robotic telerounding improvement in availability of MD.
Fallowfield 2003[153]	MD/patient	Design Type2 (RCT)— pre/postvideotape (Level 2)	At 12 months, same as 3 months (Level 3)	Oncology MDs, UK	3 day residential communication skills training course	Same effect with use of leading questions, open-ended questions, and response to patient cues; improvement in fewer interruptions, increased summarizing; decline in expressions of empathy.
Jenkins 2002[152]	MD/pt	Design Type 2 (RCT)—P-P videotape (Level 2)	At 3 months attitudes, empathy, responses (Level 3)	Oncology MDs, UK	3 day residential communication skills training course	Improved attitudes and beliefs toward psychosocial issues compared to controls; increased expressions of empathy; open questions; appropriate responses to patient cues and psychosocial probing; self-reported changes in communication styles.

Source	Communication Targets	Design Type	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Joos 1996[157]	MD/pt	Design Type 2 (RCT)—P-P questionnaire (Level 2)	Communication skills (Level 3), and compliance and utilization (Level 2)	42 MDs and 348 patients with chronic conditions	4.5 hours of training	Increased number of times MDs elicited patient and RN concerns, increased patient perception of amount of information received, no change in patient compliance with medications or appointments; no change in patient utilization.
Levinson 1993[156]	MD/pt	Design Type2 (RCT)—P-P audiotape (Level 2)	Communication skills (Level 3)	53 community-based MDs and 473 patients	A short CME program (4.5 hours) and a long CME program (2.5 days)	Short program: no effect. Long program: more open-ended questions, asked patient opinions, gave more biomedical information, patients disclosed more information, decrease in negative affect for both, patients had fewer signs of outward distress during visit.
Lozano 2004[154]	MD/children (3–17) with asthma	Design Type2 (RCT)—cluster P-P interview and questionnaire (Level 2)	Asthma symptom days, asthma-specific functional status, frequency of oral steroid courses (Level 1)	42 primary care practices in 3 locations	Peer leader education (PLE) and peer leader + nurse-mediated organizational change (PACI)	Peer leader: fewer symptom days per year & lower oral steroid rates. Peer leader + nurse: fewer symptom days per year & greater adherence to treatment by parent report.
Sullivan 2005[155]	MD/children (3–17) with asthma	Design Type 2 (RCT)—cluster P-P interview and questionnaire (Level 2)	Symptom-free days (SFDs); asthma-related health care costs (Level 1)	42 primary care practices in 3 locations	Peer leader education (PLE) and peer leader + nurse-mediated organizational change (PACI)	SFD: 6.5 with PLE vs. usual, 13.5 with PACI vs. usual; compared with usual incremental cost effectiveness ratio was $18/SFD gained for PLE and $68/SFD gained for PACI.

Source	Communication Targets	Design Type	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Tran 2002[158]	ED patients	Design Type 2 (RCT) (Level 2) questionnaire	Patient length of stay (LOS), wait time, perception of LOS, ratings of nurse skills and MD skills (Levels 3 & 4)	1 hospital ED 619 patients	Providing patients with information q 15 minutes during stay	No difference in LOS, wait time, nurse skills. Decrease in perceived LOS and wait time and increase in perception of MD skills.
Nonrandomized Controlled Trials and Quality Improvement (QI) Projects						
Boyle 2004[4]	MDs/RNs	Design Type 6 P-P 2 units no control (Level 5)	Communication skills, increased staff satisfaction, lower stress, increased problem-solving using videotape vignettes, questionnaire	1 ICU from 2 hospitals	Collaborative Communication Intervention over 8 months: 23.5 hours for 6 modules	Increased perceived RN and MD communication skills, improved nurse leadership and problem-solving, decreased staff nurse personal stress.
Copnell 2004[134]	MDs/RNs	Design Type 6 P-P 2 units no control (Level 5)	Perception of collaboration	2 NICUs	Added NP	No difference before and after NP; MDs and RNs disagreed about collaboration with MDs scoring higher.
Dechairo-Marino 2001[166]	RNs	Design Type 6 action research—P-P 1 group-no control (Level 5)	RN reports of collaboration with MDs and RN Satisfaction with decisionmaking process- (Level 3)	1 university teaching hospital; RNs in 3 med-surg units and 2 ICUs	Activities to promote interdisciplinary teamwork between MDs/RNs, including developing principles, discussion in meetings, 1 4-hour class on decisionmaking	No differences
Dutton 2002[170]	MDs, nurses, patients discharge planners	Design Type 8-no control group (Level 5)	Patient volume, LOS, ED closure (Level 3, 4)	1 hospital trauma service	Daily discharge multidisciplinary rounds	Increase in patient volume, decrease in LOS, decrease in ED closure.

Source	Communication Targets	Design Type	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Lassen 1997[169]	Well-newborn nurses, pediatricians, neonatologists	Design Type 13-QI project with a control time (Level 5)	# of admissions with R/O sepsis, LOS, # of doses of antibiotics, costs, # of readmissions, reduction in practice variation (Levels 1, 2, 3)	1 tertiary hospital	Collaborative practice decisionmaking protocol development; education	Decrease in # of R/O sepsis diagnosis, decease in % of patients treated with antibiotics, decrease in patient days, decrease in costs, decrease in readmissions.
Leonard 2004[168]	Various groups in Kaiser Permanente	Design Type 14-QI project-no control (Level 5)	Improve communication and teamwork by standardized communication (Level 3)	different groups of MDs and RNs	Introduce standardized communication methods such as SBAR, assertion, checklists, critical event training, and briefings	Standardized briefings related to reduced wrong-site surgery, decreased nurse turnover, improved employee satisfaction, improved teamwork climate, communication, and taking responsibility for errors—but few specifics provided.
McFerran 2005[167]	Perinatal RNs, certified registered nurse anesthesists and MDs	Design Type 13 QI project-no control (Level 5)	Long-term measures: birth event data, medical-legal data, patient satisfaction data (Levels 1 & 2); short-term measures: implementation of 2-3 interventions using human factors technique during 1 year (Level 3)	4 Kaiser Permanente medical centers perinatal staff	4-hour human factors education program, SBAR communication technique, revising escalation policy, identifying safe communications, debriefs after adverse events, multidisciplinary reports, assertion, just culture statement (Level 3)	No long-term measures reported; 4 sites met short-term expectations for only communication initiatives.

Source	Communication Targets	Design Type	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Roberts 1976[163]	Hospital employees (non-MD and nonsupervisors)	Design Type 3—NRCT-P-P 2 groups with 1 being control (Level 3)	Employee perception of organizational communication, job satisfaction, and opportunities for innovative job behavior (Level 3)	1 urban hospital; ED staff members	2.5-3 hour training sessions weekly for 4 consecutive weeks	Increase satisfaction with work, pay, coworkers, job; increase perception of opportunities for innovation; increase desire for interaction with peers; and decrease in information overload.
Weiss 1985[165]	MD/RN/consumer	Design Type 3—NRCT with 3 groups, with 2 being matched control groups (Level 3)	Belief regarding value of shared versus physician-dominated responsibility for health care and beliefs that powerful individuals influence consumer health status (Level 4)	Recruited in large urban area	Discussion of role relationships, and problems for 2.5 hours 1 evening/month for 20 months	Decline in belief in shared versus physician-dominated responsibility for health care and increase in belief that powerful individuals influence the consumer's health status.
Vazirani 2005[164]	Unit organization; RN, MD, residents, hospitalist, NP	Design Type 3—NCRT 2 groups with 1 being control (Level 3)	Collaboration, communication (Level 3)	1 hospital; 1 control unit and 1 intervention unit	Added NP, hospitalist, daily multidisciplinary rounds	Perception by MDs of greater collaboration between physicians and nurses with largest effect with residents, between physicians and NPs, better communication between MDs; no difference in nurse perception of communication or collaboration between nurses and MDs, nurses perceived better communication with NPs than MDs.

Source	Communication Targets	Design Type	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Systematic Literature Reviews						
Di Blasi 1996 (Cochrane Collaboration-Centre for Reviews and Dissemination)[161]	Patients with various health problems	Design Type 11 structured review (Level 1) RCTs with and without placebo	Health outcome, symptom resolution, functional status (Level 1); health service use, medication adherence, anxiety, satisfaction (Level 3)	26 studies with 3,811 participants: poor quality studies with small sample sizes	Various treatments or disease management, including labeling, changing patient expectations, combining treatment information with emotional support	Labeling: no effect; changing patient expectations: conflicting results—improved lung function with suggestion of drug effects but improved systolic blood pressure following any interaction; combined information with support: improved outcomes, mixed result—6 studies found decrease in pain with improved patient-practitioner interaction, style of interaction can influence physical health but with small effects.
Hulsman 1999 (Cochrane Collaboration-Centre for Reviews and Dissemination)[160]	Graduate or postgraduate MDs	Design Type 11 structured review (Level 1); evaluation studies RCT and NRCT P-P video, discussion, role play, audio, written, self-rating	Receptive behaviors, information behavior, interpersonal and affective behavior, psychosocial problems and emotions (Level 3); compliance, health status, psychosocial status (Level 2)	14 studies, 408 participants, 135 controls	Training, education using lecture, modeling, discussion, role play—4-96 hours over 2 days to 6 months	10 studies report some training effect with best designed reporting fewest effects; improved self-rating of communication and recognition of psychosocial patient problems, no conclusive patient compliance effect, no effect on health status, ambiguous effect of psychosocial health. The other 4 studies report no effects.

Source	Communication Targets	Design Type	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Zwarenstein 2000 (The Cochrane Collaboration)[100]	Chiropodists/podiatrists, dentists, dietitians, MDs, hygienists, psychologists, nurses, pharmacists, occupational therapists, and others	Design Type 11 structured review (Level 1); RCT, controlled before and after, and interrupted time series	Self-reported health status, disease incidence, cure rates, mortality, complication rates (Level 1); adherence, satisfaction, continuity of care, costs (Level 3)	89 studies; none met the inclusion criteria	Interprofessional education (IPE) versus single-discipline education	No conclusive evidence of the effectiveness of IPE in relation to professional practice or health outcomes.
Zwarenstein 2000 (The Cochrane Collaboration)[100]	MDs/RNs	Design Type 11 structured review (Level 1); RCT, controlled before and after, and interrupted time series	MD/RN collaboration/joint decisionmaking (Level 3), costs(Level 4); LOS, mortality (Level 1)	2 studies with 1,102 admissions in one and 417 admissions in the other	Training, workshops, ward reorganization, team development, meetings, patient-centered care, 4 times weekly rounds, weekly case conference	1st study: shorter LOS, reduced costs, no difference in mortality rate, increased staff satisfaction. 2nd study: no difference in LOS and no difference in mortality rates.
Descriptive						
Aiken 1994[171]	MDs/RNs	Design Type 4 cross-sectional (Level 5)	Medicare mortality rates (Level 1)	39 Magnet hospitals, 139 controls	None	Magnet hospitals (higher autonomy, control, MD relationships, RN hours, skill mix) had lower Medicare mortality rates.
Aiken 1999[99]	MDs/RNs	Design Type 4 cross-sectional (Level 5)	30-day mortality, patient satisfaction, nurse-patient ratios, control by bedside nurses; specialty physicians (Levels 1, 3)	40 units in 20 hospitals; 1,205 patients and 820 nurses	None	Better nurse-patient ratios, lower mortality; higher nurse control, higher patient satisfaction.
Alt-White 1983[105]	MDs/RNs	Design Type 4, 8 cross-sectional no comparison group (Level 5)	Nurse-physician collaboration (Level 3)	46 units, 446 nurses	None	Primary nurse, critical care units, unit communication, coordination, nurse satisfaction associated with better collaboration.

Source	Communication Targets	Design Type	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Baggs 1997[107]	MDs/RNs	Design Type 4, 8 cross-sectional no comparison group (Level 5)	Nurse/physician collaboration and satisfaction with decisionmaking, nurse retention (Level 3)	3 ICUs in 3 hospital	None	Collaboration was associated with satisfaction for all but more strongly for nurses; nurse satisfaction with decisionmaking was not associated with retention.
Baggs 1999[95]	MDs/RNs	Design Type 4, 8 cross-sectional no comparison group (Level 5)	Mortality, ICU readmission (Level 1)	3 ICUs in 3 hospitals	None	In the medical ICU, there was an association between nurse perception of collaboration and lower risk of patient death or ICU readmission; MD reports of collaboration were not associated with patient outcomes.
Estabrooks 2005[98]	MDs/RNs	Design Type 4, 8 cross-sectional no comparison group (Level 5	30-day mortality	49 hospitals	None	Greater nurse-physician relationships, more temporary positions, higher nurse education level, and richer skill mix associated with better 30-day mortality.
Kaissi 2003[106]	MDs/RNs	Design Type 4, 8 cross-sectional no comparison group (Level 5)	Nurse-physician interpersonal interaction/teamwork (Level 3)	2 hospitals	None	78% of nurses rated experience with MDs as very low/low or adequate.
King 1994[108]	MDs/RNs	Design Type 4, 8 cross-sectional no comparison group (Level 5)	Nurse-physician collaboration (Level 3)	90 nurses, 40 physicians, 4 hospitals, and 2 hospital ships	None	MDs & RNs disagreed with MDs perceiving higher collaboration than RNs.
Knaus 1986[97]	MDs/RNs	Design Type 4, 8 cross-sectional with no comparison group (Level 5)	Actual and predicted mortality, coordination of care (Levels 1, 3)	13 hospitals	None	Hospitals with less actual mortality than predicted had better coordination of care and communication between RNs/MDs and among MDs.

Source	Communication Targets	Design Type	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Rosenstein 2002[36]	RNs/MDs/executives	Design Type 4, 8 cross-sectional with no comparison group (Level 5)	Nurse-physician relationship (Level 3)	Network of hospitals; 1,200 responses from RNs, MDs, executives	None	MDs and RNs were significantly different; more RNs have witnessed disruptive MD behavior, more RNs say the disruptive behavior is important in nurse morale; nurses perceive less support for conflict; nurses perceive MDs as unaware of relationship.
Zimmerman 1993[103]	MDs/RNs	Design Type 4, 8 cross-sectional with no comparison group (Level 5)	Strong medical and nursing leadership, collaboration, coordination, communication, mortality, LOS (Levels 1, 3)	9 ICUs in 9 hospitals; 316 RNs and 202 MDs	None	No difference in risk-adjusted mortality or LOS between high-performing and low-performing ICUs.
Shortell 1994[101]	MDs/RNs	Design Type 4, 8 cross-sectional no comparison group (Level 5)	LOS, nurse turnover, technical quality of care, meeting family needs (Levels 3, 4)	42 ICUs	None	Higher scores on leadership, coordination, communication, conflict management, associated with shorter LOS, higher technical quality of care, greater ability to meet family needs.
Thomas 2003[70]	MDs/RNs	Design Type 4, 8 cross-sectional no comparison group (Level 5)	Collaboration, communication (Level 3)	8 ICUs in 2 hospitals; 90 MDs, 230 RNs	None	Most MDs rated collaboration and communication as high or very high; most RNs rated it as low or very low.
Zimmerman 1991[102]	MDs/RNs	Design Type 4, 8 cross-sectional no comparison group (Level 5)	ICU LOS, predicted hospital mortality (Levels 1, 3)	40 hospitals	None	Lower mortality associated with better technological adequacy and work environment; shorter LOS associated with better communication, culture, coordination, conflict management.

Appendix

Measurement Instruments

Source	Measurement Instrument	Concepts	Number of Items & Response Style
Shortell 1991[172]	ICU Nurse-Physician Questionnaire; 48 items selected from the Organizational Culture Inventory (OCI)	Organizational culture, leadership, communication, coordination, problem-solving	48 items; 1–5 point Likert scale
Roberts 1974[173]	Organizational Communication	Communication	35 items; 7–10 point Likert scale
Choi 2004[174]	Perceived Nursing Work Environment (PNWE)	Nursing management, nursing process, RN/MD collaboration, nursing competence, scheduling climate	42 items; 4 point Likert scale
Weiss 1985[175]	Collaborative Practice Scales	RN/MD interaction and influence on patient care	9 items RN & 10 items MD; 6 point Likert scale
Aiken 2000[176]	Nursing Work Index-Revised (NWI-R)	Autonomy, RN/MD relationships, control of practice	57 items; 4 point Likert scale
Temkin-Greener 2004[177]	PACE team performance questionnaire	Interdisciplinary team performance	59 items; 5 point Likert scale
Baggs 1994[178]	Collaboration and Satisfaction About Care Decisions (CSACD)	RN/MD collaboration	14 items; 7 point Likert scale

Chapter 33. Professional Communication and Team Collaboration

Michelle O'Daniel, Alan H. Rosenstein

Background

In today's health care system, delivery processes involve numerous interfaces and patient handoffs among multiple health care practitioners with varying levels of educational and occupational training. During the course of a 4-day hospital stay, a patient may interact with 50 different employees, including physicians, nurses, technicians, and others. Effective clinical practice thus involves many instances where critical information must be accurately communicated. Team collaboration is essential. When health care professionals are not communicating effectively, patient safety is at risk for several reasons: lack of critical information, misinterpretation of information, unclear orders over the telephone, and overlooked changes in status.[1]

Lack of communication creates situations where medical errors can occur. These errors have the potential to cause severe injury or unexpected patient death. Medical errors, especially those caused by a failure to communicate, are a pervasive problem in today's health care organizations. According to the Joint Commission (formerly the Joint Commission on Accreditation of Healthcare Organizations, JCHAO), if medical errors appeared on the National Center for Health Statistic's list of the top 10 causes of death in the United States, they would rank number 5—ahead of accidents, diabetes, and Alzheimer's disease, as well as AIDS, breast cancer, and gunshot wounds.[1] The 1999 Institute of Medicine (IOM) report, *To Err Is Human: Building a Safer Health System*, revealed that between 44,000 and 98,000 people die every year in U.S. hospitals because of medical errors.[2] Even more disturbing, communication failures are the leading root cause of the sentinel events reported to the Joint Commission from 1995 to 2004. More specifically, the Joint Commission cites communication failures as the leading root cause for medication errors, delays in treatment, and wrong-site surgeries, as well as the second most frequently cited root cause for operative and postoperative events and fatal falls.[1]

Traditional medical education emphasizes the importance of error-free practice, utilizing intense peer pressure to achieve perfection during both diagnosis and treatment. Errors are therefore perceived normatively as an expression of failure. This atmosphere creates an environment that precludes the fair, open discussion of mistakes required if organizational learning is to take place. In the early 1990s, Donald Berwick wrote about patients needing an open communication system instead of experiencing adverse events stemming from communication failures.[3] More than a decade later, this concept still has profound implications on our method of health care delivery. As such, this chapter will review the literature on the important role of communication and team collaboration in helping to reduce medical errors and increase patient safety.

Research Evidence

What Are Communication and Team Collaboration?

Webster's Dictionary defines communication as "the imparting or interchange of thoughts, opinions, or information by speech, writing, or signs." It is important to consider that communication is not just verbal in form. One study states that 93 percent of communication is more affected by body language, attitude, and tone, leaving only 7 percent of the meaning and intent based on the actual words said.[4] Whereas the spoken words contain the crucial content, their meaning can be influenced by the style of delivery, which includes the way speakers stand, speak, and look at a person.[1] However, critical information is often transmitted via handwritten notes, e-mails, or text messages, which can lead to serious consequences if there is miscommunication.

Collaboration in health care is defined as health care professionals assuming complementary roles and cooperatively working together, sharing responsibility for problem-solving and making decisions to formulate and carry out plans for patient care.[5, 6] Collaboration between physicians, nurses, and other health care professionals increases team members' awareness of each others' type of knowledge and skills, leading to continued improvement in decisionmaking.[7]

Effective teams are characterized by trust, respect, and collaboration. Deming[8] is one of the greatest proponents of teamwork. Teamwork, he believes, is endemic to a system in which all employees are working for the good of a goal, who have a common aim, and who work together to achieve that aim. When considering a teamwork model in health care, an interdisciplinary approach should be applied. Unlike a multidisciplinary approach, in which each team member is responsible only for the activities related to his or her own discipline and formulates separate goals for the patient, an interdisciplinary approach coalesces a joint effort on behalf of the patient with a common goal from all disciplines involved in the care plan. The pooling of specialized services leads to integrated interventions. The plan of care takes into account the multiple assessments and treatment regimens, and it packages these services to create an individualized care program that best addresses the needs of the patient. The patient finds that communication is easier with the cohesive team, rather than with numerous professionals who do not know what others are doing to mange the patient.[9] Table 1 is a compilation of some of the components found in the literature of a successful teamwork model.[10–14]

It is important to point out that fostering a team collaboration environment may have hurdles to overcome: additional time; perceived loss of autonomy; lack of confidence or trust in decisions of others; clashing perceptions; territorialism; and lack of awareness of one provider of the education, knowledge, and skills held by colleagues from other disciplines and professions.[15] However, most of these hurdles can be overcome with an open attitude and feelings of mutual respect and trust. A study determined that improved teamwork and communication are described by health care workers as among the most important factors in improving clinical effectiveness and job satisfaction.[16]

Table 1. Components of Successful Teamwork

- Open communication
- Nonpunitive environment
- Clear direction
- Clear and known roles and tasks for team members

- Respectful atmosphere
- Shared responsibility for team success
- Appropriate balance of member participation for the task at hand
- Acknowledgment and processing of conflict
- Clear specifications regarding authority and accountability
- Clear and known decisionmaking procedures
- Regular and routine communication and information sharing
- Enabling environment, including access to needed resources
- Mechanism to evaluate outcomes and adjust accordingly

Extensive review of the literature shows that communication, collaboration, and teamwork do not always occur in clinical settings. For example, a study by Sutcliff, Lewton, and Rosenthal[17] reveals that social, relational, and organizational structures contribute to communication failures that have been implicated as a large contributor to adverse clinical events and outcomes. Another study shows that the priorities of patient care differed between members of the health care team, and that verbal communication between team members was inconsistent.[16] Other evidence shows that more than one-fifth of patients hospitalized in the United States reported hospital system problems, including staff providing conflicting information and staff not knowing which physician is in charge of their care.[18] Over the past several years, we have been conducting original research on the impact of physician and nurse disruptive behaviors (defined as any inappropriate behavior, confrontation, or conflict, ranging from verbal abuse to physical or sexual harassment) and its effect on staff relationships, staff satisfaction and turnover, and patient outcomes of care, including adverse events, medical errors, compromises in patient safety, poor quality care, and links to preventable patient mortality. Many of these unwanted effects can be traced back to poor communication and collaboration, and ineffective teamwork.[19–22]

Unfortunately, many health care workers are used to poor communication and teamwork, as a result of a culture of low expectations that has developed in many health care settings. This culture, in which health care workers have come to expect faulty and incomplete exchange of information, leads to errors because even conscientious professionals tend to ignore potential red flags and clinical discrepancies. They view these warning signals as indicators of routine repetitions of poor communication rather than unusual, worrisome indicators.[23]

Although poor communication can lead to tragic consequences, a review of the literature also shows that effective communication can lead to the following positive outcomes: improved information flow, more effective interventions, improved safety, enhanced employee morale, increased patient and family satisfaction, and decreased lengths of stay.[1, 24–26] Fuss and colleagues[27] and Gittell and others[28] show that implementing systems to facilitate team communication can substantially improve quality.

Effective communication among staff encourages effective teamwork and promotes continuity and clarity within the patient care team. At its best, good communication encourages collaboration, fosters teamwork, and helps prevent errors.

Barriers to Effective Communication

Health professionals tend to work autonomously, even though they may speak of being part of a team.[29] Efforts to improve health care safety and quality are often jeopardized by the communication and collaboration barriers that exist between clinical staff. Although every organization is unique, the barriers to effective communication that organizations face have

some common themes. Table 2 indicates some common barriers to interprofessional collaboration that we have learned from our research and focus groups with hospitals across the country.

Table 2. Common Barriers to Interprofessional Communication and Collaboration

- Personal values and expectations
- Personality differences
- Hierarchy
- Disruptive behavior
- Culture and ethnicity
- Generational differences
- Gender
- Historical interprofessional and intraprofessional rivalries
- Differences in language and jargon
- Differences in schedules and professional routines
- Varying levels of preparation, qualifications, and status
- Differences in requirements, regulations, and norms of professional education
- Fears of diluted professional identity
- Differences in accountability, payment, and rewards
- Concerns regarding clinical responsibility
- Complexity of care
- Emphasis on rapid decisionmaking

The barriers indicated in Table 2 can occur within disciplines, most notably between physicians and residents, surgeons and anesthesiologists, and nurses and nurse managers.[30, 31] However, most often the barriers manifest between nurses and physicians. Even though doctors and nurses interact numerous times a day, they often have different perceptions of their roles and responsibilities as to patient needs, and thus different goals for patient care. One barrier compounding this issue is that because the United States is one of the most ethnically and culturally diverse countries in the world, many clinicians come from a variety of cultural backgrounds. In all interactions, cultural differences can exacerbate communication problems.[1] For example, in some cultures, individuals refrain from being assertive or challenging opinions openly. As a result, it is very difficult for nurses from such cultures to speak up if they see something wrong. In cultures such as these, nurses may communicate their concern in very indirect ways. Culture barriers can also hinder nonverbal communication. For example, some cultures ascribe specific meaning to eye contact, certain facial expressions, touch, tone of voice, and nods of the head.

Issues around gender differences in communication styles, values, and expectations are common in all workplace situations. In the health care industry, where most physicians are male and most nurses are female, communication problems are further accentuated by gender differences.[32]

A review of the organizational communication literature shows that a common barrier to effective communication and collaboration is hierarchies.[33–37] Sutcliff and colleagues' research[17] concurs that communication failures in the medical setting arise from vertical hierarchical differences, concerns with upward influence, role conflict, and ambiguity and struggles with interpersonal power and conflict. Communication is likely to be distorted or withheld in situations where there are hierarchical differences between two communicators, particularly

when one person is concerned about appearing incompetent, does not want to offend the other, or perceives that the other is not open to communication.

In health care environments characterized by a hierarchical culture, physicians are at the top of that hierarchy. Consequently, they may feel that the environment is collaborative and that communication is open while nurses and other direct care staff perceive communication problems. Hierarchy differences can come into play and diminish the collaborative interactions necessary to ensure that the proper treatments are delivered appropriately. When hierarchy differences exist, people on the lower end of the hierarchy tend to be uncomfortable speaking up about problems or concerns. Intimidating behavior by individuals at the top of a hierarchy can hinder communication and give the impression that the individual is unapproachable.[1, 38]

Staff who witness poor performance in their peers may be hesitant to speak up because of fear of retaliation or the impression that speaking up will not do any good. Relationships between the individuals providing patient care can have a powerful influence on how and even if important information is communicated. Research has shown that delays in patient care and recurring problems from unresolved disputes are often the by-product of physician-nurse disagreement.[39] Our research has identified a common trend in which nurses are either reluctant or refuse to call physicians, even in the face of a deteriorating status in patient care. Reasons for this include intimidation, fear of getting into a confrontational or antagonistic discussion, lack of confidentiality, fear of retaliation, and the fact that nothing ever seems to change. Many of these issues have to deal more with personality and communication style.[40] The major concern about disruptive behaviors is how frequently they occur and the potential negative impact they can have on patient care. Our research has shown that 17 percent of respondents to our survey research in 2004-2006 knew of a specific adverse event that occurred as a result of disruptive behavior. A quote from one of the respondents illustrates this point: “Poor communication post-op because of disruptive reputation of physician resulted in delayed treatment, aspiration, and eventual demise.”[19]

Leaders in both medicine and nursing have issued ongoing initiatives for the development of a cooperative rather than a competitive agenda to benefit patient care.[5, 39, 41, 42] A powerful incentive for greater teamwork among professionals is created by directing attention to the areas where changes are likely to result in measurable improvements for the patients they serve together, rather than concentrating on what, on the surface, seem to be irreconcilable professional differences. The fact that most health professionals have at least one characteristic in common, a personal desire to learn, and that they have at least one shared value, to meet the needs of their patients or clients, is a good place to start.

Practice Implications

Known Benefits of Communication and Team Collaboration

A large body of literature shows that because of the complexity of medical care, coupled with the inherent limitations of human performance, it is critically important that clinicians have standardized communication tools and create an environment in which individuals can speak up and express concerns. This literature concurs that when a team needs to communicate complex information in a short period of time, it is helpful to use structured communication techniques to ensure accuracy. Structured communication techniques can serve the same purpose that clinical practice guidelines do in assisting practitioners to make decisions and

take action. Research from aviation and wilderness firefighting is useful in health care because they all involve settings where there is a huge variability in circumstances, the need to adapt processes quickly, a quickly changing knowledge base, and highly trained professionals who must use expert judgment in dynamic settings. Research shows that in these disciplines, the adoption of standardized tools and behaviors is a very effective strategy in enhancing teamwork and reducing risks.[1, 17, 43–54, 60, 61]

Crew Resource Management (Aviation). Experts in aviation have developed safety training focused on effective team management, known as Crew Resource Management (CRM). Improvements in the safety record of commercial aviation may be due, in part, to this training. Realizing that 70 percent of commercial flight accidents stemmed from communication failures among crew members, CRM sought to standardize communication and teamwork. The concept originated in 1979, in response to a NASA workshop that examined the role that human error plays in air crashes. CRM emphasizes the role of human factors in high-stress, high-risk environments. John K. Lauber, a psychologist member of the National Transportation Safety Board, deemed CRM as "using all available sources—information, equipment, and people—to achieve safe and efficient flight operations."[44, 45] CRM encompasses team training as well as simulation, interactive group debriefings, and measurement and improvement of aircrew performance. This represents a major change in training, which had previously dealt with only the technical aspects of flying. It considers human performance limiters (such as fatigue and stress) and the nature of human error, and it defines behaviors that are countermeasures to error, such as leadership, briefings, monitoring and cross-checking, decisionmaking, and review and modification of plans. From a practical standpoint, CRM programs typically include educating crews about the limitations of human performance. Trainees develop an understanding of cognitive errors and how stressors (such as fatigue, emergencies, and work overload) contribute to the occurrence of errors. Operational concepts stressed include inquiry, seeking relevant operational information, advocacy, communicating proposed actions, conflict resolution, and decisionmaking. CRM is now required for flight crews worldwide.

The development and implementation of CRM in aviation over the last 25 years offers valuable lessons for medical care. Sexton and colleagues[51] compared flight crews with operating room personnel on several measures, including attitudes toward teamwork. This landmark study included more than 30,000 cockpit crew members (captains, first officers, and second officers) and 1,033 operating room personnel (attending surgeons, attending anesthesiologists, surgical residents, anesthesia residents, surgical nurses, and anesthesia nurses). Questionnaires were sent to crew members of major airlines around the world (over a 15-year period). The operating room participants were mailed an analogous questionnaire, administered over a period of 3 years at 12 teaching and nonteaching hospitals in the United States, Italy, Germany, Switzerland, and Israel.

The Sexton study and other analyses suggest that safety-related behaviors that have been applied and studied extensively in the aviation industry may also be relevant in health care. Study results show successful CRM applications in several dynamic decisionmaking health care environments: the operating room, labor and delivery, and the emergency room.[26, 31, 55, 56] As with aviation, the medical application of CRM has required tailoring of training approaches to mirror the areas in which human factors contribute to mishaps. In anesthesiology, 65–70 percent of safety problems (accidents or incidents) have been attributed at least in part to human error. In response, several anesthesiologists from the Veterans Affairs Palo Alto Health Care System and Stanford University developed Anesthesia Crisis Resource Management (ACRM), modeled on CRM.[55] Kaiser Permanente, a nonprofit American health care system providing care for 8.3

million patients, has also adopted CRM with successful results.[54] In response to the occurrence of a sentinel event—a medical error with serious consequences—Eglin U.S. Air Force (USAF) Regional Hospital developed and implemented a patient safety program called Medical Team Management (MTM) that was modeled on the aviation industry's CRM program and focused on communication, teamwork, and reporting to determine the impact of a patient safety program on patterns of medical error reporting.[57] This study was a retrospective review of 1,102 incident reports filed at Eglin USAF Regional Hospital in Florida between 1997 and 2001. Collected data from the comparison periods (1998 and 2001) were statistically analyzed using the chi-square test. This study indicates that, since the implementation of MTM, there has been a statistically significant increase in the number of reports filed at Eglin USAF Regional Hospital and a decline in the severity of incidents. These findings suggest that since the implementation of MTM, there have been changes in the patterns of error reporting, and with training, staff are able to prevent more serious incidents. Table 3 highlights the application of a CRM model to medicine.

Table 3. Application of a CRM Model to Medicine

- Design of systems to absorb errors through redundancy, standardization, and checklists
- Movement from placing blame to designing safe processes and procedures, i.e., applying a systems approach
- Assurance of full immunity while implementing a nonpunitive approach
- Debriefing of all events, including near misses, that have learning potential. Focus on the severity of the potential risk rather than on the severity of the event's final outcome is more conducive to establishing effective prevention programs.
- Institutionalization of a permanent program for risk identification, analysis, and dissemination of the lessons learned throughout the professional community

SBAR. Doctors and nurses often have different communication styles in part due to training. Nurses are taught to be more descriptive of clinical situations, whereas physicians learn to be very concise. Standardized communication tools are very effective in bridging this difference in communication styles.

Michael Leonard, physician coordinator of clinical informatics at Kaiser Permanente, along with colleagues, developed a technique called SBAR (Situation-Background-Assessment-Recommendation). This technique has been implemented widely at health systems such as Kaiser Permanente.[1, 17, 58] Many other hospitals have embraced the SBAR communication tool or a similar tool created by the Studer Group (see Table 4).[59] For example, the Queen's Medical Center in Honolulu has incorporated the SBAR tool as a key component of its patient safety program. The SBAR technique provides a framework for communication between members of the health care team about a patient's condition. SBAR is an easy-to-remember tool used to create mechanisms useful for framing any conversation, especially critical ones, requiring a clinician's immediate attention and action. It allows for an easy and focused way to set expectations between members of the team for what will be communicated and how, which is essential for information transfer and cohesive teamwork. Not only is there familiarity in how people communicate, but the SBAR structure helps develop desired critical-thinking skills. The person initiating the communication knows that before they pick up the telephone, they need to provide an assessment of the problem and what they think an appropriate solution is. Their conclusion may not ultimately be the answer, but there is clearly value in defining the situation. Table 5, Guidelines for Communicating with Physicians Using the SBAR Process explains how

to carry out the SBAR technique in detail. The guidelines use the physician team member as the example; however, they can be adapted for use with all other health professionals.

Table 4. Studer Group Communication Guidelines for Nurses

- Have I seen and assessed this patient myself before I call?
- Are there standing orders?
- Do I have at hand
    - The chart?
    - List of current meds, IV fluids, and labs?
    - Most recent vital signs?
    - If reporting lab work, date and time this test was done and results of previous tests for comparisons?
    - Code status?
- Have I read the most recent MD progress notes and notes from the nurse who worked the shift ahead of me?
- Have I discussed this call with my charge nurse?
- When ready to call,
  Remember to identify self, unit, patient, room number.
    - Know the admitting diagnosis and date of admission.
    - Briefly state the problem, what it is, when it happened or started, and how severe it is.
- What do I expect to happen as a result of this call?
- Document whom you spoke to, time of call, and summary of conversation.
- Engage and treat physician with respect.

[Source: Studer Group. Patient Safety Toolkit – Practical tactics that improve both patient safety and patient perceptions of care. Gulf Breeze, FL: Studer Group., 2007.]

Table 5. SBAR (Situation, Background, Assessment, Recommendation)

- SBAR – a technique for communicating critical information that requires immediate attention and action concerning a patient's condition
- Situation – What is going on with the patient?
  "I am calling about Mrs. Joseph in room 251. Chief complaint is shortness of breath of new onset."
- Background – What is the clinical background or context?
  "Patient is a 62-year-old female post-op day one from abdominal surgery. No prior history of cardiac or lung disease."
- Assessment – What do I think the problem is?
  "Breath sounds are decreased on the right side with acknowledgment of pain. Would like to rule out pneumothorax."
- Recommendation – What would I do to correct it?
  "I feel strongly the patient should be assessed now. Are you available to come in?"

[Note: Kaiser Permanente, SBAR (Situation, Background, Assessment, Recommendation) tool, 2002. Source for version in this table: Institute for Healthcare Improvement. Guidelines for communicating with physicians using the SBAR process. http://www.ihi.org/IHI/Topics/PatientSafety /SafetyGeneral/ Tools/SBARTechniq ueforCommunicationASituationalBriefing Model.htm. Accessed Nov. 18, 2004.]

STICC (Situation Task Intent Concern Calibrate) is another type of structured briefing protocol used by the U.S. Forest Service to give direction to firefighters.[1, 17, 60, 61] The following five steps are involved:

- Situation: Here's what I think we face.
- Task: Here's what I think we should do.
- Intent: Here's why.

- Concern: Here's what we should keep our eye on.
- Calibrate: Talk to me. Tell me if you don't understand, can't do it, or see something I do not.

Establishing Culture To Support Communication and Team Collaboration

The literature reviewed shows that effective teams are characterized by common purpose and intent, trust, respect, and collaboration. Team members value familiarity over formality and watch out for each other to make sure mistakes are not made. Health care teams that do not trust, respect, and collaborate with one another are more likely to make a mistake that could negatively impact the safety of patients.

One of the first crucial steps is organizational commitment and willingness to address the situation. Commitment needs to come from the top down and bottom up, making a statement about the way the organization does business. The rallying point should be around behavioral standards and their relationship to patient safety. It's ironic that ever since the publication of the original IOM report, *To Err Is Human,* organizations have spent the bulk of their time and efforts in improving patient systems rather than addressing the human factor issues highlighted in the original report.[2] Several recent reports have suggested that while we have made progress in the patient safety movement, we have a long way to go in meeting the IOM recommendations.[62] Addressing defects in communication that affect collaboration, information exchange, appreciation of roles and responsibilities, and direct accountability for patient care are key components of any patient safety program. Clinical and administrative leaders must set the tone by establishing and adhering to behavioral standards that support agreed-upon code of conduct practices backed by a nonpunitive culture and zero-tolerance policy.

The next step in the process is recognition and self-awareness. Organizations must be able to assess the prevalence, context, and impact of behaviors to identify potential opportunities for improvement. Doing an internal assessment will help pinpoint the seriousness of the situation and provide clues to areas that need to be addressed. Assessment information can be gained from formal methods such as incident reports, survey tools, focus groups, department meetings, task forces or committees, direct observation, suggestion boxes, and hot lines. Informal methods such as casual meetings and gossip can also provide valuable surface information and should be evaluated more deeply as to the source, relevance, and significance of the events to determine next steps. In many organizations there are still remnants of reluctance to address the issue head on for fear of antagonizing a prominent surgeon or staff member. With growing concerns about workforce shortages, staff satisfaction and retention, hospital reputation, liability and patient safety, and the need for compliance to the latest Joint Commission proposed standards addressing disruptive behaviors, organizations can no longer afford to take a passive approach to the situation.[63–66]

Creating opportunities for different groups to just get together is a highly effective strategy for enhancing collaboration and communication. These group interactions can be either formal or informal. Encouraging open dialogue, collaborative rounds, implementing preop and postop team briefings, and creating interdisciplinary committees or task forces that discuss problem areas frequently provides an upfront solution that reduces the likelihood of disruptive events. When a disruptive event does occur, some organizations have implemented a time-out, code

white, or red light policy that addresses the issue in real time to prevent any further serious consequences.[59]

Developing and implementing a standard set of behavior policies and procedures is vital. These policies need to be consistent and universally applied. There should not be a separate policy for any one particular discipline or service. For the medical staff, the policies should become part of the medical staff bylaws with signed agreements to abide by these policies at the time of appointment and recredentialing. Included in the policies should be a standardized protocol outlining expected standards and the process for addressing disruptive behavior issues, recommendations, followup plans, and actions to be taken in the face of individual resistance or refusal to comply. Prior to implementation, make sure all employees are familiar with the existence, purpose, and intent of the policies and procedures.

For the process to unfold, the organization needs to encourage its employees to report disruptive behaviors. The organization needs to address issues related to confidentiality, fear of retaliation, and the common feelings that there is a double standard and that nothing ever gets done. Reporting mechanisms should be made easy and must be supported by the presence of a nonpunitive environment. The ideal vehicle for reporting is to address the situation in real time, but concerns about position, appropriateness, receptiveness, fear, hostility, and retaliation are significant impediments.[67] Appropriate vehicles for reporting may include reporting of the incident to a superior, filing an incident report, using a complaint or suggestion box, or reporting directly to a task force or interdisciplinary committee with assigned responsibilities for addressing these issues.[59] Besides maintaining confidentiality and reducing risks of retaliation, one of the most crucial aspects of the reporting system is to give recognition and assurance that the complaints will be addressed and actions will be taken. Responses should be timely, appropriate, consistent, and provide necessary feedback and followup.

Taking action though appropriate intervention strategies is next. On one level, generic educational programs can do a lot to spread the message and teach basic skills necessary to promote effective communication. Appropriate topics should include sessions on team dynamics, communication skills, phone etiquette, assertiveness training, diversity training, conflict management, stress management, and any other courses necessary to foster more effective team functioning and communication flow. Courses should be offered to all staff and employees at the organization: physicians, physicians in training, nurses, nursing students, and all other staff who have patient contact or play a role in the delivery of patient care. For individuals who have consistently exhibited disruptive behavior, education may need to be supported by more focused sessions and specific counseling. Another important strategy is to promote and assure competency training at all levels of the health care team. This is a key factor affecting trust and respect, which have such a strong influence on team collaboration.

Focused team training programs have been of particular value. One of the newer approaches to improving team collaboration and patient safety is through the principles learned from the aviation industry. Fostering an environment of trust and respect, accountability, situational awareness, open communication, assertiveness, shared decisionmaking, feedback, and education, interdisciplinary CRM training has brought significant improvements to communication flow in the perioperative setting.[52, 53]

Having a clinical champion or early adopter who actively promotes the importance of appropriate behavior, communication, and team collaboration can be an extremely valuable asset. Champions can come from the executive ranks or through the voluntary interest and enthusiasm of other staff members. Co-champions may be even more effective. Some

organizations have reported that having a nurse and physician (or other health care professional) go through a joint training program will help foster mutual cooperation and collaboration between the different disciplines.[59] Followup and feedback bring closure to the process. It is important to let people know that their input is welcomed, followup actions will be taken, and appropriate feedback will be provided.

Research Implications

The existing literature adequately outlines structured communication techniques that will help minimize medical errors. However, more research is needed on how to effectively deal with miscommunication and barriers to communication in real-time crisis situations. Also, the existing literature lacks concrete research confirming a cause-and-effect relationship between human factors and clinical outcomes of care.

Conclusions

Effective clinical practice must not focus only on technological system issues, but also on the human factor. As shown in this chapter, good communication encourages collaboration and helps prevent errors. It is important for health care organizations to assess possible setups for poor communication and be diligent about offering programs and outlets to help foster team collaboration. By addressing this issue, health care organizations have an opportunity to greatly enhance their clinical outcomes.

Chapter 34. Handoffs: Implications for Nurses

Mary Ann Friesen, Susan V. White, Jacqueline F. Byers

Background

The transfer of essential information and the responsibility for care of the patient from one health care provider to another is an integral component of communication in health care. This critical transfer point is known as a handoff.[1–3] An effective handoff supports the transition of critical information and continuity of care and treatment. However, the literature continues to highlight the effects of ineffective handoffs: adverse events and patient safety risks.[4–11] The Institute of Medicine (IOM) reported that "it is in inadequate handoffs that safety often fails first"[12] (p. 45). This chapter presents an overview of handoffs, a summary of selected literature, gaps in the knowledge, and suggestions for quality improvement initiatives and recommendations for future research.

What Is a Handoff?

First one needs to recognize the term "handoff" and synonymous terms that are used in a wide variety of contexts and clinical settings. There are a number of terms used to describe the handoff process, such as handover,[1, 13, 14] sign-out,[15, 16] signover,[17] cross-coverage,[18, 19] and shift report.[20–22] For the purpose of this discussion, the term "handoff" will be used and defined as, "The transfer of information (along with authority and responsibility) during transitions in care across the continuum; to include an opportunity to ask questions, clarify and confirm"[23] (p. 31). The concept of a handoff is complex and "includes communication between the change of shift, communication between care providers about patient care, handoff, records, and information tools to assist in communication between care providers about patient care"[1] (p. 1). The handoff is also "a mechanism for transferring information, primary responsibility, and authority from one or a set of caregivers, to oncoming staff"[17] (p. 1). So, conceptually, the handoff must provide critical information about the patient, include communication methods between sender and receiver, transfer responsibility for care, and be performed within complex organizational systems and cultures that impact patient safety. The complexity and nuance of the type of information, communication methods, and various caregivers for each of these factors impact the effectiveness and efficiency of the handoff as well as patient safety.

Why Is There a Problem With Handoffs Today?

As health care has evolved and become more specialized, with greater numbers of clinicians involved in patient care, patients are likely to encounter more handoffs than in the simpler and less complex health care delivery system of a few generations ago.[11] Ineffective handoffs can contribute to gaps in patient care and breaches (i.e., failures) in patient safety, including medication errors,[19, 24] wrong-site surgery,[9] and patient deaths.[4, 7] Clinical environments are dynamic and complex, presenting many challenges for effective communication among health care providers, patients, and families.[25–27] Some nursing units may "transfer or discharge 40 percent to 70 percent of their patients every day"[28] (p. 36), thereby illustrating the frequency of handoffs encountered daily and the number of possible breaches at each transition point.

Our expanding knowledge base and technological advances in health care spawn additional categories of health care providers and specialized units designed for specific diseases, procedures, and phases of illness and/or rehabilitation. This dynamic, ever-increasing specialization, while undertaken to improve patient outcomes and enhance health care delivery, can contribute to serious risks in health care delivery and promote fragmentation of care and problems with handoffs.[3, 10, 29] It is ironic that as health care has become more sophisticated due to advances in medical technology focused on saving lives and enhancing the quality of life, the risks associated with the handoffs have garnered attention in the popular press[30] and reports from health care organizations and providers.[3, 4, 6, 10, 31–35] The hazard that "fumbled handoffs"[7, 10] pose to patient safety and the delivery of quality health care cannot be ignored. Ineffective handoffs can lead to a host of patient safety problems; research[1] and development of strategies to reduce these problems are required.[33, 34]

What contributes to fumbled handoffs? An examination of how communication breakdown occurs among other disciplines may have implications for nurses. A study of incidents reported by surgeons found communication breakdowns were a contributing factor in 43 percent of incidents, and two-thirds of these communication issues were related to handoff issues.[36] The use of sign-out sheets for communication between physicians is a common practice, yet one study found errors in 67 percent of the sheets.[15] The errors included missing allergy and weight, and incorrect medication information.[15] In another study, focused on near misses and adverse events involving novice nurses, the nurses identified handoffs as a concern, particularly related to incomplete or missing information.[37]

Acute care hospitals have become organizationally complex; this contributes to difficulty communicating with the appropriate health care provider. Due to the proliferation of specialties and clinicians providing care to a single patient, nurses and doctors have reported difficulty in even contacting the correct health care provider.[38] One study found that only 23 percent of physicians could correctly identify the primary nurse responsible for their patient, and only 42 percent of nurses could identify the physician responsible for the patient in their care.[39] This study highlights the potential gaps in communication among health care providers transferring information about care and treatment.

A handoff is largely dependent on the interpersonal communication skills of the caregiver[33] as well as the knowledge and experience level of the caregiver. There is reported variability in quality,[40] lack of structure in how handoffs usually occur,[33] and variances in shift handoffs.[22, 41–43] Concern has been raised that the transition of care between providers during handoffs will continue to be problematic as research indicates that "only 8 percent of medical schools teach how to hand off patients in formal didactic session"[3] (p. 1097), creating a large educational gap in new professionals and persistence of traditional models. Physicians and nurses communicate differently. Nurses are focused on the "big picture" with "broad and narrative"[44] (p. i86) descriptions of the situation, whereas physicians are focused on bullets of critical information.[44] A technique that seeks to bridge the gap between the different communication styles of nurses and physician is the situation, background, assessment, recommendation (SBAR) briefing model[44] that is being used successfully to enhance handoff communication.[45]

The issue of handoffs has become so prominent that the Joint Commission (formerly the Joint Commission on Accreditation of Healthcare Organizations, JCAHO) introduced a national patient safety goal on handoffs that became effective in January 2006.[45] The national safety goals, developed by the Joint Commission with input from the Sentinel Event Advisory Group, identify new actions with the potential to protect patient safety.[46] The patient safety goal requires

health care organizations to "implement a standardized approach to "handoff" communications, including an opportunity to ask and respond to questions."[47] While the goal is simply stated, it is challenging to develop and implement effective strategies for handoffs across various health care settings, given the complexity of health care delivery. The Joint Commission's guidelines for implementation of the safety goal are presented in Table 1,[48] and suggested strategies for effective handoffs are listed in Table 2.

Table 1. Joint Commission 2008 Hospital Patient Safety Goals Implementation Expectations for Handoffs

1.	Interactive communications allowing for the opportunity for questioning between the giver and receiver of patient information.
2.	Up-to-date information regarding the patient's care, treatment and services, condition, and any recent or anticipated changes.
3.	A process for verification of the received information, including repeat-back or read-back, as appropriate.
4.	An opportunity for the receiver of the handoff information to review relevant patient historical data, which may include previous care, treatment, and services.
5.	Interruptions during handoffs are limited to minimize the possibility that information would fail to be conveyed or would be forgotten.

Source: Adapted from Joint Commission, National Patient Safety Goals Hospital Program.[48]

Following are examples of each of these handoff expectations:

1. Nurse Brown on unit A is receiving report from Nurse Green who is transferring the patient from unit B to unit A. The patient medication administration record (MAR) does not indicate the patient has received any pain medication in the past shift. When Nurse Brown asks about this, Nurse Green realizes she gave morphine sulfate but did not document it on the MAR. Due to Nurse Brown's question, Nurse Green realizes the omission and communicates the information and documents it in the medical record, preventing an accidental overdose of a medication.
2. A patient who had undergone a surgical procedure has not been out of bed since being transferred to the nursing unit. The offgoing nurse alerts the oncoming nurses that the patient will need help getting out of bed, possibly preventing a patient fall.
3. Handoffs require a process for verification of the received information, including read back, as appropriate. For example, the receiver of the telephone message regarding a laboratory value is asked to write it down and read the message back, including the name of the patient, the test, and the test result/interpretation.[49, 50] Information to be recorded should also include the name and credentials of sender and receiver and the date and time.[50]

   Laboratory Technician: I am calling with the lab results on Mr. Green.
   Nurse: Let me get a notepad. You are calling the lab results for Mrs. Marie White?
   Laboratory Technician: No, I am calling results for Mr. Tom Green ID #12345678. Mr. Green's potassium level is 5.1, which was drawn at 0700 today.
   Nurse: You reported that Mr. Tom Green's potassium level is 5.1. This is Nancy Jones, RN.
   Laboratory Technician: Thank you, Nancy. That is correct; Mr. Tom Green's potassium level is 5.1 This is Bill Smith, lab tech.
4. The receiver of the handoff information has an opportunity to review relevant patient/client/resident historical data, which may include previous care, treatment, and services. A patient has been transferred, and the nurse notes several omissions from

previous medication orders, including insulin. The nurse notifies the physician and obtains correct and complete medication orders, thereby avoiding a potentially serious medication error.

5. A nursing unit schedules staffing coverage to accommodate the shift change and minimize the occurrence of interruptions during change-of-shift report. Ancillary staff does not leave the nursing unit until report is completed to assure phones are answered and timely responses to call lights are made so nurses can provide report effectively and efficiently.

Table 2. Strategies to Improve Handoff Communication

	Strategy	Example
1.	Use clear language and avoid use of abbreviations or terms that can be misinterpreted.	During the reconciliation process, the nurse noted a medication that is usually administered once daily being given every other day. The handwritten order for daily was written QD but read as QOD. QD and QOD are on the Joint Commission official "Do Not Use" list.[51] According to the list, "daily" should be written instead of QD and QOD should be written as "every other day."[51]
2.	Use effective communication techniques. Limit interruptions. Implement and utilize read-backs or check-back techniques.	In the middle of a shift handoff, the unit clerk interrupts the nurse to inform her that a patient needs assistance to go to the bathroom. The nurse must leave report to assist the patient or find a nurse's aide to help the patient. During this interruption, the offgoing nurse is in a rush to leave and get her son from child care. Due to the need to leave quickly, the offgoing nurse forgets to document and report to the oncoming nurse that a patient fell right before the shift change. Efforts need to be made to ensure adequate staffing during shift report to minimize interruptions.
3.	Standardize reporting shift-to-shift and unit-to-unit.	The surgical unit standardized shift-to-shift handoff report with a one-page tool that is used for each patient, thereby providing a comprehensive, structured approach to providing the critical information on new and recovering postoperative patients.
4.	Assure smooth handoffs between settings.	One of the busiest units in the hospital is the emergency department (ED). Patients must be discharged or moved quickly out of the ED to an inpatient unit. To ensure rapid patient flow, a new handoff process is established that includes a phone call to the receiving unit, the assignment of an admission nurse so that there are no delays on the receiving unit, telephone report so the receiving unit can prepare any special equipment, and then a final verbal handoff between the two nurses while viewing the patient to verify the condition of the patient and ensure no changes from one setting to another.
5.	Use technology to enhance communication. Electronic records can support the timely and efficient transmission of patient information.	The hospital has an electronic record and utilizes portable computers. Walking rounds are made by the offgoing and oncoming nurse using the portable computer and visiting each patient for introductions and quick visual assessment. The use of this technology allows the nurse to view the patient's plan of care, medications, and IVs at a glance to prepare for care during the next shift.

Table 3. Nurse-to-Nurse Change-of-Shift Handoff Report

Type of report	Strengths cited in literature	Weakness cited in literature	Practice implications (strategies for reducing errors and improving safety)
Verbal report on nursing unit	• Allows face-to-face interaction.[41] • Allows staff to debrief and discuss situations.[41] • Allows for clarification of information.[41] • Can present educational opportunity for staff.[41]	• Verbal only—poor retention of information by receiver.[55] • There may discrepancies between reported status and actual patient status.[22] • May be difficult to access all relevant information[41] for concise report. • Time consuming.[41] • Sensory Overload.[22, 75]	• Augment verbal report with preprinted, patient-specific forms containing data that can be transferred to the oncoming shift to decrease loss of information.[55] • Use electronic support to provide easily accessible data that is accurate and up to date.[34, 58] • Include bedside rounds to check patient status and congruence between report and patient condition.[22] • Use standardized process to assure transmission of essential information.[34, 45, 47, 55]
Verbal report at the patient's bedside	• Allows face-to-face interaction.[41] • Allows for clarification.[41] • Nurses can assess patient together.[41] • Allow the remedy of errors.[41] • Involve patient.[41, 52, 56]	• Confidentiality issues need to be addressed.[13, 41, 56] • Not all patients wish to participate in bedside report.[52] • Terms (jargon) used by nurses in report may pose a concern to patients if not explained.[52] • Nurses may be interrupted.[41]	• Monitor to assure confidentiality is protected, report in private setting.[56, 57] • Introduce self to patient.[57] • Encourage patient to participate, but not all patients will want or be able to participate and this needs to be respected.[52] • Develop protocol to guide the bedside handover process.[57] • Use standardized process to promote transmission of essential information.[34, 47]

Type of report	Strengths cited in literature	Weakness cited in literature	Practice implications (strategies for reducing errors and improving safety)
Audiotaped report	• Can be a more efficient process, concise[53] and "less time consuming"[41] • Tape may be repeated.[53] • Nurses who taped report can provide patient care while oncoming shift is listening to report.[53]	• May be difficult to hear or understand.[41] • Need access to equipment[2] • Question and answer interaction must be built into the process.[47] • Sensory Overload.[22] • There may discrepancies between reported status and actual patient status.[22] • Lack of educational opportunity.[41] • May not be current; timeliness of information dependent on when report was taped.[41]	• Need to assure there is an opportunity to ask questions about the report and interact between offgoing and oncoming shifts.[34, 47] • Include bedside rounds to check patient status and congruence between report and patient condition.[22] • Ensure sound quality of technology.[53] • Use standardized process to assure transmission of essential information.[34, 47] NOTE: Joint Commission National Patient Safety Standards require there to be an opportunity for exchange of information and ability to ask and answer questions.[47]
Written report	• Improvement in documentation.[54] • Effective management.[54] • Allows oncoming shift to review data.[54]	• Question and answer interaction must be built into the process.[47] • May be missing essential information if not documented.[54] • Quality of documentation may vary.[54]	• Need to assure there is an opportunity to ask questions about the report and interact between off going and oncoming shifts.[47] • Information also provided verbally with written report.[54] • Use standardized process to assure transmission of essential information.[34, 47] NOTE: Joint Commission National Patient Safety Standards require there to be an opportunity for exchange of information and ability to ask and answer questions.

Source: Adapted from O'Connell (2001), Challenging the handover ritual: recommendations for research and practice.

It is important to understand the context in which care is provided and be cognizant of the impact of the environmental processes on health care providers. The physical work environment may not be conducive to effective handoffs as it may be noisy[58, 59] and prone to interruptions, (i.e., pagers, phone calls),[60–63] and the handoff may be conducted under physical and emotional pressures.[11] A study examining communication patterns among physicians and nurses found thirty one percent of communication exchanges involved interruption, translating into roughly 11 interruptions an hour for physicians and nurses.[60] Spencer and colleagues[62] found 15 interruptions per hour. Barriers to transmission of accurate information in a patient transfer include incomplete medical record, lack of complete information provided by nurses, and the omission of essential information.[64] Handoffs are compromised if critical pieces of information are omitted because of difficulties with data access[4, 29] or if documentation is illegible[31, 33] or not transferred.[55] Despite efforts to promote the use of electronic patient records, according to a 2002 survey, less than 10 percent of hospitals have complete access to electronic systems such as computerized physician order entry (CPOE).[65]

The ever-increasing abundance of data requires that health care providers synthesize and make decisions using large amounts of complex information. Unfortunately, data quickly degrades; for example, critically ill patients have many clinical parameters that are being monitored frequently.[66] Decisions need to be based on trends in the data and current information, which is essential to making informed decisions.[66] Tremendous amounts of information are constantly being generated, such as monitored clinical parameters, diagnostic tests, and multidisciplinary assessments. When this large amount of information is combined with the numerous individuals—clinical and nonclinical—who come in contact with a patient during a treatment episode and data transmission, not all members of the health care team may be aware of all the information pertinent to each patient.[66]

In an effort to compress information and make it manageable among health care providers, handoffs may result in a "progressive loss of information known as *funneling*, as certain information is missed, forgotten or otherwise not conveyed" [66] (p. 211). The omission of information or lack of easy accessibility to vital information by health care providers can have devastating consequences.[4, 11] Such gaps in health care communication can cause discontinuity in the provision of safe care[67] and impede the therapeutic trajectory for a patient. These gaps present major patient safety threats and can impact the quality of care delivered.

Where Do Handoffs Occur?

Handoffs occur across the entire health care continuum in all types of settings. There are different types of handoffs from one health care provider to another, such as in the transfer of a patient from one location to another within the hospital[64] or the transition of information and responsibility during the handoff between shifts on the same unit.[1, 41, 43] Interdisciplinary handoffs occur between nurses and physicians, and nurses and diagnostic personnel, while intradisciplinary handoffs occur between physicians[3, 15, 31] or between nurses.[13, 14, 41, 42,43] Interfacility handoffs occur between hospitals and among multiple organizations,[68] including home health agencies,[69, 70] hospices,[71] and extended-care facilities.[72, 73]

Handoffs may involve use of specialized technology (e.g., audio recorders, pagers, hand-held devices, and computerized records),[2] fax,[73, 74] written documents,[54] and oral communication.[41, 75, 77] Each type and location of handoff presents similar as well as unique challenges. Given the variety of handoffs, the following discussion will focus on:

- Shift-to-shift handoff
- Nursing unit-to-nursing unit handoff
- Nursing unit to diagnostic area.
- Special settings (operating room, emergency department).
- Discharge and interfacility transfer handoff
- Handoffs and medications
- Physician-to-physician handoffs

Shift-to-Shift Handoff

There are paradoxes in communication and handoffs, especially at shift changes.[20] Many human factors play a role. Human factors (ergonomics) focus on behavior and interaction between human beings and their environment. Human factors engineering focuses on "how humans interact with the world around them and the application of that knowledge to the design of systems that are safe, efficient, and comfortable"[76] (p. 3). The handoff poses numerous human factors engineering implications. From the perspective of patient safety, the primary purpose of the shift report or shift handoff is to convey essential patient care information,[14, 43, 55, 78, 79] promote continuity of care[13, 41, 77, 78, 80] to meet therapeutic goals, and assure the safe transfer of care of the patient to a qualified and competent nurse. However, other reported purposes of shift report include education,[41, 78, 81] debriefing,[14, 41] socialization,[78, 82] planning and organization,[78] enhancement of teamwork,[81] and supportive functions.[83]

The intershift handoff is influenced by various factors, including the organizational culture. An organization that promotes open communication and allows all levels of personnel to ask questions and express concerns in a nonhierarchical fashion is congruent with an environment that promotes a culture of safety.[58] Interestingly, one study reported novice nurses seeking information approached those seen as "less authoritarian."[84] The importance of facilitating communication is critical in promoting patient safety. The shift-to-shift handoff is a multifaceted activity.[78, 85, 86] A poor shift report may contribute to an adverse outcome for a patient.[55]

Handoff intricacies. A phenomenon well known to nurses is the use of nurse-developed notations, "cheat sheets" or "scraps" of information, while receiving or giving intershift reports. A study of such note taking found scraps are used for a variety of purposes, including creating to-do lists and recording specific information and perceptions about the patient and family.[87] This approach presents some challenges, as no one else has easy access to the information; therefore, continuity of care may be compromised during a meal break, for example, or if the scrap or cheat sheet is misplaced.

Method of shift-to-shift handoff. Handoffs are given using various methods:[13, 41, 88, 89] verbally,[75, 77] with handwritten notes,[80, 87] at the bedside,[41, 52, 56, 57, 90, 92] by telephone,[91] by audiotape,[41, 53] nonverbally,[54] using electronic reports,[92] computers printouts,[14] and memory.[14] The strength of the bedside report method is its effort to focus on and include the patient in the report. There have been concerns regarding patient confidentiality,[41, 52, 56, 90] which could be compromised if not carefully addressed. A qualitative study focused on describing the perceptions of patients who were present during a bedside report found some patients are in favor of bedside handoff, while others are not.[52] Patients also expressed concern regarding the jargon used by nurses.[52] One patient noted that including the patient in the handoff added another level of safety as erroneous data could be addressed and corrected.[52] Case studies indicate the bedside handoff may be implemented for a number of reasons, including addressing specific

issues and improving care delivery.[57, 92] A summary of the strengths and weaknesses of verbal, bedside, written, and taped shift-to-shift reports is included in Table 3.

The challenge during handoffs across settings and times is to identify methods and implement strategies that protect against information decay and funneling,[66] contributing to the loss of important clinical information. It is a challenge to develop a handoff process that is efficient and comprehensive, as case studies illustrate.[57, 88, 92, 93] Observation of shift handoffs reveals that 84.6 percent of information presented in handoffs could be documented in the medical record.[42] A concern that emerged in this study was some handoff reports actually "promote confusion," and therefore the authors advocated improving the handoff process.[42]

Another concern with handoffs is the degree to which the report is actually congruent with the patient's condition. One study found 70 percent congruence between the shift report and the patient's actual condition, with an omission rate of 12 percent.[22] A synthesized case example of a psychiatric patient presents the adverse consequences for the patient if essential information is not communicated.[94] The importance of communicating objective descriptions of the patient condition is highlighted.

A study focusing on assessing the effects of manipulating information in a shift handoff on the receiving nurse's care planning found in the different types of taped reports that the information recalled ranged from 20 percent to 34 percent.[95] Another study, by Pothier and colleagues,[55] examined different methods for transferring information during 5 consecutive simulated handoffs of 12 fictional patients. Three methods of handoffs were analyzed; the method demonstrating the greatest amount of information retention involved utilization of a preprinted sheet containing patient information with verbal report, followed by note taking and verbal report method, and lastly, only verbal report. The retained total data points for each style of handoff varied considerably during the five handoffs. Over 96 percent to 100 percent of information was retained using the preprinted sheet containing patient information and verbal report. Only 31 percent to 58 percent of the data were retained using the note taking style and verbal report.[55] The verbal-only style demonstrated the greatest amount of information loss, with retention ranging from 0 percent to 26 percent.[55] None of the data was retained using the verbal-only method for two handoff cycles. The insertion of incorrect information was observed in the verbal-only method. The generation of incorrect data did not occur at all during the handoff with the written or preprinted form style of report. This study[55] supports the use of a consistent preprinted form with relevant patient information during shift report, with less reliance on verbal-only reports, in order to optimize communication.

Nursing Unit-to-Nursing Unit Handoff

Patients may be transferred frequently during their hospital stays.[28] Yet, the patient transfer is fraught with potential problems and can have an adverse impact on patients.[96, 97] Issues have been identified in the transfer handoff process, including incomplete medical records and omission of essential information during the handoff report.[64] A number of factors that contribute to inefficiency during patient transfers from one nursing unit to another have been identified,[97] including delay or wasted time caused by communication breakdowns, waiting for responses from other nurses or physicians or a response from patient placement management or bed control.[97] Bed control involves personnel who manage the bed assignments of new and transferring patients. Decreasing the number of transfers is a possible strategy to decrease risks associated with handoffs.[58]

Nursing Unit to Diagnostic Area

Patients are frequently sent from a nursing unit to diagnostic areas during the normal course of a hospitalization. Transfers have been cited as a contributor to medication errors between nursing units and diagnostic areas (e.g., radiology, cardiac catheterization, nuclear medicine).[19] It is important when patients change nursing units, particularly to a different level of care, or go to a procedure in another department that there is clear, consistent communication and that the receiving area staff have the information they need to safely care for the patient.[34] Complexity of the patient's condition may require that the nurse caring for the patient actually accompanies the patient to the new setting.

Special Settings

Operating room and postanesthesia. Several special handoff situations occur in certain hospital settings. The operating room (OR) is considered "one of the most complex work environments in health care"[98] (p. 159), with a reported mean of 4.8 handoffs per case. Nursing staff average 2.8 handoffs per case, with a range of one to seven handoffs.[98]

There have been at least 615 wrong-site surgeries reported to the Joint Commission between 1995 and 2007.[99] To help prevent wrong-site surgery, the Joint Commission developed the Universal Protocol for Preventing Wrong Site Surgery, Wrong Procedure, Wrong Person Surgery™.[100, 101] It is based on the consensus of experts and endorsed by more than 50 professional organizations.[100] Effective interdisciplinary communication is critical. For example, a health care organization using a perioperative briefing process reported that no wrong-site surgeries have occurred since the adoption of the interdisciplinary briefings.[44]

Dierks suggests five categories for handoffs in the OR: (1) baseline metrics/benchmarks, (2) most recent phase of care, (3) current status, (4) expectations for the next phase of care, and (5) other issues such as "who is to be contacted for specific issues"[102] (p. 10). The use of a team checklist in the OR was pilot tested in another study and found to show "promise as a method for improving the quality and safety of patient care in the OR"[103] (p. 345).

A study focused on OR communication processes identified a number of patterns and found the most common reason for communication in 2,074 episodes was coordination of equipment, followed by "preparedness" for surgery.[104] The authors recommend increasing the use of automated processes to enhance process flow, especially related to "equipment management," thereby helping with transmission of information in a more efficient manner.[104]

Communication in handoffs is critical in all phases of care. However, a survey of 276 handoffs conducted in a postanesthesia care unit (PACU) revealed 20 percent of postoperative instructions were either not documented or written illegibly.[105] The nurses rated the handoffs from anesthesia staff as "good" in 48 percent of cases, "satisfactory" in 28 percent, and "bad" in 24 percent.[105] A number of suggestions for improving the quality of the postanesthesia care unit handoff protocol were presented including the need to communicate information verbally to the nurse.[105]

Emergency department. A study of five emergency departments (EDs) revealed that there were differences in the characteristics of handoffs among the EDs studied, but "nearly universal" attributes of handoffs were also noted.[106] The researchers developed a conceptual framework for addressing handoffs in the emergency setting. The handoffs were not one way communication processes as both the offgoing and oncoming providers were engaged in interactive handoffs. [106]

According to Behara and colleagues,[106] 8 of 21 handoff strategies used in other industries[2] were observed "consistently" in the ED setting, while four were used less often and nine were not or rarely used. The handoff in the ED setting is viewed as a "rich source for adverse events"[17] (p. 1). There are inherent risks in handoffs, but it was also noted that the handoff can provide the opportunity for two health care providers to assess the same situation and identify a "previously unrecognized problem"[17] (p. 2).

Studies focused on emergency nursing handoffs highlight unique aspects of this process.[107, 108] Currie reported in a survey of 28 ED nurses that the top three concerns nurses had with handoffs were missing information, distractions, and lack of confidentiality.[108] Recommendations included the development of guidelines to improve the handoff process in the ED.

Discharge and Interfacility Transfer Handoff

Handoffs from one facility to another occur frequently between many different settings.[68–70, 71, 72, 73, 109–111] Handoffs take place between hospitals when patients require a different level of care. The usual interfacility handoffs are between hospitals and long-term care facilities, rehabilitation centers, home health agencies, and hospice organizations. The factor that tends to make these handoffs challenging is gaps and barriers to communication among these agencies.[68, 111, 112] Handoffs between facilities are also impacted by the cultural differences between the types of facility.[73] Agencies are often geographically separate, requiring physical relocation of the patient, belongings, and paper records. Once the transfer has taken place, seeking additional information becomes a challenge.[73]

The continuity of patient care requires communication among various health care organizations.[68, 71, 73, 110, 113–115] One problem noted is nurses in different settings have different perceptions about what is important to be conveyed, such as different perceptions between the hospital and home health care.[70, 116] Another area of concern noted in transfers from hospitals to other health care organizations is incomplete documentation. More information was transmitted when a standard form to communicate information was utilized between a hospital and home health agency (HHA).[69] The usage of referral forms varies among health care institutions.[109] Rates of transmission of information differ from hospitals to HHAs[69, 109, 113] and to extended-care facilities.[72] It was found that HHAs affiliated with hospitals received more referral data than free-standing HHAs.[113]

Discharge planning forms address "the anticipation of a certain type of gap and also of an effort to create a bridge to permit care to flow smoothly over the gap"[67] (p. 793). One example of the development of such a form using "a consensus process" resulted in the implementation of a Patient Transition Information Checklist to help improve communication between hospitals and nursing homes.[114] Another type of form for communication of patient information among health care organizations was developed in Germany; however, followup revealed use of the form was not as widespread as anticipated because process barriers emerged, precluding users from easily completing and transmitting the forms.[111] Development of any type of "patient accompanying form"[111] requires numerous considerations and a balance between being comprehensive and not being cumbersome to use.[111] There also needs to be adequate resources to allow health care providers to retrieve necessary data and transmit patient information between agencies.[111]

Inadequate discharge planning has been implicated in adverse outcomes of patients.[117, 118, 119] A study of 400 patients found 76 patients incurred an adverse outcome after discharge from the hospital. The researchers reported "ineffective communication contributed to many of the

preventable and ameliorable adverse events"[119] (p. 166). The most frequent type of adverse event was related to medications. The implications of this study indicate the need to enhance communication in the handoff between the hospital and posthospital care. Suggested potential strategies to improve the handoff include discharge planning and education of patients related to medications prior to discharge.[119]

A number of contributors to a failed handoff in the discharge planning process have been identified, including, lack of knowledge about the discharge process,[117] lack of time,[117] lack of effective communication,[119, 120] patient and family issues,[117, 120] system issues,[120] and staffing issues.[117, 120] Communication issues have emerged as a potential contributor to readmissions.[121] An ineffective nursing handoff has been identified as a contributor to miscommunication within the discharge process.[122] The improvement of discharge planning requires that emphasis be placed on collaboration and interdisciplinary communication.[112] Well-orchestrated discharge planning is recommended to help improve patient safety[123] by controlling the risk of gaps occurring in the discharge process and its inherent handoffs.

Handoffs and Medications

Medication errors are considered preventable events.[124] Handoff issues (e.g., transfer, shift change, cross-coverage) have been identified by the United States Pharmacopeia (USP) through its MEDMARX® reporting program as a contributing factor to medication errors within health care organizations.[19, 24]

Incomplete transfer of medication information is recognized as a possible contributor to patient safety problems as patients are discharged from the hospital.[119, 125] Reasons for medication handoff failures include incomplete patient education and the "inability of ambulatory care providers (including nursing homes) to receive discharge medication information"[126] (p. 93). Medication changes during the transition (handoff) from hospital to skilled nursing facilities were identified as a cause of adverse drug events in a New York study.[127] One study reported patients who received medication information and counseling demonstrated more compliance with their medication regimen than patients who did not receive such information.[128]

There are multiple case examples of medication errors related to handoffs across the continuum of care.[129, 130] In fact, USP has reported that 66 percent of medication reconciliation errors occur during the transfer or transition of a patient to another care level.[130] A number of recommendations have been developed to improve the medication reconciliation process and reduce risks for patients.[130, 131] In addition, medication reconciliation is a Joint Commission patient safety goal,[47] with specific requirements for the process.[47, 132]

Physician-to-Physician Handoffs

Studies conducted to better understand physician-to-physician handoffs[31, 33] may have implications for nurses. Poor handoffs included omissions of essential information such as medications, code status, and anticipated problems.[31] Other issues contributing to failed communication processes included lack of face-to-face interaction and illegible documentation.[31] The weaknesses identified in another handoff study included incomplete and or illegible information, difficulty accessing clinical information quickly, communication failures, and difficulty contacting other doctors.[33] Strategies to address handoff problems include providing

legible, accurate, relevant, comprehensive information and the use of a face-to-face report.[31] Suggestions for improvement include development of a process to enhance transmission of information, for example, the adoption of templates; use of technology; use of communication processes such as SBAR, education, and evaluation of handoffs;[31] and a standardized handoff process.[33]

Evidence-Based Practice Implications—Handoffs for Today's Health Care Environment

The Australian Council for Safety and Quality in Health Care evaluated 777 papers for possible inclusion in a literature review on handoffs.[1] A total of 27 papers met the inclusion criteria, but it was reported that "no best practice" (p. 2) existed related to systems emerged in the search—although a number of recommendations were provided for systems, organizational, and individual factors.[1] Handoffs are an extremely complex phenomenon to study as they occur in a variety of settings; stages along the continuum of care; and among various personnel with different skill sets, priorities, and educational levels.

Contributors to handoff problems included failed communication,[4, 5, 6, 7, 10, 31] omissions,[31, 64, 108] distractions,[108] lack of or illegible documentation,[31, 33, 73] lack of utilization of transfer forms,[69] incomplete medical records,[64] lack of medication reconciliation,[129, 130] and lack of easy accessibility to information.[6, 33, 73] A variety of environmental issues emerged—including designs[28, 58]—that served to increase, rather than decrease, the number of handoffs. Interfacility handoffs posed a number of challenges, including cultural differences[73] and lack of integrated systems, thereby increasing the likelihood of transmission difficulties between organizations. Organizational and system failures or lack of systems to support the handoff process emerged as contributors to adverse events.[4, 6, 7, 10] A lack of knowledge was found regarding effective handoff processes,[117] and education on effective handoff strategies was also lacking.[3, 117] Handoff processes need to include consideration of the person involved in the handoff and their level of education, expertise, and comprehension (e.g., the novice nurse's informational needs may be different from the expert nurse).[41] Novices also differ from expert nurses in their use of information.[84]

There must be an organizational commitment to the development and implementation of systems that support effective handoffs as well as a just culture.[133, 134] This includes cultures of safety and learning.[134] A safety culture supports identifications of problems and errors to be addressed to prevent the recurrence.[134–136] A culture of learning promotes learning from the experiences of the past to prevent a recurrence of tragic fumbled handoffs. Environments and processes need to be designed to promote desired outcomes[76] and enhance patient safety.[137]

Electronic Support of Handoffs

A number of reports and studies have called for systems that allow ease of access to accurate information to improve handoffs.[6, 10, 15, 29, 89, 138] Electronic technology requires that design issues be considered and adequate resources be allocated for successful implementation and acceptance.[139] Research of computerized support for physician handoffs suggests this is a strategy that merits further consideration and evaluation.[16] A study at two hospitals reported the implementation of a computerized system for resident handoff enhanced delivery of care and decreased the number of patients missed on rounds.[138] There have been limited studies on

computerized clinical documentation systems (CDS) in the nursing shift handoff. One study reported nurses perceived shift-to-shift handoffs more positively after the implementation of the CDS.[140] Access to a physician computerized sign-out was rated positively by nurses and was reported to improve communication.[141]

Decrease Transfers of Patients

Decreasing the number of patient transfers may reduce the risks that occur during handoffs.[58] It has been suggested that "many patient transfers could be prevented by altering facility designs and nursing care models found in acute care hospitals"[97] (p. 163), thereby decreasing the need for handoffs. The implementation of "acuity-adaptable rooms" demonstrated a 90-percent decrease in patient transports; the same study also reported a decrease in medication errors of 70 percent.[28] More research of this strategy is recommended.[58]

Effective Handoff Process

A recurrent theme observed in the handoff literature is the need to convey essential information to the oncoming shift or provider. A standardized process to guide the transfer of critical information has been recommended.[33, 34, 45, 48, 108] The use of protocols that include the use of phonetic and numeric clarifications are important in helping convey information accurately.[11, 136] The Sentara health care organization adopted behavior-based expectations to improve the handoff process and used tools including the five Ps (patient/project, plan, purpose, problems, and precautions).[136] It reported a 21-percent increase in effective handoffs.[142] A medical center using SBAR in the handoff process reported less missing information in handoffs after implementation of SBAR.[45] The use of protocols such as safe practice recommendations related to reconciling medications[131, 132] and communicating critical test results[49, 50] should be used in designing strategies for more effective handoffs. Some hospitals have reported developing strategies to improve the communication between the hospital and other providers.[44, 71, 73, 74, 114] A summary of problems and barriers with handoffs observed in this review of literature are presented in Tables 4, 5, and 6. Strategies that have been reported in the literature are also included in the tables; however, more research is needed to identify evidence-based guidelines. The Evidence Table at the end of this chapter presents a summary of selected sources addressing handoffs.

Human Factors

The study of human factors engineering is currently being used to improve patient safety,[76] and there are an increasing number of strategies and tools that can be used to design systems in a manner to decrease adverse outcomes. Designs to promote patient safety should include integration with "forcing" functions to prevent errors. However, there needs to be testing of proposed solutions to assure validity of these tools in the health care environment.[76] Lessons learned from other industries are fostering the adoption of human factors principles and increasingly being used in health care.[44, 137, 143–146]

Studies of handoffs in other industries have been analyzed for possible implications for health care. Patterson and colleagues[2] analyzed data from four studies[147–150] and described 21 handoff strategies. According to their findings, strategies that could be applied to shift handoff

included interactive questioning, face-to-face handoff, forcing functions such as passing a pager to initiate handoff to the oncoming nurse to indicate an unambiguous transfer of responsibility, flagging critical information, and reduction of interruptions.[2] The researchers note a question remains "if the strategies can be generalized to health care"[2] (p. 132), and call for additional research in this area.

Research Implications

Following are suggested questions for future research:

- What are the best systems designs to reduce unnecessary handoffs? How can they best be implemented?
- What are best strategies for handoffs in various settings (i.e., nurse to nurse, unit to unit, agency to agency, physician to nurse)?
- What are the most effective strategies, instruments, and tools to employ to assure maximum transfer of and receipt of accurate, relevant, up-to-date information?
- How can electronic technology best be deployed to support and enhance effective handoffs, decrease errors, and improve patient safety and patient outcomes?
- What are the best techniques for assuring critical information is forwarded and not omitted or overlooked when received?
- How can handoff contributors to medication errors be addressed and decreased?
- What are the critical data elements that should be transferred by type of service, specialty, profession, and setting?

Basic to the provision of quality health care is the ability to communicate with one another and safely handoff patient care in a seamless manner so every patient can benefit from each phase of care through a well-executed handoff. This is a process that is ubiquitous but also a high-risk endeavor in many settings. More research is needed in this critical patient safety arena to promote interdisciplinary approaches to patient safety throughout the continuum of care.

Table 4. Factors, Problems, and Strategies Cited in the Literature

External & internal factors that contribute to errors	Problem/barrier associated with patient safety issues	Practice implications (strategies for reducing errors and improving safety)	References
Handoff communication	Language problems may contribute to problems during handoffs in several ways. Different dialects, accents, and nuances may be misunderstood or misinterpreted by the nurse receiving report. Abbreviations and acronyms that are unique to certain settings may be confusing to a nurse working in a different setting or specialty. Medications may have similar sounding names, increasing risk for confusion.	• Face-to-face handoff is preferred[31, 35] to allow verbal and nonverbal exchanges and interactive communication and questions.[47, 48] • Standardize forms, checklists, or tools (customized as agreed to by clinicians for specific practice areas) so that all users will understand the information from the same context.[34] • Allow opportunity for questions and clarification during the handoff.[2, 34, 47, 48] • Use a "read back" "repeat back" to decrease communications errors.[34, 47, 49] • Use phonetic and numeric clarifications.[136] • Verify information.[47] • Implement safe practice recommendations for communicating critical test results[50] • Speak in simple, clear, straightforward manner and be specific in description of patient and situation.[34] • Avoid the use of abbreviations and jargon, which may not be understood.[34, 151] • Provide definition of ambiguous terms. • Allow receiver of handoff to review relevant summary and data (history, treatments, and services) and current information.[48] • Allow for oncoming and offgoing clinicians to assess situation.[35] • Include anticipated problems or changes in report.[31]	Arora 2005[31] Barenfanger 2004[49] Haig 2006[45] Hanna 2005[50] ISMP 2005[151] Joint Commission[47, 48] Joint Commission International Center for Patient Safety 2005[34] Simpson 2005[35] Yates 2005[136]
Distractions	Situational factors during a handoff can contribute to distractions.	• Provide handoff in a location/environment that minimizes distractions.[157]	White 2004[157]
Interruptions	Interruptions are reported to occur frequently in the health care setting.	• Limit and discourage interruptions.[2, 4, 34, 48, 108] and provide coverage of other duties during handoff to support focused transition	Beach 2006[4] Currie 2002[108] Joint Commission 2008[48] Joint Commission International Center for Patient Safety[34] Patterson 2004[2]

External & internal factors that contribute to errors	Problem/barrier associated with patient safety issues	Practice implications (strategies for reducing errors and improving safety)	References
Noise	Background noises such as pagers, phones, overhead paging, equipment noise, alarms, and talking contribute to increased difficulty in hearing report and can lead to inaccurate interpretation of information.	• Provide handoff in a location/environment that allows those involved in the handoff to clearly hear the information.[3] • Use a "read back" to decrease communications errors.[47, 49] • Use phonetic and numeric clarifications.[136]	Barenfanger 2004[49] Joint Commission[47] Solet 2005[3] Yates 2005[136]
Fatigue	Increased errors are noted in nurses working prolonged shifts.	• Limit the amount of hours worked to reduce fatigue and errors associated with fatigue.[58, 153, 154, 155]	Hughes & Rogers 2004[153] Institute of Medicine 2004[58] Rogers 2004[154] Scott 2006[155]
Memory	Short-term memory is limited and lapses may occur when large amounts of information are communicated during a handoff.	• Design systems to reduce reliance on memory.[76, 157] • Use preprinted patient information forms for accuracy and completeness of information in handoff.[55] • Provide health care providers with access to data to reduce reliance on memory in handoff.[55, 157]	Gosbee & Gosbee 2005[76] Parker & Coiera 2000[152] Pothier 2005[55] White 2004[157]
Knowledge/ experiences in handoffs	Novice nurses and expert nurses have different needs.[158] Novice nurses may encounter issues with handoffs. Novice nurse may need supplemental information during the handoff. Staff may not have been educated on strategies for an effective handoff and discharge planning.	• Support novice nurses with orientation and preceptor programs. • Provide continuing education programs on effective handoff strategies.[45] • Provide experienced consultants to less-experienced nurses as they may not have skills in their repertoire for advanced problem-solving.[37, 84] • Provide comprehensive, pertinent information, but avoid overload during handoff.[78]	Benner 1984[158] Ebright 2004[37] Haig 2006[45] Kerr 2002[78] Taylor 2002[84]
Written communication	Trying to interpret illegible notes from another provider may create errors in communication.	• Use electronic strategies to decrease problems with illegibility.[159] • Use standardized processes (customized to a clinical area, practice setting) to assure critical information is communicated in handoff.[34, 35]	Joint Commission International Center for Patient Safety 2005[34] Simpson 2005[35] Upperman 2005[159]

External & internal factors that contribute to errors	Problem/barrier associated with patient safety issues	Practice implications (strategies for reducing errors and improving safety)	References
Variation in processes	There may be wide variance in the way a handoff is conducted that may lead to omission of critical information and contribute to medical and medication errors.	• Adopt a standardized, consistent approach to the handoff to decrease errors.[33,34] • Adopt and use behavior-based expectations to reduce risks and promote patient safety. Tools to use during handoffs include the 5 Ps for Patient/Project, Plan, Purpose, Problems, Precautions[136] and Situation, Background, Assessment Recommendation (SBAR).[34, 44, 45] • Communicate essential patient care information.[34] • Develop and implement a systematic process for the reconciliation of patient's medications to decrease risk associated with transfers and transitions to other levels of care.[130, 131, 132]	Bomba & Prakash 2005[33] Joint Commission 2006[132] Joint Commission International Center for Patient Safety 2005, 2006[34] Haig 2006[45] Leonard 2004[44] Massachusetts Coalition for the Prevention of Medical Errors 2005[131] USP 2005[130] Yates 2005[136]

Table 5. Issues, Problems, and Strategies Cited in the Literature

Organizational/system issues that contribute to errors	Problem/barrier associated with patient safety issues	Practice implications (strategies for reducing errors and improving safety)	References
Culture	In a culture that lacks sufficient focus on safety and learning, staff may be reluctant to report problems or may not feel comfortable asking questions.	• Support the development of a culture of safety where reporting of errors and problems is accepted and encouraged.[58, 133, 134] • Encourage the development of a "learning culture"[134] and a "just culture."[133, 134]	Institute of Medicine 2004[58] Marx 2001[133] Reason 1997[134]
Hierarchy	Hierarchical structure may impede open communication. The nurse may not feel comfortable asking questions to clarify information or may feel intimidated.	• Promote culture of safety where open communication is supported.[58, 160, 161] • Develop protocols or policies that support a culture of respect, collaboration, and collegiality among all nurses and health care providers.[161] • Provide education for all health care providers on effective communication strategies such as the use of SBAR (situation, background, assessment and recommendation) to enhance communication.[44, 45, 144]	American Association of Critical-Care Nurses 2005[161] Haig 2006[45] Institute of Medicine 2004[58] Leonard 2004[44] McFerran 2005[144] White 2004[160]

Organizational/system issues that contribute to errors	Problem/barrier associated with patient safety issues	Practice implications (strategies for reducing errors and improving safety)	References
Systems support	Lack of time to access information and complete report will reduce time for questions and answers.	• Assure that there is time to complete the handoff report. • The receiving health care provider needs to have access to pertinent, accurate, timely patient information.[34, 48] • Recognize that a handoff requires the opportunity for interactive questions and answers.[34, 48] • Develop systems that support efficient operations in the retrieval of data in a timely manner to allow updated, current, accurate information to be provided to the receiver of the handoff.[34, 138, 141]	Joint Commission 2008[48] Joint Commission International Center for Patient Safety 2005[34] Sidlow & Katz-Sidlow 2006[141] Van Eaton 2005[138]
Infrastructure	There may be inadequate staff, tools, or equipment for effective handoffs.	• The leadership needs to promote the design and implementation of systems within an environment to provide safe patient care.[58] • Provide adequate human resources, equipment, technology, and educational opportunities to promote optimal handoffs.[58] • Involve nurses in the design of work environments.[58]	Institute of Medicine 2004[58]
Transfer of patients (within health care organization)	Increased number of transfers increases the need for handoffs.	• Consider health care delivery design models in which patient transfers are minimized.[28] • Include nursing staff in the design of handoff processes.[58]	Hendrich 2004[28] Institute of Medicine 2004[58]
Physical space limitations for handoffs	Environment may not be conducive to conducting a handoff (interruptions, noisy).	• Include health care providers in the design of work environments so adequate space requirement and configurations are identified.	Institute of Medicine 2004[58]
Technology limitations and use of manual reports and records/ difficulty accessing essential information	Lack of technology may create voluminous paper records (medication records, lab reports) with multiple reports to be referenced for handoffs to another unit, setting, or facility.	• Design electronic systems that support the easy retrieval of accurate and timely data.[34, 141, 163] • Provide for adequate planning processes, infrastructure, human resources, and education to successfully implement electronic support.[139, 162]	Ash 2003[162] Joint Commission International Center for Patient Safety 2005[34] Karsh 2004[139] Sidlow & Katz-Sidlow 2006[141] Van Eaton 2004[163]
Different cultures or organizations	Organizations may have different goals, focus, and resources.	• Develop processes between sending and receiving organizations to assure both organizations are aware of requirements for handoff.[44, 73] • Plan resource allocation to meet the patient needs.[44]	Davis 2005[73] Leonard 2004[44]

Organizational/system issues that contribute to errors	Problem/barrier associated with patient safety issues	Practice implications (strategies for reducing errors and improving safety)	References
Intra- or extra-system transfers	Transfers to a setting/facility within a single system may create fewer problems than a transfer to a different system/health care provider in which different forms and technologies are used. Transfers require efforts to assure continuity of care as the patient transitions to another level of care.	• Seek to design systems, processes, and policies that allow for collaboration and efficient transfer of essential information between organizations during handoff.[68, 69, 73, 111, 112, 115] • Complete medication reconciliation process.[129, 132] • Remove barriers to communication. • Assure a bidirectional communication process between health care providers.[110] • Communication involves verbal, written, and electronic means. • Monitor process for opportunities for improvement.[44]	Anderson & Helms 1993[69] Anderson & Helms 2000[68] Coleman & Boult 2003[110] Cortes 2004[114] Davis 2005[73] Hansen[112] Institute for Safe Medication Practices 2005[129] Joint Commission International Center for Patient Safety 2006[132] Leonard 2004[44] Nicholson 2003[74] Satzinger 2005[111] USP 2005[129] Wachter & Shojania 2004[11]
Staffing limitations	Staffing shortages may contribute to gaps in transmission of information in handoff.	• Allocate adequate human resources to support handoffs and meet patient care needs/functions.[58, 111]	Institute of Medicine 2004[58] Satzinger 2005[111]
Equipment failures	A number of devices are used in a handoff. Critical information may not be transmitted if electronic devices fail.	• Follow up on critical information to assure it was received.[2] • Monitor, replace equipment, supplies to reduce contributors to communication failures.[53] • Upgrade equipment to improve communication processes.[2]	Patterson 2004[2] Prouse 1995[53]
Lines of responsibility	Persons entering into a handoff situation may not be clear on when responsibility of patient/situation is transferred, which can lead to a “fumbled” handoff, if the responsibility for care of patient and of followup is not clearly delineated.	• Use a forcing function[2, 44] to indicate the transfer of responsibility such as by passing a pager indicating that the receiving nurse is accepting responsibly for the patient and confirming the transfer of responsibility.[2,] • Unambiguous transfer of responsibility.[2] • Clearly define responsibility at transition.[4]	Beach 2006[4] Leonard 2004[44] Patterson 2004[2]
Tight time constraints	Time constraints during handoffs (e.g., pressure to increase patient flow across the system) may contribute to a report that is rushed and incomplete.	• Assure there is time for interaction and question and answer during a handoff.[34] • Allow receiver of information to review relevant information.[48]	Joint Commission International Center for Patient Safety 2005[34] Joint Commission 2008[48]

Table 6. Issues, Problems, and Strategies Cited in the Literature

Special Issues	Problem/barrier associated with handoff	Practice implications (strategies for reducing errors and improving safety)	References
Emergency situations/critical activities	Handoffs in a critical situation present a number of challenges.	• Remain for the completion of handoff until it is clear that critical information has been received and the transfer of responsibility has occurred by the accepting health care provider team.[35] • It may be necessary to delay handoff in critical situation to assure concerns are addressed.[2,4 35] • Exercise caution and situational awareness in emergency situations to assure all information is transmitted and received and continuity of care is provided.[4]	Beach 2006[4] Patterson 2004[2] Simpson 2005[35]
Code status	Code (Do Not Resuscitate (DNR)) status may be omitted from handoff report and not documented in medical record, or information may not be accessible.	• DNR status needs to be documented and communicated so members of the health care team are aware of status.[164] • Communicate code status in handoffs.[31, 164]	Arora 2005[31] Goldstein 2006[164]
Critically ill or labile patient	Offgoing and oncoming shifts may perceive patient situation differently, and the patient situation may change during the actual shift transition.	• Bedside report, walking rounds afford both the offgoing and oncoming shifts the opportunity to observe the patient together; address and problem-solve together; clarify issues; answer questions; and assure continuity of care.[17, 22, 35]	Perry 2004[17] Richard 1988[22] Simpson 2005[35]
Variable resources on, off shifts	Transfer handoff may occur after normal business hours when resources are less available, increasing the possibility information will be omitted.	• Assure critical information is documented and transmitted. In addition allow for an interactive report so that questions can be answered and issues addressed.[44] • Assure that all medication information is documented for the receiving facility. • Reconcile medications.[129, 130, 131, 132] • Design “forcing functions” to reduce ambiguity and confirm acceptance of assignment.[2, 44] • Coordinate adequate staff coverage to support patient care handoffs.[44] • Communicate to and confirm acceptance of transfer and allow exchange of essential information.[35, 44]	ISMP 2005[129] Joint Commission International Center for Patient Safety 2006[132] Leonard 2004[44] Patterson 2004[2] Simpson 2005[35] USP 2005[130]

Search Strategy

To retrieve pertinent literature on the topic of handoffs, the following databases were reviewed: Academic Search Premier, CINAHL, Pre-CINAHL, EMBASE, Ovid's Medline, PubMed, and PsychInfo. The databases were searched for variants of the words "handover" and "handoff," "shift report," and "changeover." Additionally, the databases were searched for groups of subject terms representing the concepts of patient transfer, communication, and continuity of care. The use and combination of subject headings varied depending on the characteristics of each database. Searches for the concept of patient transfer used the following subject headings: transfer, discharge; transfer, intrahospital; patient discharge; transportation of patients; and patient transfer. The concept of communication was represented by terms such as "communication barriers," "communication," "communication skills," "communication theory," and "interpersonal communication." Subject headings focusing on the concept of overall health care delivery or quality included quality of care, health care delivery, continuity of patient care, patient safety, and medical care.

Acknowledgment

The authors wish to acknowledge Stephanie Narva Dennis, M.L.S., for support and assistance in conducting the literature search.

Evidence Table. Selected Sources on Handoffs—Nursing Handoffs, Quality Improvement Activities, Interdisciplinary Handoffs

Source	Safety issue related to practice	Type	Study outcome measures	Setting & study population	Intervention	Key findings
Anderson & Helms 1993[69]	Handoff between hospital and home health agency (HHA)	Descriptive retrospective study	Inventory Referral Information (IRI) 40 items. Score 0–40 Monitor type, amount of information the HHA received from the hospital	Illinois, Iowa 300 patient records 1988–1990 Referrals of 6 hospitals to 4 HHAs	No intervention	• Scores ranged from 7 to 35 items completed • Hospital affiliated HHA received more data than nonaffiliated HHA • More information transmitted between hospital and HHA when a standard form used
Atwal 2002[122]	Discharge planning	Qualitative	Interview of nurses utilizing critical incident technique Observation of nurses and other health care providers	19 nurses Interviewed Observation at multidisciplinary meetings	No intervention	• Miscommunication of information • Observed other priorities precluded attendance at multidisciplinary meetings • Strained “interprofessional relationships”
Australian Council for Safety and Quality in Health Care 2005[1]	Handoffs	Literature review	Retrieval of literature that addresses handover and safety in both health and nonhealth literature The literature review report includes sources from 1993–2004.	777 papers reviewed Only 27 met inclusion criteria 8 non-health care 19 health care Another 21 papers did not meet criteria but were termed useful.	Studies with interventions reviewed included computerized documentation system, interdisciplinary rounds, Other reports included observational studies cases studies	• Quality of evidence on clinical handoffs deemed “extremely poor” (p. 5). • Majority are descriptive studies. • Three domains identified. • System design factors: 17 papers • Organizational/culture: 6 papers • Individual factors: 4 papers • Recommendations for each of the three domains are provided.

Source	Safety issue related to practice	Type	Study outcome measures	Setting & study population	Intervention	Key findings
Bruce & Suserud 2005[107]	Experiences of emergency nurses receiving patients who are attended by ambulance nurses	Qualitative descriptive	Four themes were identified: prehospital reporting, symbolic handover, ideal handover, nonideal handover.	Sweden 6 nurses	No intervention Analyze experiences of emergency nurses and the handover and triage process	• Reportedly the first study of ambulance nurse to emergency nurse handover. • Interface between prehospital and hospital is critical. • The researchers recommend "the handover process needs to be structured and made uniform" (p. 208). • The ideal handover was described as one that was patient focused and the problems were communicated "clearly." • Authors identify questions to be asked during the handoff.
Behara 2005[106]	Emergency department (ED) transitions	Qualitative ethnographic	Observation of shift changes, and additional types of exchanges and investigations. Content analysis and grounded theory. Development of conceptual framework.	United States and Canada 5 EDs: 3 inner city 1 private tertiary center 1 community	No intervention	• Variety in types of handovers observed • "Nearly universal" attributes of ED handoffs identified. • Conceptual framework included four attributes: 1. Type of process 2. Content 3. Structure 4. Dynamic
Cahill 1998[52]	Bedside handoff (patient perceptions)	Qualitative design using a grounded theory approach	Three major categories emerged from the interviews with patients: • 'Maintaining a professional distance' • 'Establishing professional sharing' • 'Maintaining patient safety'	Nursing Unit 10 patients	No intervention	• Maintaining patient safety identified as "primary purpose" • Patients expressed concern not always understanding the terms used by nurses in report. • The patients reported handoffs were short in duration, lasting no longer than 2 minutes. • Some patients did wish to be involved in the handoff process, but not all patients did.

Source	Safety issue related to practice	Type	Study outcome measures	Setting & study population	Intervention	Key findings
Currie 2002[108]	The handoff in an ED setting	Survey/ Questionnaire	Questionnaire addressed 12 topics in handoff (examples include; patient name & age, medical history & medications, vital signs, plan of care, and other topics.) Also included problems with handoff and preference for bedside or nurses' station handoff.	Emergency admissions and assessment unit. 28 nurses	No intervention	• Problems with handoffs included missing information, distractions, and lack of confidentiality. • High-priority topics included reason for admission, treatment, name, age, restrictions, plan of care, and medical history. • Recommended a standard handoff and use of clinical guideline • Suggested a strategy for handoffs using an acronym of confidential, uninterrupted, brief, accurate, and named nurse (CUBAN); however, it has not been evaluated.
Dowding 2001[95]	Shift report	Experimental factorial design	Two independent variables: 1. Type of shift report (retrospective, prospective) 2. Schema-type information (consistent, inconsistent) Dependent variables: amount of information documented, recalled and the plan of care.	Scotland Two hospitals Medical and surgical wards 48 nurses	Manipulation of a handoff (shift report). Explore the effect of manipulating information on nurse's care planning. The nurses were randomly assigned to one of the four experimental conditions.	• Type of shift report had significant effect on plan of care score. • Type of schema did have a significant effect on documentation and recall, but no effect on plan of care. • Recall of information ranged 20.1% to 34.2% depending on type of report and schema. • The study conditions used an audiotape and did not allow for "'normal' shift report" with interaction and questions. • Further research is needed in a more natural setting.

Source	Safety issue related to practice	Type	Study outcome measures	Setting & study population	Intervention	Key findings
Footitt 1997[91]	Evaluation of a pilot of telephone method for shift report	Piloting a new system Quality improvement	Communications and cost effectiveness of handoff process using new telephone-based system.	United Kingdom Gynecology department of hospital Sample size not specified	Implementation of Nurse Communicator System (telephone system for reports) in spring 1995	• Reported system reduced time spent in the report (handoff) • Deemed "affordable" • Allowed reinvestment of resources • Need adequate number of phone lines to support the handoff process
Greaves 1999[90]	Bedside handoff (patient perceptions)	Qualitative	Patients were interviewed and asked questions about the handoff process. Aspects explored included likes, dislikes, privacy, experience with past handoffs, areas for improvement.	Hospital Four patients Assess patient perceptions of handoffs at the bedside	No intervention	• Four themes emerged from interviews and analysis of data 1. Access to information and a desire to be included in the handoff 2. Confidentiality of patient information 3. Continuity— the communication of information from one shift to another 4. Neglect— the staff need to be available during a handoff to care for patients so patients are not at risk for "neglect"
Haig 2006[45]	Communication	Quality Improvement	Use of SBAR <u>Outcome Measures</u> Medication reconciliation Adverse events	Bloomington, Illinois Medical center	Effort to implement situation, background, assessment and recommendation (SBAR) communication tool.	• SBAR use increased to 96% in 2005. • Use of SBAR in discharge medication reconciliation increased from 53% to 89%. • Adverse events decreased.

Source	Safety issue related to practice	Type	Study outcome measures	Setting & study population	Intervention	Key findings
Hardey 2000[87]	Communication of information	Qualitative ethnographic	Communication process, specifically the use of "scraps" examined. "Scraps" are "personalized recordings of information" (p. 209) on paper or in notebooks by nurses. Grounded theory analysis.	England 5 wards (geriatric) Observation of 23 handovers Observation of interactions Interviews with 34 nursing personnel Written records	No intervention	• Scraps are used for a variety of purposes such as a 'to do' list, and record information about the patient's clinical status. • Scraps were used by nurses to augment documentation due to "perceived inadequacies." • Three themes were identified related to the use of scraps: construction and content of scraps, role and use of scraps, confidentiality and disposal.
Hendrich 2004[28]	Impact of acuity-adaptable rooms on transfers, medical errors, satisfaction	Pre-post method	12 outcomes-based questions (seven addressed in article). Outcomes studied: patient complications & mortality, sentinel events, clinician satisfaction, patient satisfaction, recruitment and retention of nurses, market impact, costs	United States Hospital 2 years baseline data 3 years postimplementation data	Use of acuity-adaptable rooms	Postimplementation • 90% decrease in patient transports • 70% decrease in medication errors • Decrease in number of patient falls • Decrease in patient dissatisfaction
Hopkinson 2002[83]	Handover related to the dying patient	Qualitative phenomenological approach	Nurses were interviewed and asked to discuss caring for a dying patient.	United Kingdom Two hospital trusts Eight hospital medical wards 28 nurses	No intervention	• Two major functions of the handoff: 1. Seen as supportive as allowed nurses a venue to discuss opinions and express feelings 2. Exchange information in order to provide care .

Source	Safety issue related to practice	Type	Study outcome measures	Setting & study population	Intervention	Key findings
Kassean & Jagoo 2005[57]	Handoff process	Quality improvement project Use of force field analysis	Evaluation of bedside handover using 6 criteria based on observation Perceptions of patients' regarding bedside handoff using a 6-item, semistructured interview	Mauritius 28-bed ward 10 nonparticipant observation handovers Semistructured interviews of 40 patients	Implementation of bedside handoff	• Observation of 10 handoffs revealed a compliance rate ranging from 90% to 100% for individual criteria. • 40 patients interviewed,100% indicate confidentiality handled with sensitivity at the beside handoff. • The "targeted" goal of 80% was exceeded on this unit.
Kelly 1999[85]	Handoff process in the critical care unit	Qualitative Ethnomethodo-logical approach	The components of the handoff were examined, including the initiation, content, the handing over to the next shift.	Critical care unit 2 handover transcripts (2 handoffs)	No intervention	• Examples of the text of the shift report are provided, and interaction of the nurses is examined in depth. • Fourteen "specimens" observed related to the handoff are delineated.
Kennedy 1999[54]	Nonverbal handoff	Qualitative Study Quality improvement	Pre Non-Verbal Handoff Nonparticipant observation of bedside handoff Post nonverbal handoff Qualitative data obtained via semistructured interview of staff, Eight months post implementation of nonverbal handoff an audit of documentation was conducted	28-bed ward 41% (9) members of nursing team Stratified sample Documentation	The implementation of a nonverbal handoff system	Post nonverbal handoff: • The documentation of information addresses reporting that one "didn't hear information in the handoff. • Disadvantage: "forgetting" to document and quality of some reports. • Team preferred the nonverbal handoff • However, interviews indicated all nursing team members still passed on information verbally in addition to the nonverbal report. • Audit results indicate there was a 60% improvement in documentation 8 months post-implementation of nonverbal handoffs.

Source	Safety issue related to practice	Type	Study outcome measures	Setting & study population	Intervention	Key findings
Kerr 2002[78]	Shift "handover" (handoff)	Qualitative	The handoff was observed by researchers. An interview guide was used and focused on three issues: practice (7 questions), functions (3 questions), and problems and effectiveness (9 questions).	2 pediatric units 20 handovers per unit 12 individual per unit and 2 group interviews per unit Participants included nurses, support worker, students	No intervention	• Four main functions of handoff: informational, social, organizational, educational • Three phases of handoff: pre-handover, intershift (meeting), post-handover. • A number of tensions were identified inherent in the handoff process, including tension between being comprehensive versus information overload; confidentiality issues versus family-centered care.
Lally 1999[81]	Intershift handoff	Qualitative Observation	Research question: To what extent does the intershift handover involve social cohesion of the group/team? Observation Audiotaped the handovers, used field notes, transcribed the data, and conducted qualitative analysis.	United Kingdom One ward in a hospital in the 6 shift handovers	No intervention	• The study of shift handoff revealed 16 themes within 5 categories: nursing process, learning the ropes, them and us, model in action, foreword and appendices • A number of functions were identified in the handover, including transfer of information, teaching, and enhancement of group cohesion.

Source	Safety issue related to practice	Type	Study outcome measures	Setting & study population	Intervention	Key findings
Lamond 2000[21]	Shift report	Two-by-two design comparing 2 hospitals Content analysis used on audio and written data	Multidimensional scalogram analysis (MSA) of content comparing shift report and documentation Types of information in report and documentation analyzed included general, physical, physical measures (i.e., pulse, blood pressure, etc.), psychological, social, family, nursing interventions, medical treatment, global judgments, management issues.	England 2 hospitals 2 medical 2 surgical wards 5 consecutive shift handoff reports on each ward, total of 20 reports Records documentation (medical notes, kardex, care plans, etc.) from 15 patients per ward, total of 60 patients	No intervention	• Shift reports ranged from 15 to 55 minutes in duration, average 34 minutes. • Correlation between information in documentation and report was r = 0.47, *P* < 0.001.(D.Dowding, personal communication January 3, 2008) • Shift report was provided in a certain sequence on each ward. • More information recorded in records than transmitted via report • The most frequently reported aggregated items were patient name, age, consultant, diagnosis, date of admission, surgical interventions.
Leonard 2004[44]	Communication	Quality improvement	Patient transfer to skilled nursing facilities (SNFs), communication of data checklists, Employee satisfaction scores. Turnover Wrong site surgery	Kaiser Permanente	Implementation of standardized communication process (SBAR), checklists for patient transfers, briefings	Checklist: • Improvement in communication between hospital and SNF • Improvement in patient having correct medication when transferred to SNF Briefings: • Improvement in employee satisfaction by 19% • Nursing turnover decreased • No wrong site surgeries reported after briefing implemented

Source	Safety issue related to practice	Type	Study outcome measures	Setting & study population	Intervention	Key findings
Lingard 2005[103]	Communication in the operating room (OR)	Qualitative	Ethnographic observation of implementation of checklist Informal interviews to assess the benefits and disadvantages of checklist Grounded theory approach	OR of teaching medical center 33 OR staff (surgeons, nurses, anesthesiologists, residents) 18 procedures 11 interviews	Implementation of a Preoperative Team Checklist	• Checklist used successfully • Checklist discussion duration 1–6 minutes • Some inconvenience noted • Discussions were perceived as efficient by participants • Benefits outweighed inconvenience • 6 functions of checklist identified: 1. detailed, case-related information 2. confirmation of case-specific details 3. articulation of concern or ambiguity 4. decisionmaking 5. team building 6. education
Liukkonen 1993[77]	Handoff content	Content analysis qualitative and quantitative	Identified type of information discussed in the shift handoff; a total of 28,891 statements were placed in 5 content classes.	2 wards in 2 geriatric homes Audio recording of shift reports Transcripts 1,034 pages	No intervention	• Handoff reports lasted 30–90 minutes. • Most of the content related to physical needs of the patients followed by medical treatment.
Manias & Street 2000[86]	Communication practices of nurses in a handoff	Qualitative Critical ethnography	Focus on issues and activities related to handoff, including nurses' interactions. The data was analyzed using textual analysis followed by more in-depth analysis using a 4-question guide	Australia 16 bed critical care unit 6 nurses Professional journaling, observation 3 focus group interviews 2 interviews per participant	No intervention	• First a "global" handoff was presented to all nurses. Second, after assignments of nurses to patients, bedside handoff occurred, focused on individual cases • Complex communication practices emerged. • Five specific practices were identified: global handover, examination, tyranny of tidiness, tyranny of busyness, and sense of finality.

Source	Safety issue related to practice	Type	Study outcome measures	Setting & study population	Intervention	Key findings
McKenna & Walsh 1997[88]	Shift handoffs	Action research model	Four goals were identified: 1. Assess present handoff processes, trial a handoff method. 2. Complete handoffs within 30 minutes. 3. Continue care during handoff. 4. Care continuity between shifts.	Australia 44 wards medical, surgical, high dependency unit, oncology/ palliative care Audit of duration of handoff and comments from the staff	• A variety of handoff methods were trialed on the 4 wards. • Handoff methods included bedside, verbal and bedside, verbal by nurse in charge, verbal, tape recorded.	• On average handoff length decreased to less than 30 minutes. • Challenges were encountered on different units in changing the handoff process. • Different handoff processes may be suitable for some nursing wards (units) and not for others.
Menke 2001[140]	Computerized clinical documentation system (CDS)	One group pretest–post-test design	Pre- and post-test time study of nursing care /charting, medication delivery, clinical decisionmaking, documentation quality; continuity of care (shift-to-shift report)	Pediatric intensive care unit Schedule and delivery time of medications, chart review, lab values, computer record review, and questionnaire	Implementation of a computerized CDS	• After implementation of a computerized CDS, no change in time for patient care or documentation, • Improved quality of documentation. • Unable to analyze related lab normalization information due to missing information from “paper chart.” • Improved access to medical record • Increase in reimbursement

Source	Safety issue related to practice	Type	Study outcome measures	Setting & study population	Intervention	Key findings
Miller 1998[13]	Continuity of care, types of handover (handoff)	Literature review	Review of articles addressing four types of shift handoffs: recorded, bedside, written, and verbal. Literature review included other components related to the handoff, ritual, "what to say," and quality.	Literature review nursing handoffs spanning a 15-year period (1983–1998)	Literature review	• The literature addresses the "ritual" of the handover, suggestions for the content, quality of the handover. • Issue noted with the "inconsistency of information" in the handover. • Three recommendations provided: - Formal reviews of handoffs - Develop guidelines for content of handoffs - Utilize an approved "handover sheet" for nurses
O'Connell & Penney 2001[41]	Shift handover	Qualitative Grounded theory approach	Assess how nursing care is 1. determined 2. delivered 3. communicated in the hospital Three handoff methods were studied: 1. face-to-face verbal in office 2. face-to-face at the bedside 3. tape recorded	Teaching hospital 1.Semistructured interviews (n = 27) nurses, patients, relatives 2. Field observation (5 sites) 3. Informal interviews (n > 40 nurses)	No intervention	• Strengths and limitations identified for all 3 types of handoff reports. • Handoff is forum to communicate about patient. • Forum for nurses to debrief and seek clarification. • Recommendations include develop forms to guide handoff.

Chapter 35. Error Reporting and Disclosure

Zane Robinson Wolf, Ronda G. Hughes

Background

This chapter examines reporting of health care errors (e.g., verbal, written, or other form of communication and/or recording of near miss and patient safety events that generally involves some form of reporting system) and these events' disclosure (e.g., communication of errors to patients and their families), including the ethical aspects of error-reporting mechanisms. The potential benefits of intrainstitutional and Web-based databases might assist nurses and other providers to prevent similar hazards and improve patient safety. Clinicians' fears of lawsuits and their self-perceptions of incompetence could be dispelled by organizational cultures emphasizing safety rather than blame. This chapter focuses on the assertion that reporting errors that result in patient harm as well as seemingly trivial errors and near misses has the potential to strengthen processes of care and improve the quality of care afforded patients.

Reporting Errors

Reporting errors is fundamental to error prevention. The focus on medical errors that followed the release of the Institute of Medicine's (IOM) report *To Err Is Human: Building a Safer Health System*[1] centered on the suggestion that preventable adverse events in hospital were a leading cause of death in the United States. This report emphasized findings from the Harvard Medical Practice Study that found that more than 70 percent of errors resulting in adverse events were considered to be secondary to negligence, and more than 90 percent were judged to be preventable.[2, 3] The IOM report also emphasized the importance of reporting errors, using systems to "hold providers accountable for performance," and "provide information that leads to improved safety." Conceptually these purposes are not incompatible, but in reality they can prove difficult to satisfy simultaneously[1] (p. 156). Nonetheless, reporting potentially harmful errors that were intercepted before harm was done, errors that did not cause harm, and near-miss errors is as important as reporting the ones that do harm patients. Patient safety initiatives target systems-related failures that contribute to errors within the complex environment of health care. Because many errors are never reported voluntarily or captured through other mechanisms, these improvement efforts may fail.

Errors that occur either do or do not harm patients and reflect numerous problems in the system,[4] such as a culture not driven toward safety and the presence of unfavorable working conditions for nurses. To effectively avoid future errors that can cause patient harm, improvements must be made on the underlying, more-common and less-harmful systems problems[5] most often associated with near misses. Systems problems can be detected through reports of errors that harm patients, errors that occur but do not result in patient harm, and errors that could have caused harm but were mitigated in some manner before they ever reached the patient. Reporting near misses (i.e., an event/occurrence where harm to the patient was avoided), which can occur 300 times more frequently than adverse events, can provide invaluable information for proactively reducing errors.[6] Analysis of reported errors have revealed many "hidden dangers" (near misses, dangerous situations, and deviations or variations) that point to

system vulnerabilities, not intentional acts of clinician performance that may eventually cause patients harm.[7]

Opinions and experiences of hospital leaders about State reporting systems were solicited from chief executive and chief operating officers of hospitals in six States with a variety of reporting systems: mandatory, nonconfidential; mandatory, confidential; and voluntary systems.[8] Questionnaires addressed perceptions of the effect of mandatory systems on error reporting, since it was thought that they reduced the frequency of error reports. Items elicited perceptions on the likelihood of lawsuits, overall patient safety, attitudes regarding release of incident reports to the public, and likelihood of reporting incidents to the States or affected patients based on hypothetical clinical vignettes varying in type and severity of patient injury. Safety was a high priority across hospitals. Most hospital leaders reported that a mandatory, nonconfidential reporting system run by the State deterred reporting of patient safety incidents to internal reporting systems. The majority thought that a mandatory, nonconfidential system encouraged lawsuits. Over half indicated that patients should learn details of errors on request by patients or families. They preferred that individual practitioner and hospital names be kept confidential and that incidents involving serious injury be reported to the State. Most indicated that the State should not release information to patients under certain circumstances. Definitions of reportable events varied by State, bringing hospital leaders to call for specific, national definitions of errors.

Just because an error did not result in a serious or potentially serious event does not negate the fact that it was and still is an error. Since reporting both errors and near misses has been key for many industries to improve safety,[6] health care organizations and the patients they serve can benefit from enabling reporting. Reporting sets up a process so that errors and near misses can be communicated to key stakeholders. Once data are compiled, health care agencies can then evaluate causes and revise and create processes to reduce the risk of errors. As such, organizations have implemented strategies, such as staff education, elicitation of staff advice, and budget appropriations, to ease the implementation of patient safety systems and to improve internal (e.g., intrainstitutional) reporting and disclosure to patients and families.

The ramifications of errors that do cause patient harm can provide critical information to inform the modification or creation of policies and procedures for averting similar errors from harming future patients. The position taken by the Joint Commission is that once errors are identified and the underlying factors/problems or "root causes" are identified, similar errors can be reduced and patient safety increased. When both errors and near misses are reported, the information can help organizations better understand exactly what happened, identify the combination of factors that caused the error/near miss to occur, determine its frequency, and predict whether it could happen again. Underreporting and failure to report errors and near misses prevents efforts to avoid future errors and thwarts the organization's and clinicians' obligation to inform/disclose to patients about the error.

As patients become more aware of actual and potential errors, they not only want to be informed, they want to know that quality improvement efforts supported by shared learning will prevent similar future errors.[9] Patients and the public support error reporting,[10, 11] particularly mandatory reporting,[12] and want to know that clinicians and organizations acknowledge errors[13] to leaders, managers, and peers, and that errors are reported as soon as they are detected.[14]

Ethical Implications of Reporting and Disclosure

Health care providers are typically so devastated and embarrassed by their mistakes that they may attempt to conceal them or defend themselves by shifting the blame to someone or something else.[15] Some attribute failure of honestly acknowledging health care mistakes to providers' personal difficulty with admitting mistakes and incriminating other providers.[16–19] Ethical frameworks operate when health care mistakes are made.[20] Respect for patient autonomy is paramount, as is the importance of veracity. Fidelity, beneficence, and nonmaleficence are all principles that orient reporting and disclosure policies. Providers might benefit from accepting responsibility for errors, reporting and discussing errors with colleagues, and disclosing errors to patients and apologizing to them.[21]

When providers tell the truth, practitioners and patients share trust. The fiduciary responsibility of institutions exists in patients' and families' trust that providers will take care of them. If providers cover up errors and mistakes, they do not necessarily stay hidden and often result in compromising the mission of health care organizations. Consistent with their mission, institutions have an ethical obligation to admit clinical mistakes. Professional and organizational policies and procedures, risk management, and performance improvement initiatives demand prompt reporting. When patients, families, and communities do not trust health care agencies, suspicion and adversarial relationships result.[18] Likewise, the breach of the principle of fidelity or truthfulness by deception damages provider-patient relationships.[22] Fidelity and trust, implicit to the provider-patient relationship, do not coexist with deception.[23]

Physicians, nurses, and other health care providers have legal and ethical obligation to report risks, benefits, and alternative treatments through informed consent mandates. Legal self-interest and vulnerability after errors are committed must be tempered by the principle of fidelity (truthfulness and loyalty).[24–26] This ethical principle has been reinforced by practical lessons learned from errors; especially when an adverse event causes serious harm or even death, there is an ethical and moral obligation to disclose information.[27, 28] Candid reports and disclosure of errors by physicians as well as other health care providers (or institutional leadership if the physician refuses to disclose)[19] might result in greater patient trust and less litigation.[29] Furthermore, it is essential to act after errors are reported, with interventions aimed at protecting the welfare of patients by targeting iatrogenic problems and documenting the care given.

Additionally, the ethical principles of beneficence (doing good) and nonmaleficence (preventing harm) are violated when errors are not reported or disclosed. These ethical principles, beneficence and nonmaleficence, shape caring nursing practice, and caring presupposes that nurses act in the best interests of patients. For example, sharing information and preventing harm to patients through truth telling, regardless of good or bad news, build relationships between elder residents and nursing home staff.[30] Putting residents' interests first represents nurse caring and characterizes relationships in which sharing information, rather than hiding it, surrenders nurses' control related to withholding information. Thus, failure to disclose health care mistakes can be viewed from the perspective of provider control over the rights of patients or residents.

Error-Reporting Mechanisms

Traditional mechanisms have utilized verbal reports and paper-based incident reports to detect and document clinically significant medical errors; yet the correlation with actual errors

has been low.[31] The benefits of these reports are dependent upon the design of the system, how and what information is collected, and whether the information is used to inform a sophisticated investigation of specific errors to understand the nature and magnitude of the problem. Additionally, reports can reflect the clinician's ability to recognize an error and willingness to report it, whether through formal reporting mechanisms or documentation in patient records. A consistent finding in the literature is that nurses and physicians can identify error events, but nurses are more likely to submit written reports or use error-reporting systems than are physicians.

Many types of errors that involve medications, health care acquired infections, and medical devices have been targeted for reporting and dissemination mechanisms.[32] In the case of medication errors, errors made by nurses during the administration of medications to patients are more likely to be reported in incident reports than are errors made by the prescribers (e.g., physicians) or distributors (e.g., pharmacists).[33] That said, it is important to note that physicians do not necessarily use incident-reporting systems.[31]

Error-reporting mechanisms may capture only a fraction of actual errors. Research has approached potential errors using direct observation, which, while expensive and not necessarily practical in all practice settings, generates more accurate error reports.[34] More recent approaches have been focusing on increasing and simplifying error reporting, and automating the detection of errors, including creating Web-based forms or adapted standard spreadsheets to reveal patterns of errors.[35] Many of these efforts have focused on improving physician participation and emphasize voluntary[31] and confidential reporting.[36] Most have encouraged reports of errors and near misses and shared occurrences with risk managers, other agency leaders, and patient safety specialists.[37] Perhaps a combination of reporting mechanisms, both concurrent and retrospective, might improve reporting and ideally result in safer processes.

Some of the challenges in using error-reporting mechanisms are associated with the lack of standard definitions, gaining easy access to databases, and the associated cost of electronic applications.[38] The capability of health care organizations' networks and hardware, the existing policies and reporting processes, including reporting actual errors and near misses, and whether the new system will provide error details to assist quality improvement initiatives must be evaluated.

Patients can also be a source of information for reports about the occurrence of adverse effects associated with medical interventions. In institutional settings, patients can provide information on new symptoms that may not be readily detected by clinician observation or testing. In outpatient settings, it could be argued that when there is no direct communication between patients and their outpatient clinicians, some unplanned emergency department (ED) visits and hospitalizations have been used to determine patients with significant, reportable, and actionable adverse drug reactions (ADRs). Two studies of patients in an outpatient setting found that patients reported more information about ADRs, the majority of which did not warrant an ED visit or hospitalization, when specifically asked, providing clinicians the opportunity to make changes in the patient's medication therapy. Without the patient's report of an ADR, clinicians would not know about the majority of ADRs affecting patients.[39, 40]

Voluntary Versus Mandatory Reporting

The IOM differentiated between mandatory and voluntary reporting of health care errors.[41] Voluntary reports may encourage practitioners to report near misses and errors, thus producing

important information that might reduce future errors. However, there is concern that with voluntary reporting, the true error frequency may be many times greater than what is actually reported.[42] Both of these types of reporting programs can be Web-based and nationally representative. Mandatory and voluntary reporting systems differ in relation to the details required in the information that is reported.

Mandatory reporting systems, usually enacted under State law, generally require reporting of sentinel events, such as specific errors, adverse events causing patient harm, and unanticipated outcomes (e.g., serious patient injury or death. It is estimated that less than half the States have some form of mandatory reporting system for adverse events—a number that is expected to grow in the next few years. One such State-mandated system is created by Pennsylvania's Medical Care Availability and Reduction of Error (MCARE) Act of 2002 (on the Web at www.mcare.state.pa.us/mclf/lib/mclf/hb1802.pdf). Another example is the New York Patient Occurrence Reporting and Tracking System (NYPORTS), a Web-based, external, confidential, mandatory reporting system that has been in existence since 1998. The focus of NYPORTS is on serious complications of acute disease, tests, and treatments. The system has 9 occurrence categories (aspiration, embolic, burns/falls, intravascular catheter related, laparoscopic, medication errors, perioperative/periprocedural, procedure related, and other statutory events) and 54 specific event codes.[43, 44]

Sentinel events, such as serious medication errors resulting in deaths, are incidents that can be voluntarily submitted to the Joint Commission in accordance with their Sentinel Event Policy (accessible at www.jointcommission.org/SentinelEvents/PolicyandProcedures), which is based on root-cause analyses. Root-cause analysis is a systematic investigation of the reported event to discover the underlying causes. The Joint Commission's position on mandatory reporting is that providers who are forced to report errors may not describe the details of the event, since they are motivated by a requirement. Nationally, the Joint Commission's Sentinel Alerts provide electronic access to selected sentinel events, identify common underlying causes, and recommend steps to prevent future events. The alerts provide clinicians the opportunity to learn about root causes of errors. Sentinel event statistics are available for clinicians to note error trends and root causes.

An example of voluntary external reporting mechanisms, specifically a Web-based, anonymous/confidential system, is the Medication Errors Reporting Program (MERP) of the United States Pharmacopoeia and the Institute for Safe Medication Practices (assessable at www.usp.org/hqi/patientSafety/mer). Reported errors make up the MEDMARX® database, which subscribing hospitals and health care systems can use as part of their quality improvement initiatives. Employees of subscriber organizations enter, review, and release data to a central data repository that is then available for all subscribers to search. Comparisons can be made within institutions of a single health care system and across participating health care systems. The sharing of data allows medication error types, locations in agencies, level of staff involved, products, and facts contributing to errors to be known and serves to alert clinicians to safety hazards. Actual, intercepted, and potential errors are all included. MEDMARX® examines the medication use process, systems, and technologies rather than individual blame and emphasizes the Joint Commission's framework for root-cause analysis.

Barriers to Error Reporting

Many errors go unreported by health care workers.[45] The major concern they have is that self-reporting will result in repercussions.[46–48] Providers' emotional responses to errors inhibit reporting, yet some are relieved when they share the events of the error with patients.[49] Health care professionals report feeling worried, guilty, and depressed following serious errors, as well as being concerned for patient safety and fearful of disciplinary actions. They also are aware of their direct responsibility for errors.[16, 50] Many nurses accept responsibility and blame themselves for serious-outcome errors.[51] Similarly, physicians responded to memorable mistakes with self-doubt, self-blame, and shame.[52] The need of clinicians for support may be fulfilled by discussing their mistake with another person. However, many received support most often from spouses rather than colleagues. Instead of bearing the pain of mistakes in silence, clinicians should admit them, share them with peers, and dispel the myth of perfect practice. However, this support might keep disclosure within the disciplinary culture and practice of medicine rather than bringing mistakes to multidisciplinary teams.

Self-reporting errors can be thwarted by several factors. First, clinicians fear career-threatening disciplinary actions and possible malpractice litigation and liability.[22, 24, 53, 54] Health care leaders who do not protect reporters of errors from negative consequences reinforce this fear,[8, 55] as does the criminalization of fatal health care mistakes.[56, 57] Fear of these negative consequences can lead to reporting errors only when a patient is harmed or when the error could not be "covered up";[58] yet more health care providers are vulnerable to legal action if detailed error reports are documented for events that could formerly be concealed.[27, 28] Additionally, the moral residue of previous mistakes may also restrict disclosure of errors.[59] This residue could be replaced in providers' memories by efforts encouraging reporting in a nonpunitive milieu[60] and incorporating the systems improvements that follow. Clinicians do not want to intentionally harm patients; yet when they conceal errors, they place patients at increased risk of some type of harm.

Second, clinicians working in a culture of blame and punishment do not report all errors, primarily because they fear punishment. A long-held tradition in health care is the "name you, blame you, shame you"[61] mantra. Many organizations have been challenged to provide an environment in which it is safe to admit errors and understand why the errors occurred.[41] Fears of reprisal and punishment have led to a norm of silence. But silence kills, and health care professionals need to have conversations about their concerns at work, including errors and dangerous behavior of coworkers.[62] Among health care providers, especially nurses, individual blame has been the predominant reaction for errors.[63] When individuals and organizations are able to move from individual blame toward a culture of safety, where the blame and shame of errors is eliminated and reporting is rewarded, organizations are enabled to institutionalize reporting systems and increase reporting of all types of errors.[64, 65] To do so, clinicians and others must know that safety can be improved by nonpunitive reporting of error and that organizational flaws cause errors.[1] As communication, collaboration, and safety are inextricably linked in the pursuit of quality care, risk managers, safety officers, and other leaders in health care institutions are encouraging the development of a culture of safety. In a culture of safety, open communication facilitates reporting and disclosure among stakeholders and is considered the norm.[20] Yet even in organizations with a culture of safety, creating a nonpunitive environment is a work in progress.[66]

Third, there is significant variation in how errors are defined, what information is reported, and who should be involved in reporting and mitigating the effects of errors. Differing definitions of errors and near misses and significant differences in reporting—among health care providers working in the same institution and across health care systems—make it difficult to act and prevent similar errors. One of the greatest challenges confronting the patient safety movement is agreeing on standard definitions of what constitutes errors.[67] Reporting near misses can facilitate a blame-free approach (a hallmark of a culture of safety) and fewer cultural and psychological barriers. Yet, clinicians who believe that an error or near miss was unimportant or caused no harm, especially if intercepted, might decide that a report of a near miss is not warranted;[68–70] near misses are not frequently reported.[71]

Lastly, error reports are difficult to complete, and feedback about needed system changes to improve safety is not commonly given.[55] The lack of standardization in the information that is reported and collected makes comparisons and trending as well as preventing future errors difficult. Implementing and using standardized reports of error events, such as those available in hospital databases, is just one example of an open communication strategy, benefiting both clinicians and ultimately the patients they serve.[72] However, the process for reviewing events is not consistently applied nor conducted in matter conducive to providing feedback and improving safety.[73]

These and other barriers to reporting and disclosing errors must be breached to accomplish safer health care.[25] Reporting errors and near misses through established systems provides opportunities to prevent future similar, and perhaps even more serious, errors. Failure to report and speak up about errors and near misses is unacceptable because the welfare of patients is at stake. Investigations into the reporting behaviors of clinicians have found that clinicians are more likely to report an error if the patient was not harmed.[74] Clinicians would also be likely to report an error made by a colleague regardless of patient harm.[74]

Several factors are necessary to increase error reporting: having leadership committed to patient safety; eliminating a punitive culture and institutionalizing a culture of safety; increasing reporting of near misses; providing timely feedback and followup actions and improvements to avert future errors; and having a multidisciplinary approach to reporting.[64, 65] Only through reporting errors can nurses and other health care providers learn which system design and operational failures contribute to human fallibilities and subsequently improve the quality of care. Additionally, one study found that physicians, pharmacists, advanced practitioners, and nurses considered the following to be modifiable barriers to reporting: lack of error reporting system or forms, lack of information on how to report an error, and lack of feedback to the reporter.[75]

Error Disclosure

Disclosure of health care errors is not only another type of error reporting, it is also an account of a mistake. It involves an admission that a mistake was made and typically, but not exclusively, refers to a provider telling a patient about mistakes or unanticipated outcomes. Disclosure addresses the needs of the recipient of care (including patients and family members) and is often delivered by attending physicians and chief nurse executives. However, while physicians' willingness to disclose errors may be stimulated by accountability, honesty, trust, and reducing risk of malpractice, physicians may hesitate to disclose because of professional repercussions, humiliation, guilt, and lack of anonymity.[76]

Disclosure also sometimes calls for a formal verbal apology, in some institutions presented in writing by patient safety officers. Often the providers involved in the error apologize. The central element of disclosure is the trust relationship between patients (or residents of long-term care facilities) and health care providers. Agency policies specify the disclosure approach and identify the person—for example, the primary care provider or safety officer—who communicates the error, adverse event, or unanticipated outcome to the patient or resident, or family member. Some institutions make error disclosure mandatory, and some disclose errors on a voluntary basis.

Providers were concerned about disclosure. They felt shame and fear about their mistakes. "Medical missteps" were transformed into clinical mistakes after practice standards were developed; next, malpractice suits followed. As a result, mistakes were subsequently hidden, creating a negative cycle of events.[72] Furthermore, physicians' anxiety about malpractice litigation and liability and their defensive behavior toward patients have blocked individual and group strategies for preventing and reducing medical errors, thus hindering error reduction attempts.[22] Hiding errors at times resulted in providers being involved in litigation. The association between hiding errors and reducing costs seemed less certain than formerly believed.[29]

When patients' concerns are not addressed, they are more unwilling to return for future care needs[77]and follow medical advice, and are more likely to seek malpractice lawsuits.[78–80] Several surveys of patients and the general public have found that they believe health care to be only moderately safe and that they are concerned about errors affecting them if the seek care in hospitals.[54, 81–84] Specifically, patients are concerned about misdiagnoses, physician errors,[85] medication errors, nursing errors,[77, 85] wrong test/procedure errors, [85] and problems with medical equipment.[77]

Another dimension of reporting and disclosing errors is the role patients can have. Patients can understand, perceive the risk of, and are concerned about health care errors. As more is learned about errors, patients and clinicians have opportunities to improve health care quality. Patients want full disclosure[86] and to know everything about medical errors that impact them. Disclosure can avert patients seeking another physician and can improve patient satisfaction, trust, and positive emotional response to an error, as well as decrease the likelihood of patients seeking legal advice following the error.[87] Patients have the right to know; patients and the public strongly desire disclosure.[86, 87] Failure to disclose mistakes and unanticipated outcomes limits opportunities for evaluation of systems and processes, and for sharing knowledge gained by publishing safety alerts across organizations, conducting educational sessions, modifying practice, and offering opportunities for improved performance.[88] Disclosure is also an element that contributes to the creation of a culture of safety[89] and as such must be accepted as a strategy in health care institutions interested in becoming high-reliability organizations, "those in which error seldom occurs even in dangerous environments"[90] (p. 121).

A significant barrier to disclosing errors is the clinicians' willingness to do so. This may in part be due to the lack of clarity as to exactly what should be disclosed, when the discussion should take place, and who (e.g., a hospital administrator, physician, or nurse) should disclose the error. When it comes to what should be disclosed, research has found that physicians and nurses want to disclose only what had happened,[81] but there are no universal rules for doing so.[86] Decisions to disclose or not to disclose are complex and depend on how errors are defined and if they are recognized or detected. Health care providers are heavily influenced by their perceived

professional responsibility, fears, and training, while patients are influenced by their desire for information, their level of health care sophistication, and their rapport with their provider.[91]

Both health care providers and patients seem to agree that errors disclosure should take place when patients are harmed and that corrective action should involve systems improvement.[91] Other research has found that the likelihood of disclosure increased for physicians, nurses, and emergency medical technicians (EMTs) as the severity of the error increased.[92] Somewhat conflicting with this is the assertion that patients would suffer additional harm when "unnecessary" information was shared about a mistake.[30] Unfortunately, this line of reasoning has its roots in the dubious contention that patients might be more harmed when told the truth as compared with disclosing the mistake.

Physicians have argued that they should be responsible for disclosing errors to the patient.[93] This is borne out in some research that has shown that in practice, at least among emergency care providers, nurses were less likely (23 percent to 54 percent) to disclose an error than were physicians (71 percent to 74 percent).[92, 94]

Because there are instances when error disclosure has been followed by the "victims" seeking further action, the disclosure of errors in practice may not reflect all errors that have harmed patients,[95–97] nor all those that could or should have been disclosed. In many instances, patients may be less likely to seek legal action if the error is disclosed by the physician[82, 83] and if they do not suspect a cover-up.[78] However, it is not known if there is a causal relationship between disclosure of errors and adverse consequences such as litigation.[87]

Disclosure policies. Written policies on disclosing health care mistakes stand to benefit institutions because they can reduce idiosyncratic responses of reporters.[19] Specific policies and systems of error disclosure are preferred over position statements.[98, 99] This is because policies stipulate health care personnel to be notified, patient care to be given following the mistake, and the content of the disclosure notification. Plans to care for the patient are also included. "True informed consent can only be as a result of discussion between a patient and physician"[19] (p. 155). Such a policy fits within a systemwide approach to quality and safety. Underreporting may be addressed by a standardized patient safety event form, integration of databases for event reporting, ongoing education to reinforce the need for providers to report, and patient and family involvement in care delivery processes.[100]

A disclosure policy implemented by the Veterans Affairs (VA) Medical Center in Lexington, Kentucky,[91] resulted in liability payments that were more moderate than such payments at similar facilities. The policy required disclosure to patients of unanticipated outcomes (accidents or medical negligence).[101] This developing, national VA initiative continued its focus on research and policy related to health care error, error-reporting systems and analysis, and feedback methods. Improving systems of care was the target of the ongoing initiative.[102] The VA's disclosure policy included reporting details of incidents, expressing institutional regret, and identifying corrective actions. Comparable liability payments resulted when contrasted with other VA hospitals. Another solution instituted was the granting of a waiver for practitioners who reported errors. Many voluntary adverse event/health care error-reporting systems created for acute care hospitals have built on the VA reporting system.[44] Nonetheless, many health care organizations may not disclose errors to patients,[53] although virtually all have traditionally reported errors through paper incident reports that remained internal and confidential. Error-communication strategies are changing, since several States have mandated that health care institutions notify patients about unanticipated outcomes.[103]

Policies can be supported by advisories, which have historically relied on relatively few contributions from patients. Patients' responses to drafts of advisories were explored best with Medicare beneficiaries.[104] While not specifying advisory content on disclosure of health care errors, recommendations included the involvement of patients and providers. Discussions on patient roles in safety enhancement and the development of protocols for inclusion in safety advisories were encouraged.

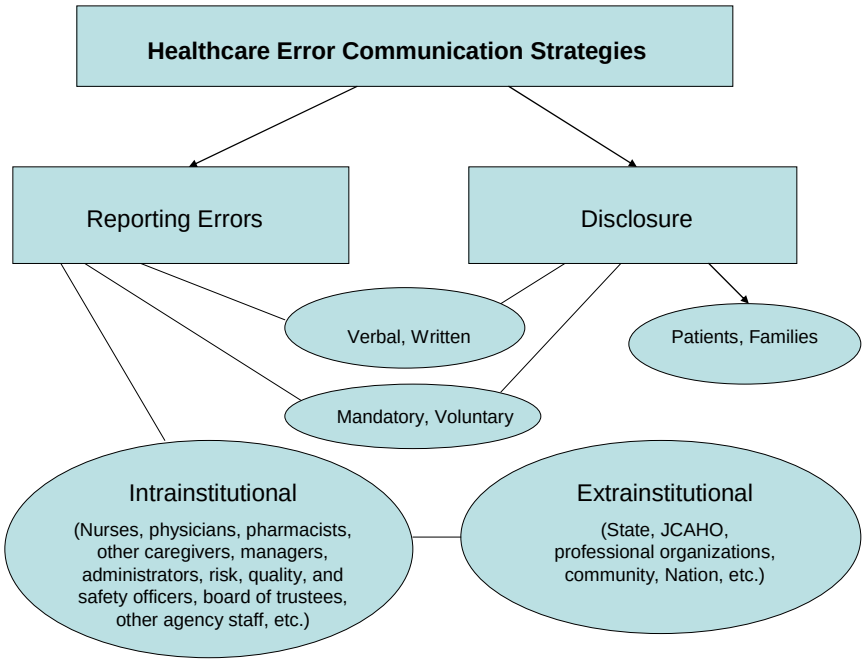
The development and implementation of disclosure policies should be part of an organization-wide effort predicated on cultural change that includes open communication, truth telling, and no blame.[20, 60] Debate regarding the assignment of blame has not negated the importance of counseling some clinicians when policies are intentionally violated—or prosecuted in the case of criminal behavior. Policies on disclosure, including apologies to patients and families, have been justified; respect for patients and their autonomy prevails as a source and support of patients' right to information about health care errors. The aforementioned changes for disclosure policies—for example, open communication, truth telling, and no blame—apply to error-reporting systems as well.

Differences between reporting and disclosure. It is important to place health care error-communication strategies, specifically definitions of reporting and disclosure, in context (see Figure 1). The process of reporting errors is sometimes referred to as disclosure of errors, causing confusion. A report of a health care error is defined as an account of the mistake that conveys details of the occurrences, at times implicating health care providers, patients, or family members in error events. Both clinicians and patients can detect and report errors.[105] Each report of a health care error can be communicated through established and informal systems existing in health care agencies (internal) and outside organizations (external), and may be written (e.g., electronic or paper) or verbal, voluntary or mandatory (policy driven). The core value supporting reporting is nonmaleficence, do no harm, or preventing the recurrence of errors.

An error report may be transmitted internally to health care agency administrators, managers, physicians, nurses, pharmacists, laboratory technicians, other caregivers, and agency legal counsel. Reporting is often directly related to risk management activities intended to prevent actual or potential threats of harm. Intrainstitutional or internal reporting examples are incident reports, nurses' notes, safety committee reports, patient care rounds, and change-of-shift reports. Intrainstitutional reports have increased since the initial IOM report and the elimination of the culture of blame in many health care agencies. Of these, the most common means of reporting serious errors for nurses has been through incident reports, a mechanism that has been criticized as being subjective and ineffective in improving patient safety.[106, 107]

Extrainstitutional or external reporting systems include accounts submitted to agencies such as the Medical Event Reporting System for Transfusion Medicine (MERS-TM), MERP, the Joint Commission, and various State departments of health, as well databases such as United States Pharmacopeia's MEDMARX® Reporting System (U.S. Pharmacopeial Convention 2006), as illustrated in Figure 1. Additional reporting methods have been called for, such as databases that allow for analysis and communication of alerts to key stakeholders in single agencies and across systems.

Figure 1. Heath Care Error-Communication Strategies



Reporting (providing accounts of mistakes) and disclosing (sharing with patients and significant others) actual errors and near misses provide opportunities to reduce the effects of errors and prevent the likelihood of future errors by, in effect, warning others about the potential risk of harm. Reporting reduces the number of future errors, diminishing personal suffering[108] and decreasing financial costs. In contrast, disclosure is thought to benefit patients and providers by supplying them with immediate answers about errors and reducing lengthy litigation.[109] Although clinicians and health care managers and administrators feel uncomfortable with disclosure, disclosure is a duty.

Error Reporting and Detecting Strategies

Several strategies have been used to improve error reporting. In a literature review of incident-reporting research published between 1990 and 2000, the effectiveness of chart reviews, computer monitoring, and voluntary reporting were compared. The investigators found that the most adverse drug events were identified through chart reviews; the least effective method was voluntary reporting. The most efficient method of understanding errors was computer-based monitoring because more adverse drug events were found than with voluntary reporting and it took less time than chart reviews.[110]

A strategy tested in another project, developed within a hospital, used an electronic, anonymous paper report to increase close call (i.e., near miss) incident reporting. Close call categories included blood/transfusions, diagnostic tests/procedures, falls, medications, other treatments, surgery, and therapeutic procedures. The final template included five main screens and was received very positively by providers. A clinical analyst assisted in communicating feedback and describing the etiology of close call situations, and urgent close calls were rapidly

communicated. The investigators found that improved reporting systems may encourage providers to report near misses. Once identified and shared with front-line providers, errors may be prevented.[111]

Several Web-based systems have also been used in hospitals to improve error reporting. One study investigated reported errors, intercepted errors, and data quality after a Web-based software application was introduced for medication error event internal reporting. The reporting system generated occurrence reports, documented anonymously submitted reports, and allowed for the possibility of real-time reporting and more rapid investigation of contributing factors. The investigators found that error reports increased as well as intercepted error threats (near misses), and intercepted nurse, physician, and pharmacist medication errors increased. The details of cause-of-error reporting also increased as did the participation of hospital leadership.[112] In another study, Wu and colleagues[113] described the use of Web-based internal reporting in the intensive care unit setting. The researchers found that analyzing and disseminating error and near miss data, so that providers are alerted to safety risks, could reduce errors. Additionally, patient safety would most likely improve when providers see the benefits of reporting through systems improvements.[113] One other project occurred when leaders at Baylor Medical Center at Grapevine partnered with DoctorQuality to create a Web-based form for reporting errors.[114] At the same time, they implemented strategies to change the culture of the organization, supported by education on the use of the reporting system, incident reporting, communication, and feedback information about errors. Investigators found that event reporting doubled, suggesting that even with increased reporting, the actual number of errors may not be identified. Proactive risk management allowed for timely followup, the percentage of errors submitted increased after implementation, and the average days from event to submission shortened.[115]

Using a voluntary, regional external reporting database and United States Pharmacopeia's MEDMARX® database increased medication error reports across critical access hospitals.[116] Most errors reported to the regional database and MEDMARX® did not result in harm to patients. However, significant differences existed in severity, phase, and types of error when comparing the two external reporting systems. More error reports from the critical access hospital database (Nebraska Center for Rural Health Research) reached patients than did MEDMARX® errors. Increased reporting of potential and near-miss errors by nursing and pharmacy personnel was associated with easily accessible pharmacist availability.

Another strategy to improve awareness of errors is the assessment of medical records to detect errors that were not otherwise reported. Two prospective, cross-sectional studies compared facilitated incident monitoring to retrospective review of patient medical records in hospitals. The first[117] compared medical record review to physician reporting prompts by daily electronic reminders for 3,146 medical patients in an urban teaching hospital. The investigators found that the physician reporting method identified nearly the same number (2.7 percent) of adverse events as did the retrospective medical record review (2.8 percent), but the electronic reminders detected more preventable adverse events (62.5 percent vs. 32.9 percent), was less costly than the record review ($15,000 vs. $54,000), and could be integrated in the daily routine through electronic health information technology. The second, smaller study[118] compared facilitated discussions to medical record review in one 12-bed intensive care unit (ICU) with 164 patients in an Australian hospital with an established incident reporting system. The investigators found that facilitated discussions, in addition to the incident reporting system, identified more preventable incidents than retrospective medical record review and was not as resource intensive

as medical record reviews (50 hours vs. 65 hours). However, medical record review detected some incidents not captured by the incident reporting system.

Research Evidence

Over the past 11 years, research on the reporting of errors among nurses targeted four key areas: (1) description of who reports errors and what errors are and perceived to be reported; (2) barriers to error reporting; (3) disclosure preferences; and (4) reporting systems and frameworks, including the development of effective reporting systems. The researchers used different methods to assess reporting preferences and what was reported, including surveys, retrospectively assessed error reports,[116, 119–128] a 2-week journal,[129] error scenarios,[81, 92, 130] and focus groups.[91, 131, 132] One study used a mixture of methods.[58] Most of the research included in this analysis involved discussions of reporting involving health care providers using existing systems, while 11 studies assessed the effects of new or revised error-reporting systems.

Who Is Reporting

Verbal, paper-based, electronic, and Web-based error-reporting mechanisms have been used to capture, record, and communicate errors. Nurses were found to report the majority of errors. The proportion of error report submitted by nurses ranged from 67.1 percent[133] to 93.3 percent.[124] Nurses reported 27 percent more errors than did physicians.[134] Physicians submitted 2 percent[135] to 23.1 percent, and 9.5 percent were submitted by others.[133] Considering the 11 surveys included in this analysis that investigated who submitted error reports, all found that nurses reported the majority of incident reports.[36, 46, 106, 120, 123, 124, 133–137]

Factors that have influenced the submission of error reports included believing it was beneficial to do so[131] and having quality management processes in place.[138] Feeling comfortable reporting, working in a climate of patient-centered care, job satisfaction, and the serious nature of the error enabled error reporting.[131] In terms of characteristics associated with those likely to report errors, nurses with more than 5 years of experience were more likely to believe there was no value in reporting near misses.[106] This contradicts findings from another survey where the frequency of error reporting was found to be higher among nurses with 5 to 10 years of experience.[139] Another finding that complicates this notion is that in one survey, nurse managers reported more errors than did staff nurses,[139] but this could have been associated with organizational structure rather than ability of staff nurses. Additional characteristics were that nurses providing direct patient care were more likely to report,[140] and that pediatric nurses reported medication errors more frequently than adult nurses.[141]

Compared to physicians, nurses seemed to have more knowledge/awareness of the reporting process/system,[106, 132] know what should be reported,[69, 142] know when the error should be reported,[142] be more likely to have submitted an error/incident report, know how to use an incident report form, and know where to submit the report.[106] One survey found that while 98.3 percent of physicians and nurses knew about incident reporting systems within their organizations, nurses were more likely to know how to submit an error report, have experience with submitting an error report, and know where to submit the report.[106] Another survey found that 54 percent of residents and 97 percent of nurses knew about their hospital's error-reporting system, and 13 percent of residents and 72 percent of nurses were likely to use the reporting system.[143] Conversely, another survey found that less than 10 percent of physicians and nurses

were aware of their State's mandatory reporting system, and only a small subset of the ones familiar with the system (less than 50 percent of nurses and 20 percent of physicians) had actually submitted a report using the mandatory system.[144]

Who reported was also be associated with their understanding of what should be reported. One survey of medication administration errors found that nurses acknowledged differences in how reportable errors were defined among staff.[145] Similar findings were found in another survey of nurses in Korea, where nurses were not clear as to what should be reported.[139]

Nurses tended to be more likely to report errors, considering it a professional obligation. One survey of nurses in rural hospitals found that nurses believed they were responsible for reporting errors, getting needed education, recommending changes in policies and procedures to prevent future errors, and participating in investigations of the causes of errors.[58] Another found that physicians believed that nurses were responsible for reporting errors.[144] Similar findings were found using error scenarios, where nurses believed that error reporting was a professional responsibility and that nurses should report the errors made by other nurses if they did not do so themselves.[130] However, another survey found that nurses were more comfortable reporting their own errors than they were of those of colleagues.[146] Another found that 54 percent of residents and 91 percent of nurses believed that they would report their own error or someone else's, and 25 percent of residents and 1 percent of nurses would report the errors of others if they did not like the person who caused the error.[143]

What Is Reported

What is reported could depend upon the understanding of nurses as to what should be reported, which is associated with how reportable errors and near misses are defined. If nurses, nurse managers, and physicians question the value of reporting because they did not see improved patient safety in practice and policies,[132] few errors may be reported. If nurses did not understand the definition of errors and near misses, they were not able to identify or differentiate errors and near misses when they occurred. For example, one very small study gave four error scenarios to 13 perioperative nurses to assess whether they could detect errors and their reporting preferences. The investigators found that 58 percent of the theoretical errors were identified as errors, but only 26.7 percent of them would have been reported.[130] However, when nurses were given definitions of errors and near misses, one study indicated that nurses reported 58 percent of errors and 59 percent of near misses.[129] Among the respondents, 61 percent reported one error and 38 percent reported making between two and five errors during a 2-week period.

The severity of errors and who is doing the reporting influence which errors are reported. One survey found that 58 percent of nurses did not report minor medication errors.[69] Another survey found that while nurses reported 27 percent more errors than physicians, physicians reported more major events and nurses reported more minor events because they had a more "inclusive view." Both physicians and nurses reported near misses.[134] Analysis of error reports in Japan found similar differences in error reporting among different types of clinicians. One study found that nurses and pharmacists submitted more reports of events that were considered minor, while physicians submitted reports when errors were detected and prevented by nurses or pharmacists.[123] The other study of error reports submitted by physicians and nurses in a hospital found that 99.5 percent of the reports—the majority of which were submitted by nurses—were for what were considered minor incidents. Additionally, the lag time for reporting major events

was 18 percent shorter than it was for minor reports, but 75 percent longer when physicians submitted the error report.[124]

Several surveys assessed whether errors that resulted in harm to patients were reported. One survey of physicians and nurses in England found that error reporting was more likely if the error harmed a patient, yet physicians were less likely to report errors than were nurses or midwives. Clinicians were less likely to report errors made by senior colleagues, and physicians in particular were unlikely to report violations of clinical protocols, whereas nurses and midwives would.[46] A review of error reports found that when an error harmed a patient, 34 percent of the reports were submitted by physicians and 27 percent of the reports were submitted by nurses. When errors did not harm patients, 31 percent of the reports were submitted by nurses and 17 percent were submitted by physicians.[133] One survey found that nurses would report errors whether they harmed the patient or not.[140] A survey in Korea found that 67 percent of nurses believed they always reported errors that harmed patients.[139] A very small study found that reporting errors that harmed patients was a secondary concern for nurses; nurses believed that errors that fell outside the scope of the nurse's practice should be reported by the responsible individual (i.e., not the nurse).[130] A related study found that errors resulting in either patient harm or worker injury were underreported.[138] Thus, events that may harm patients are at risk for not being reported.

What is reported may also be associated with whether the reports are confidential or anonymous. Informal reporting mechanisms were used by both nurses and physicians. One survey found that nurses also informally reported to physicians when a dose was withheld or omitted, but they were less likely to formally report the missed dose as an error.[142] Nurses also had a greater tendency to informally report errors to nurse colleagues.[130] Reviewers found that confidential reports were more complete than anonymous ones, but the types of patient harm did not vary between anonymous and confidential reports.[121] Since voluntary reporting depends on health care professionals to report medication errors so that the more realistic frequency and type of errors that happened can be known, several surveys encouraged anonymous responses to identify the barriers to reporting medication administration errors.[58, 69, 142, 147–149] While only brief descriptions of the survey instruments were discussed in each of the studies, the surveys did capture error reports that may not have been communicated or known otherwise.

Type of Errors Reported

An analysis of error reports found that the most serious reports involved rule violations, management practices, and nonstandardized nursing practices.[125] One study found that the majority of error reports involved delays or omissions of medications, diagnostic tests, or necessary/planned procedures; medication errors, and malfunctioning equipment. Ten percent of the reported errors required life-sustaining interventions (61 percent of which resulted from delays/omissions of prescribed nonmedication treatments and necessary planned procedures), and 3 percent might have caused the patient's death.[137]

In a study of surgical ICUs, the type of events reported were related to medications, tests, treatments, or procedures.[136] Researchers in another study found that 47 percent of reported errors were associated with diagnostic tests, 35 percent with medications, and 14 percent with both diagnostic tests and medications. The investigators believed that 71 percent of these errors were associated with communication breakdowns.[121] One study found that nurses generally were more likely to report patient falls than pressure ulcers or near-miss medication errors, and nurses

with fewer than 5 years experience were more likely to report deep vein thrombosis.[106] Another retrospective analysis of error reports in six Japanese hospitals found that reported error rates were high for prevention of problematic behavior, patient suicide, patient falls, and subcutaneous injections of insulin. A high number of error reports in some hospitals were associated with maintenance of dialysis, endoscopy preparation and assistance, administration of preoperative treatments, and blood transfusions. There were more reported errors in the elderly, hemodialysis patients, and those with problematic types of behavior.[125] Another study found that the major types of errors reported were for unsafe conditions or near misses, adverse events that harmed patients, medication/infusion errors, and patient falls.[135] In yet another study, researchers found that the majority of reports involved medication errors, surgical errors, falls, and problems with procedures.[127]

Additionally, the type of errors reported can be associated with characteristics of the patient population. For example, the findings from one survey indicated that medication error rates, which were computed from actual occurrence reports, were higher on pediatric units than adult units.[141] Children's vulnerability to adverse outcomes from medication errors was attributed to weight-based drug dosing, dilution of stock solutions, and immature physiological buffering systems, situations that are unique to children.

Estimations and Perceptions of Error Reporting

Several surveys asked nurses to estimate how many and what types of errors were reported by colleagues and themselves. There was significant variation when nurses were asked to estimate how many errors were reported. Respondents in one survey estimated that an average of 45.6 percent of errors were reported.[142] Nurses may not easily estimate how many errors are reported, as indicated in one study where staff nurses were not consistent estimators of medication administration errors.[145] Another study of medication errors in 29 rural hospitals in nine States found that less than half of nurses believed that all medication errors were reported,[58] while another study found that 44 percent of nurses estimated that 25 percent of medication errors were reported.[69] Another survey found that nurses estimated that less than half of all medication administration errors were reported,[138] an estimate that is lower than those in other surveys.[70, 150–152]

Estimation may also reflect where one works as well as one's experience. In terms of where nurses work, one survey found that nurses working in neonatal ICUs perceived higher reported errors than did those working in medical/surgical units. The mean perceived percentage of reported errors was 46 percent.[142] Another survey found that pediatric nurses estimated that 67 percent of medication errors were reported, while adult nurses estimated 56 percent. The stronger the agreement with management-related and individual/personal reasons for not reporting errors, the lower the estimates of errors reported by pediatric nurses.[141] In terms of experience, one survey found that staff nurses relied on personal experience to estimate medication administration errors on their unit.[145]

Other surveys investigated what nurses thought should be reported. One study divided nurses into high- and low-reporting rates; groups differed by definition of what makes up a reportable error, by personal experience when estimating unit error reporting, and by willingness to share occurrence data with other nurses. Also, nurses were surveyed on the perspectives of types of errors that should be reported, the proportion of errors reported, worker safety, and opinions about the work environment and job satisfaction.[138] Although nurses indicated that all errors

except near misses should be reported, less than half of medication administration errors were reported. Intravenous medication errors were the highest percentage reported events; patient falls were associated with major injuries. Not reporting medication errors was attributed to nurses' concerns about administrative responses and personal fears such as imagining the poor opinion of their coworkers. Sharps injuries, exposure to body fluids, and back injuries threatened nurse safety. Some questioned hospitals' quality management processes.

The perceived rates of error reporting may be associated with organizational characteristics. For example, the perceived rates of medication administration error reporting were compared by organizational cultures of hospitals and extent of applied continuous quality improvement (CQI) philosophy and principles.[151] As bed size increased, perceived rate of medication administration error reporting decreased. Larger hospitals tended to be more hierarchical in nature. Group-oriented hospital culture (norms and values associated with affiliation and trust, flexibility, a people-oriented culture with concerned and supportive leadership) and higher levels of CQI implementation were positively associated with the estimated overall percentage of medication administration errors reported.

Perceived Barriers to Reporting Medication Errors

There were 15 identified studies that surveyed nurses about their perceptions of what factors (e.g., organizational, process, individual) precluded them from reporting errors. Fourteen of these studies used cross-sectional surveys of nurses,[69, 70, 106, 120, 131, 138, 141, 142, 147–151, 153] and all but one of the surveys[131] were in hospitals. Of the two studies that used focus groups, one interviewed clinicians in 20 community hospitals,[132] the other in ambulatory care settings.[131] Several themes emerged from these studies, as illustrated in Table 1. The types of responses given by nurses may have depended upon the questions asked, but that is not known. In all, research findings seem to indicate that, as Wakefield and colleagues[151] found, the greater the number of barriers, the lower the reporting of errors.

One survey of nurses in the Midwest found that nurses were able to recognize errors and events associated with intentional wrongdoing related to questionable behavior. Nurses were more apt to report serious errors but not unintentional errors.[153]

Other clinicians are concerned about reporting barriers as well. In one survey of physicians and nurses, physicians identified twice as many barriers to reporting than did nurses; both identified time and extra work involved in documenting an error. However, nurses were more concerned about anonymity, "telling" on someone else, fear of lawsuits, and the necessity of reporting errors that did not result in patient harm.[149]

Additional barriers were identified as well. One survey in a State with mandatory reporting found that both physicians (40 percent) and nurses (30 percent) were concerned about the lack of anonymity of reports and that the reports would be used punitively against the individual who submitted the report.[144] Another survey of nurses in Korea found that 32 percent were worried that their errors were kept in files; 66 percent felt that their suggestions to improve patient safety were ignored; 83 percent felt that it was by chance that more errors did not happen; 52 percent believed their units had serious patient safety problems; and 56 percent reported problems talking with physicians.[139]

Table 1. Reasons why clinicians do not report and disclose errors and near misses

Reporting Barriers
Fear
Fear[69, 138, 148, 150, 151]
Fear of being blamed for negative patient outcome[70, 147]
Fear other providers will consider provider who made the error incompetent[70, 138, 141, 142, 147]
Fear of reprimand from physician(s)[70, 147, 148]
Fear patients will develop negative attitudes[70, 147]
Fear of legal liability, belief that disclosure of errors to patients results in lawsuits[149]
Fear of "telling" on someone else[149]
Fear of adverse consequences from reporting[70, 141, 147, 148]
Fear of reporting that is not anonymous[149]
Understanding
Confusion over definition of errors and near misses[70]
Disagreement with the organizations' definition of error[70, 148, 151]
Providers unaware that errors occurred[70, 142, 147]
Providers' bias about which incidents should be reported[70, 149, 153]
Some incidents, i.e., near misses, thought too trivial/unimportant to report[106]
No perceived benefit[131, 149]
Administrative/Management/Organizational
Administrative response[138, 142, 148, 150, 151]
Lack of feedback on reported errors[70, 120, 147, 148]
Persistence of the culture of blame/shame, blaming the individual[70]
Excessive emphasis on medication error rates as quality measure of care[70, 147]
Poor match of administrative response to errors with severity of errors[70, 148]
Burden of Effort[148]
Incident reports take too long to complete[70, 131, 147, 149, 151]
Verbal reports to physicians take too long or contacting the doctor takes too much time[70]
Providers forget to make a report, too busy[106, 131]
Extra work involved in reporting[149]

Five studies provided additional information about reporting barriers for nurses. In a survey of nurses in Taiwan, nurses did not vary in their concerns about the effects of reporting barriers based on factors such as the age of the nurse, type of education, length of experiences, and length of employment. Yet nurses who perceived more error reporting barriers also believed that errors were over- or underreported, compared to nurses who reported that the error reporting rates were accurate. In this study, factors that could thwart error reporting were positively correlated with the power hierarchy and face-saving concern. On the other hand, the better the work environment, quality management, and relationships with peers, the fewer the perceived barriers for error reporting.[147]

Factors about the organization's culture may be barriers to error reporting. In one survey of clinicians in rural hospitals, the majority agreed that hospital administrators did not punish error reporters. Most agreed that the hospital culture recognized that mistakes could be made (64 percent) and that error reporting could be done by all employees (86 percent). The majority felt comfortable (65 percent) or somewhat comfortable (32 percent) discussing medical errors, and

have learned and would like to continue to learn from the mistakes of others. Attempts to maintain collegiality and their belief about lacking authority prevented nurses from questioning physicians. Nonphysicians attributed many errors to nursing practices. In fact, if an error occurred, 96 percent of nurses and more than 90 percent of physicians, administrators, and pharmacists would have assigned patient safety responsibility to nurses. Only 22 percent of respondents believed that clinicians and administrators shared equal responsibility for patient safety.[58]

Three studies by Wakefield and colleagues[70, 150, 151] asked nurses about organizational and leadership/management factors that could thwart error reporting. Staff nurses believed that having an organizational culture that did not support error reporting[70] and management practices and beliefs (e.g., supervisors not viewing fear of an administrative response as a barrier to error reporting)[150] thwarted error reporting. Wakefield and colleagues[151] found in another survey that hospital culture types varied; smaller institutions tended to have group-oriented cultures while larger institutions tended to be more hierarchal (which was negatively associated with error reporting). They also found that the extent of CQI implementation increased with bed size of the hospital, and perceived rate of medication administration error reporting decreased. Considered together, the presence of a group-oriented culture and higher levels of CQI implementation were positively but not significantly associated with reporting errors.

One study surveyed physicians and nurses about barriers that could be modified to enable error reporting. The modifiable barriers they identified were the structure and processes for reporting errors and the lack of education about errors. The least modifiable barriers they reported were fear of lawsuits, fear of being blamed, and motivational issues.[149]

Error-Reporting Strategies

Thirteen studies investigated the effects of new and revised error-reporting systems on error reporting. Investigators examined a clinical pharmacist on units;[119] education, a revised reporting system, and a call center;[120] a voluntary reporting system;[121, 122] a voluntary system for near misses;[154] a voluntary, paper-based reporting system;[133, 136, 137] a confidential, electronic-based reporting system;[135] education enhanced by error report summaries;[115] education of nurse case managers;[126] a Web-based anonymous reporting system;[112] and confidential peer interviews.[36] Only one study assessed the impact of mandatory error reporting.[144]

Three of the studies introduced an “expert” to assist providers in detecting errors. In one, a clinical pharmacist was introduced on units to improve medication safety and increase medication error reporting as well as error reporting generally. Error reports remained relatively constant, yet error reports from physicians decreased. The severity of errors decreased over time, and the reporting of near misses increased from 9 percent to 51 percent.[119] Another study introduced an “expert peer” to prompt assessment of patients, using confidential peer interviews during morning rounds or via e-mail. Verbal reports of errors were confirmed with the patient medical records, but only one incident report was submitted by a house officer for a patient fall. Nurses submitted the majority of incident reports for errors involving patient slips and falls, medication errors, and other events.[36] In the third study, a hospital introduced nurse case managers to review patient medications, detect adverse drug events (ADEs), and report detected ADEs. Once the nurse case managers began reviewing medications and submitting ADE reports, the majority of which were for serious ADEs and possible ADEs, the reports of ADEs nearly doubled.[126]

Researchers in one study provided error reporting education to staff, revised their current reporting system, and introduced a call center. As a result, reporting increased throughout the hospital—more physicians in the emergency department and more nurses in medical units submitted error reports—and there were more anonymous reports compared to the hospital used as a control. More reports were submitted using the one-page form than through the call center. Nurses continued to submit the majority of reports.[120]

One study aimed to improve error reporting through educational initiatives in 10 critical access hospitals. The investigators conducted several education workshops about the nature of errors, the design of safety systems, and best practices in medication safety. Then they collected error reports from all the hospitals and provided quarterly reports from the error reports to each of the hospitals, including the results and averages from the group of hospitals. The investigators found that most of the errors were not harmful and were associated with medication administration, mostly for dose omissions. The reports helped hospitals identify and address systems factors that were conducive to errors.[116]

Five studies tested the effects of new, voluntary error-reporting systems. One study assessed the impact of introducing an error-reporting system in community, primary care research networks. Investigators found that the number of reports increased, but the confidential reports were more complete than the anonymous ones.[121] Another study also found that error reports increased after the introduction of a voluntary reporting system, that nurses submitted the majority of the errors reports, followed by pharmacists, and physicians submitted an error report only if the error was detected and prevented by the nurse.[122] A teaching hospital in New York implemented a new confidential, electronic-based error-reporting system along with an educational program. Investigators found that error reporting increased, but reporting remained low among physicians.[135] Another study assessed the effects of introducing a new Web-based anonymous reporting system. Investigators found that error reports, including those for intercepted errors, increased, and errors attributed to physicians increased while those attributed to nurses and pharmacists decreased.[112] The last of these five studies assessed the impact of using a voluntary reporting that called near misses, "close calls" and frequent feedback reports. The investigators found that after six months, the number of error reports increased by 1,468 percent.[154]

The association between voluntary error reporting and the number of error reports submitted was tested in two prospective, interrelated studies, using paper-based SAFE (Safety, Actions, Focus, Everyone) cards. One tested these cards in the medical ICU,[137] the other in the surgical ICU.[136] The SAFE report card was used over a period of 6 months to document types of events, including errors in tests, treatments, and procedures; medication; equipment; blood products; intravenous complications; behavioral/psychiatric; laboratory; surgery; and falls. This new reporting system resulted in more reported events (232 events) than what was captured by the existing hospitalwide database used to register errors and high-risk events (29 events before and 26 events during the intervention). The investigators believed that the system fostered reporting by unit team members and could reduce events proactively through improved practice.[136] The second study used similar methodology and added an additional step: the cards were withdrawn then reintroduced. The cards were reintroduced once the investigators assessed the significant drop in error reporting. The initial use of the cards increased nurse and physician reporting. After the cards were withdrawn, there was a decrease in reports by both nurses and physicians; instead, there were an increased number of reports submitted to the hospital electronic reporting system by nurses. The investigators found that a higher proportion of events reported by physicians were

for events that resulted in patient harm, whereas the higher proportion for nurses was for events that did not result in patient harm.[136] In both studies, nurses submitted the majority of reports and physician reporting increased.

Disclosure Preferences

Five studies investigated factors associated with disclosure preferences of nurses. Two studies investigated disclosure preferences of patients and clinicians. In one of these studies, which used surveys with error scenarios, patients reported wanting full disclose of errors, yet physicians and nurses wanted to disclose only what happened.[81] In the other study, which used focus groups, patients and clinicians agreed that errors should be disclosed when the patient was harmed. The degree of harm caused by errors and whether patients and others were aware of errors were related to disclosure preferences. Institutional culture (perceived tolerance for error and supportive infrastructure) was important to the disclosure decision. Relevant patient factors were health care sophistication, desire for information, and rapport with provider. Provider factors included fears of malpractice, reputation, job threat, and change in rapport with the patient, as well as perceived professional responsibility, medical training, lack of confidence in disclosure skills, and personal discomfort.[91]

Three studies used surveys to investigate disclosure preferences of EMTs, physicians, and nurses. In one study that specifically asked only nurses, nurses reported that they were less likely than physicians to want to disclose errors.[81] Another survey found that 74 percent of physicians, 23 percent of nurses, and 19 percent of EMTs had disclosed errors.[95] Physicians were also more likely to disclose (71 percent) an error than were nurses (59 percent), but nurses (68 percent) were more likely to report an error than were physicians (54 percent).[92]

Another survey found that 29 percent of physicians and 64 percent of nurses reported feeling comfortable discussing mistakes. Also, 42 percent of physicians and 44 percent of nurses reported feeling uncomfortable discussing errors with patients.[143]

Evidence-Based Practice Implications

Given the history of error reporting and the role nurses have in patient care, it is important to emphasize that nurses are pivotal in improving patient safety via error reporting. Patient safety will improve when systems effectively assure and improve safety, predicated on a culture in which the reporting of errors or near misses is considered valuable, and positive actions lead to study and change for improvement, not blame.[155] To avert underreporting of errors and to effectively learn from errors, administrators in health care agencies need to develop policies that support the routine reporting of errors, so that increased numbers of reports of actual errors and near misses are rewarded on an individual or unit basis. By easing the transition of an institution to a culture of safety, eliminating blame and the pressure of a punitive environment, error reporting will most likely increase. Additionally, it is evident that caregivers and patients profit from detailed accounts and increased reports, specifically in hospitals that act on unsafe practices identified through analysis of error reports. Systems improvements need to be communicated with all stakeholders so that they benefit from seeing the feedback loop in action.

Ethical principles—including beneficence, fiduciary responsibility, respect for autonomy, justice, and honesty—guide clinical practice and mandate reporting and disclosure.[156] These principles guide safety efforts and must be espoused by administrators and providers. Improved

safety practices begin with policy and procedure development and continue with the allocation of resources for developing reporting systems and databases as well as educating caregivers.

New systems of reporting errors are generally developed in-house or purchased by health care agencies. Electronic systems that are Web-based—that include easy reporting and standard definitions of errors, near misses, and potential root causes as well as personnel responsible for analyzing and sharing safety hazards—provide opportunities for data management and pattern identification of unsafe practices. They also save time for providers as reports are entered into databases and help to shorten the time from incident to report. Developing new systems of reporting requires administrators to budget accordingly so that additional personnel and electronic reporting systems as well as complementary software are financed. Periodic training of personnel and upgrading reporting databases are necessary, as are systems improvements that depend on error-report analysis.

Patients and families desire disclosure of health care errors by health care providers. Providers have an ethical responsibility to disclose. Generally, organizations use verbal reports, followed by written reports offered by patient safety officers, in consultation with agency attorneys, in accord with institutional reporting and disclosure policies. Refusing to disclose suggests fear and a need for provider control rather than patients' and families' need for honesty about their care. Disclosure policies must be created with honesty and respect for patient autonomy in mind; apologies must be required.

The emotional responses and perceptions of caregivers about errors are important barriers to reporting. Providers consider themselves at risk when they report errors because many providers carry the residue from previous experiences with mistakes. Anger from coworkers, shame, lack of confidence, and the like combine with guilt about the suffering of patients and fear of potential litigation to hinder reporting and disclosure. Nurses respond similarly to errors as physicians. They feel vulnerable to disciplinary action and legal repercussions; thus errors go underreported. Providers must experience changes in institutional culture, where systems improvements are targeted rather than individual blame.

Teamwork training improves error reporting and reduces clinical errors. Teamwork principles include increased communication among health care providers. One element of a teamwork training program, cross-monitoring, might result in decreased errors as providers observe each other, identify unsafe behaviors, and act to correct each others' mistakes. Status barriers must be penetrated. Cross-monitoring involves interdisciplinary/caregiver observations, identifying unsafe behaviors, and acting to correct unsafe behaviors. The challenge is how this team training element might be successfully initiated and consistently reinforced in acute care hospitals, critical access hospitals, nursing homes, long-term care facilities, and other agencies. Along these lines, nurse educators are challenged to include teamwork strategies and exercises aimed at increasing safety practices in health care agencies in undergraduate and graduate nursing courses, taking into account content on existing status issues among health care providers.

Research Implications

The majority of the research on error reporting has occurred within the past 10 years. While the studies included in this analysis provide important insight into what is being reported, they were primarily descriptive and none were nonrandomized or randomized controlled trials. Thus, additional well-designed studies are called for. Teamwork training holds promise as an

intervention that might affect frequency and severity of reported errors. Emphasizing cross-monitoring and increased communication as team training strategies might also affect outcomes. Teamwork training could include scenarios that challenge clinicians to determine how and what to report. Multisite team training programs should be investigated. The benefit of team training is in the development of expertise in reporting and disclosure among front-line providers. However, additional research is needed on the effect of team training on error frequency and reporting and disclosure skills, especially among nurses. Examples of research questions might be, Are there differences in patient and family member satisfaction when disclosure of errors is provided by team-trained versus usual-approach health care providers? Does team training affect error and near-miss reporting rates?

Additional studies could be conducted in which disclosure of errors to patients and families is linked to differences in outcomes, for example, claims reports and monetary awards. More research is needed on the impact of Web-based reporting systems on time used for reporting via data entry, time from incident to report, time to systems improvement, as well as a classification of systems improvement strategies and the effect of strategies on error outcomes. Examples of research questions might be, Are there differences in severity scores following errors when Web-based versus incident-report methods of reporting are used by health care providers? Are there differences in frequency of error reports when Web-based versus incident reporting systems are used? Comparisons also might be made between physician and administrator methods of disclosure to patients and families in which simplicity or complexity of disclosure events are examined. Examples of research questions might be, Are there differences in patient and family satisfaction when physician/administrator disclosers are trained using standard, simple script versus unscripted (usual) disclosure communication approaches? Are there differences in the number of liability claims and monetary awards when mandatory versus voluntary disclosure policies are used?

Notable in the reviewed literature was the dearth of studies on reporting and disclosure regarding the variety of adverse events, for example, blood transfusion errors, device malfunctions, health care acquired infections, and others. Most addressed were medication errors. Data are needed across all settings; most research on reporting is hospital-based. Community settings, nursing homes, free-standing short-procedure units, and primary care offices also require additional study regarding error reporting and disclosure. Consequently, there are many research opportunities for nurse investigators. Research is needed describing initial patterns of errors across various settings and focusing on other events, including blood transfusions, surgical incidents, device malfunctions, etc. Comparisons might also be made in liability lawsuit statistics between institutions that have disseminated and acted on the no-blame cultural approach versus those that have initially instituted this approach.

Conclusions

Sustained and collaborative efforts to reduce the occurrence and severity of health care errors are required so that safer, higher quality care results. To improve safety, error-reporting strategies should include identifying errors, admitting mistakes, correcting unsafe conditions, and reporting systems improvements to stakeholders. The greater the number of actual errors and near misses reported, the more reliable a health care organization or system could be, from a safety viewpoint, when systems improvements are consistent with error patterns.

Clinicians appreciate seeing the results of the reports they submitted transformed into systems improvements. Understanding and communicating the root causes of errors and near misses can decrease the risk of future errors, and support the concept that health care errors are often systemic and multifactorial. Reporting errors and near misses may increase through voluntary reporting systems, because voluntary systems provide additional evidence that the blame/shame patterns are being eliminated in health care organizations and systems.

Electronic error-reporting systems can possibly make the time required to report shorter, shorten the time for correcting unsafe conditions, and alert providers to emerging unsafe patterns. Some systems can also facilitate quality improvement initiatives through enhanced error-reporting systems. The benefits of Web-based health care reporting systems that clinicians find easy to use and see the effects of their reporting in changes to systems might ultimately reduce the incidence of serious errors, and significantly improve the safety and quality of health care afforded patients.

Search Strategy

Various databases were searched to locate studies and related literature on reporting and disclosing health care errors, including CINAHL®, PubMed®, and Psycharticles. Search terms included "medical errors" and "medical error reports." Published results in a non-English language, expert opinions, case reports, and letters were excluded. Studies specifically assessing rates, types, and causes of reported medication administration errors were excluded as well. To be included in the analysis, each article had to involve nursing and report findings specific to nurses. Most of the articles identified in the literature search were primarily descriptive.

Evidence Table

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Balas 2004[129]	Error reporting Reporting near errors	Cross-sectional study	Qualitative, voluntary, anonymous, self-reported recording of 14-days of shift work, sleep, and errors using a journal (Level 4)	119 full-time hospital registered nurses (RNs). Note: subset of the larger study with 393 full-time RNs described in other articles.	None	58% of reported errors and 59% of near misses were medication related. 73 nurses reported 1 error, while 45 reported making between 2 and 5 errors during the study period.
Blegen 2004[138]	Barriers to reporting medication administration errors (MAEs) and near misses	Cross-sectional study	Survey, including falls and MAEs, near misses, staff injury, and reporting barriers (Level 4)	1,105 RN respondents in 25 acute care hospitals nationally	None	Reporting rates varied, with 47% errors reported overall; intravenous MAEs highest rate overall. Reporting inhibited by fear of being blamed, peer reactions, patients becoming negative, reprimands by physicians, losing license, and public reporting. Reporting of MAEs was higher in units with quality management processes. Errors resulting in patient and staff injuries were underreported.
Chiang 2006[147]	Barriers to error reporting	Cross-sectional study	Self-administered survey of barriers to reporting MAEs (Level 4)	597 nurses in 1 hospital in Taiwan	None	Fear was the main barrier to reporting MAEs, significantly associated with organizational power hierarchy and face-saving concerns.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Cook 2004[58]	Responsibility for errors Defining medical errors	Cross-sectional study	Assessed hospital data and administered the "Close Call Pilot Culture Assessment," error reports, staff patient safety instrument, e-mailed questionnaires, staff patient-safety survey, case studies, and telephone interviews (Level 4)	485 clinicians (305 nurses, 49 physicians, and others) in 29 hospitals in 9 States	None	Majority agreed that hospital administrators did not punish error reporters. Staff have learned and would like to continue to learn from mistakes of others. Most agreed that the hospital culture recognized that mistakes could be made (64%) and that error reporting could be done by all employees (86%). Majority felt comfortable (65%) or somewhat comfortable (32%) discussing medical errors. Attempts to maintain collegiality and their belief about lacking authority prevented nurses from questioning physicians. Pharmacists were more confident in their ability to recognize errors. Nurses reported most frequent problem was unclear or confusing patient orders. Nonphysicians attributed many errors to nursing practices. 96% of nurses and more than 90% of physicians, administers, and pharmacists assigned patient safety responsibility to nurses. 22% of respondents believed that clinicians and administrators shared equal responsibility for patient safety. Nurses reported that they were responsible for reporting errors (99%), educating themselves (98%), recommending changes in procedures (88%) and policy (86%), reviewing reported events (79%), and participating in investigations of errors (72%). However fewer than half had participated in investigating, reviewing, or analyzing errors.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Costello 2007[119]	Error reporting	Pretest and post-test	Retrospectively assessed error reports, then again assessed error reports after several interventions (Level 4)	Physicians and nurses in a pediatric critical care center	Introduction of clinical pharmacists to raise awareness of medication safety and encourage reporting of all errors	Medication error reporting increased overall, but reports from nurses remained relatively constant and the reports from physicians decreased. The pharmacist did not change the error reporting culture.
Day 2004[134]	Reporting adverse events	Cross-sectional study	Administered a retrospective questionnaire about experience in reporting errors (Level 4)	32 physicians, 175 nurses, and 44 others (a 43% response rate) in 1 hospital in Utah	None	Physicians and nurses reported similar reporting experiences, but nurses reported 27% more. 34% of ICU staff reported errors. Physicians reported more major events while nurses reported more minor events; nurses had a more "inclusive view." Physicians and nurses reported more near misses. 47% reported time and 27% reported fear of punitive actions as the major barriers to reporting.
Elder 2007[131]	Barriers to error reporting Reasons to report errors	Cross-sectional study	Conducted focus groups on errors related to testing, issues involved in error reporting, and the effects of error reporting on office systems (Level 4)	Physicians, nurse practitioners, physician assistants, office staff, and nurses in 8 family physicians offices	None	Majority of reporting barriers were a lack of time, forgetfulness, and confusion about what to and who should report. Most common reported reason for reporting errors was a perceived benefit.
Espin 2006[81]	Error disclosure and reporting	Cross-sectional study	Questionnaire using 4 scenarios	9 surgeons, 9 nurses, 10 anesthesiologists in operating rooms at 2 teaching hospitals	None	Patients want full disclosure, while physicians and nurses want to disclose only what happened. Nurses (the only clinician type asked) were less likely to want to report errors than patients.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Espin 2007[130]	Error reporting	Cross-sectional study	Administered 4 error scenarios to nurses	13 perioperative nurses at 1 hospital in Canada	None	58% of theoretical errors were identified as errors, only 26.7% of which would have been reported by the nurses. Nurses perceived error reporting as a profession-specific responsibility; nurses should report errors made by nurses. The presence of a negative outcome appeared to be a secondary consideration for nurse error reporting. Nurses had a greater tendency to report errors informally with a nurse colleague or nurse manager.
Evans 2006[106]	Barriers to error reporting	Cross-sectional study	Anonymous survey of physicians and nurses about their knowledge of their organizations' reporting system, how often they reported errors, and reasons why errors were not reported (Level 4)	70.7 response rate for physicians and 73.6% for nurses in hospitals in southern Australia	None	98.3% of physicians and nurses were aware of the incident reporting system. Nurses were more likely to know how to submit an error report (88.3%), to have completed an error report (89.2%), and to know where to submit an error report (81.9%).
Evans 2007[120]	Error reporting	Nonrandomized trial	Comparison of incident reporting rates between 1 control and 1 intervention hospital (Level 3)	2 hospitals in Australia	Educational intervention was combined with a revised reporting system, with an option for a call center.	Reporting increased throughout the hospitals. More reports were initiated by physicians in EDs and were anonymous. Nurses generated 84% of error reports.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Fein 2005[91]	Error disclosure	Case control study	Focus group interviews, on ethical perceptions and details of error disclosure (Level 4)	Hospital personnel and former patients (n = 240), 25 focus groups: separate stakeholder groups of attending physicians, residents, nurses, administrators, former patients	None	All agreed that errors should be disclosed when patients are harmed. Degree of harm caused by error and whether patients and others were aware of errors were characteristics related to disclosure. Institutional culture (perceived tolerance for error and supportive infrastructure) was important to disclosure decision. Patient factors were health care sophistication, desire for information, and rapport with provider. Provider factors included fears of malpractice, reputation, job threat, and change in rapport with the patient, as well as perceived professional responsibility, medical training, lack of confidence in disclosure skills, and personal discomfort.
Fernald 2004[121]	Error reporting in ambulatory settings	Cross-sectional study	Collected and analyzed error reports from clinicians and staff, using a voluntary reporting system (Level 4)	2 practice-based research networks	Implemented a voluntary reporting system	47% of reported errors were associated with diagnostic tests, 35.4% with medications, and 13.6% with both medication and a diagnostic test; 70.8% of error reports were associated with communication errors. Confidential reports were more complete than anonymous reports. Reporting different types of patient harm did not vary between anonymous and confidential reports.
France 2003[122]	Reporting system	Quality improvement	Assessed utilization of a voluntary reporting system and provider-initiated improvements (Level 4)	1 hospital in Tennessee	Implemented a voluntary reporting system	Nurse reporting significantly decreased after implementation, while pharmacy reporting significantly increased.
Furukawa 2003[123]	Reporting medication errors	Cross-sectional study	Errors reported using a Web-based system during a 2-year period (Level 4)	Physicians, nurses, pharmacists, technologists, and others in 1 hospital in Japan	None	Nurses reported 78% of errors, an average of 2.2 reports per nurse. The majority of error reports submitted by nurses and pharmacists were considered minor. Physicians were found to report errors only when detected and prevented by nurses or pharmacists.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Harper 2005[144]	Barriers to error reporting	Cross-sectional study	Self-report survey (Reporting Culture Survey) on mandatory reporting system in hospitals transitioning to close-call reporting system: scaled and open-ended items (Level 4)	858 nurses and physicians (a 41% response rate) at 2 hospitals in Texas	None	Less than 10% of respondents had knowledge of the mandatory reporting system, but less than half of nurses and 20% of physicians reported using the system. Physicians and nurses were not positive about the effectiveness of a hospital-based reporting system. Physicians reported that nurses were responsible for reporting errors. 40% of physicians and 30% of nurses were concerned about the anonymity of reporters, yet 86% of nurses and 81% of physicians favored feedback on corrective action taken in response to the report. 40% of physicians and 30% of nurses were concerned that the reporting system would be used punitively.
Harris 2007[133]	Error reporting	Prospective cohort study	Assessment of error reports once a new reporting system had been put in place (Level 4)	3 ICUs in a 1,371-bed urban teaching hospital	A new, card-based reporting program to encourage anonymous reporting of errors	Nurses submitted 67.1% of error reports, followed by 23.1% by physicians and 9.5% by other reporters. Of the reports where errors did not reach the patient, 31.1% were from nurses, 36.2% from other staff, and 17% from physicians. Of the reports were errors harmed patients, 33.9% were from physicians, 27.2% from nurses, and 13% from other staff.
Hirose 2007[124]	Error reporting	Cross-sectional study	Evaluation of lag time of submission of 6,880 reports filed by nurses and physicians during a 3-year period (Level 3)	Reports submitted by nurses and physicians in 1 hospital in central Japan	None	Nurses filed 93.3% of the reports, 99.5% of which were categorized as minor incidents. Physicians submitted 32 reports (an annual reporting rate of 0.26 per physician), while nurses submitted 31 reports (an annual reporting rate of 3.43 per nurse) for major errors. Lag time was 18% shorter for major events than minor, and 75% longer for physicians.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Hobgood 2004[100]	Error disclosure Error reporting	Cross-sectional study	Retrospective survey of health care providers' experiences with disclosing medical errors (Level 4)	41 EMTs, 33 RNs, and 42 physicians in 1 tertiary care academic medical center	None	Disclosure to patients was associated with provider type (19% EMTs, 23% RNs, and 74% physicians). 59% of physicians reported observing another provider disclose an error.
Hobgood 2006[92]	Error disclosure Error reporting	Cross-sectional study	Survey using 10 clinical vignettes (Level 4)	40 physicians, 26 nurses, and 35 EMTs in 1 tertiary care academic emergency department	None	Physicians were more likely (71%) to disclose an error than were nurses (59%), but nurses were more likely (68%) to report the error than were physicians (54%).
Inoue 2004[125]	Types of error reports	Cross-sectional study	Retrospective analysis of errors reported through incident reports (Level 4)	Incident reports submitted by nurses in 6 urban hospitals in Japan	None	Error rates were high for prevention of problematic behavior, prevention of suicide, safeguarding against falls, and subcutaneous injections of insulin. Error rates that were high in some hospitals, but not all, were maintenance of dialysis, endoscopy preparation and assistance, administration of preoperative treatments, and blood transfusions. Error rates were higher in hemodialysis patients, those with problematic types of behavior, and the elderly. Incidence of errors was associated with rule violations, management practices, and nonstandardized nursing practices.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Jeffe 2004[132]	Perceptions of error reporting Barriers to error reporting	Cross-sectional study	Verbatim transcribed focus groups, recommendations for systems change to improve reporting, including awareness of provider status, benefits of feedback, and culture change (Level 4)	9 focus groups with 49 nurses, 10 nurse managers, and 30 physicians in 20 community and academic hospitals	None	Culture change might be accomplished as providers' concern and responses were considered in systems changes to improve reporting and policy revisions; how best to improve error reporting and disseminate information about errors might benefit when considering perceived barriers to reporting and including front-line providers' perspectives on clear guidelines on what to report, education on reporting mechanisms, anonymous reporting mechanisms, personnel, and routine followup of error reports for education and hospital action. Nurses were more knowledgeable about how to report errors. All mentioned barriers—fear of reprisals, lack of confidentiality, time, and feedback after an error—are reported. Both physicians and nurses agreed that reporting was intended to change practice and policy to promote patient safety.
Jones 2004[116]	Error reporting	Quality improvement	Standardized voluntary medication reporting form and database, compared with MEDMARX; NCC MERP severity index was used to categorize severity of harm to the patient (Level 4)	10 critical access hospitals	Conducted education workshops about nature of errors, the design of safety systems, and best practices in medication safety; provided quarterly reports from the error reports the hospitals	Most errors were not harmful; greater availability of pharmacists associated with reporting greater proportions of Category A errors (circumstances have the capacity to cause error) and Category B errors (an error occurred, but the error did not reach the patient). Nurses submitted 97% of error reports.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Kim 2006[157]	Electronic error reporting	Cross-sectional study	Structured interview (Level 4)	Chairs of nursing departments (a 35% response rate) throughout Korea	None	Only 3% of hospitals used health information technology (HIT); HIT mainly used for medication administration, order entry, and radiology.
Kim 2007[139]	Error reporting Barriers to error reporting	Cross-sectional study	AHRQ's patient safety culture survey (Level 4)	886 nurses (a 92.3% response rate) in 8 teaching hospitals in Korea	None	67% of nurses reported always reporting errors resulting in patient harm. About half were unclear about what should be reported. 32% worried that their errors were kept in files. 52% reported having been given feedback and informed about errors made. 48% reported speaking out if they saw something negative, and 38% would voice opinions that differed from those in authority. 66% felt that their suggestions to improve patient safety were ignored. 83% felt that more errors should have happened than did, and 52% reported their units had serious patient safety problems. 56% reported problems talking with physicians. Frequency of reporting errors was higher among nurses with 5 to 10 years experience. Head nurses reported errors more frequently than did staff.
King 2001[153]	Error reporting	Cross-sectional study	Mailed surveys of error scenarios to RNs to elicit error reporting behaviors (Level 4)	372 nurses in the Midwest	None	Nurses were able to differentiate between intentional wrongdoing, which was related to questionable behavior. The perception of severity determined whether the error was reported. Unintentional errors would not be reported.
Lata 2004[126]	Improving adverse drug event (ADE) reporting	Cross-sectional study	Determine whether nurse case managers and pharmacists increase reporting of serious ADEs (Level 4)	1 community hospital in rural Wisconsin	Nurse case managers were educated that they were expected to report ADEs.	Nurse case managers reported 62% of ADEs, compared to 17% by pharmacists, and 75% of serious adverse drug reactions.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Lawton 2002[46]	Barriers to error reporting	Cross-sectional study	Questionnaire about willingness to report errors of others; included error scenarios (Level 4)	73 physicians, 145 nurses, and 92 midwives (a 53% response rate) in 3 NHS trusts in England	None	Reporting was more likely if there was a bad outcome. Physicians were less likely to make a report than were nurses or midwives. Health care professionals were less likely to report errors of senior colleagues. Physicians were unlikely to report violations of clinical protocols, whereas nurses and midwives were more likely.
Mayo 2004[142]	Error reporting	Cross-sectional study	Random sample of RNs surveyed about perceived causes of medication errors, percentage of medication errors reported to nurse managers, types of reportable incidents, and reporting behaviors, including medication errors scenarios (Level 4)	983 RNs (20% response rate) in the United Nurses Association of California/ Union of Health Care Professionals	None	When the dose was withheld or omitted, the majority would report the event to the physician, but few would have completed an incident report for the withheld medication, compared to about half for the omitted dose. Nurses working in neonatal intensive care units perceived higher reported errors (52.5%) than did those working in medical/surgical units (35.3%). The mean perceived percentage of reported errors was 45.6%. 92.6% reported knowing what a medication error was, and 91.3% reported knowing when to use an incident report. Reporting barriers were fear of manager reactions (76.9%), fear of coworker reactions (61.4%), and considering error was not serious enough to warrant reporting (52.9%).
Mick 2007[154]	Reporting Errors	Cross-sectional study	Assessed error reports	300 employees (out of a possible 800) in 5 inpatient units	New close call error reporting program, called the Good Catch Program with periodic feedback to staff.	The new program resulted in a 1,468% increase (from 175 before to 2,744 afterwards) in the number of reports. Reports facilitated the targeting of interventions to improve patient safety.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Nuckols 2007[127]	Reporting errors	Cross-sectional study	Analyzed 3,875 reports from 2 hospitals (Level 4)	1 academic tertiary referral hospital and 1 affiliated community hospital in Southern California	None	The majority of reports were for errors involving medications, operations, falls, and procedures. 89% of incident reports were from nurses. 48% of incidents occurred on general floors, 21% in ICUs, and 14% in operating rooms. Nurses were involved in 43% of the potentially preventable events, while physicians were involved in 16%.
Osborne 1999[69]	Perceptions of errors Reporting medication errors Barriers to error reporting	Cross-sectional study	Survey to RNs about perceived causes of medication errors (Level 4)	57 RNs (61.9% response rate) on medical-surgical units in a 700-bed community hospital in South Florida	None	43.9% of respondents reported that only 25% of medication errors were reported. 84.2% of respondents indicated that they knew what defined an error, and 86% that medication errors were not reported because of fear. 57.9% reported that they did not report a medication error when they did not consider it serious. There was no difference in perceptions associated with age, years of experience, or level of education.
Osmon 2004[137]	Reporting errors	Cross-sectional study	Prospective analysis following implementation of a new error reporting process, specific to the hospital (Level 4)	1 urban teaching hospital in Missouri	Implementation of new hospital-based error reporting system using the SAFE reporting cards	Reporting rate for medical events was 31.9 per 100 ICU patient admissions. Nurses reported the majority of events (59.1%), followed by medical students (27.2%) and ICU attending physicians (2.6%). Most reports involved delays or omissions (e.g., medications, diagnostic tests, or necessary/planned procedures (36.5%)), medication errors (20.2%), and malfunctioning equipment (7.9%). 9.9% of events required life-sustaining interventions, and 3% may have led to the patient's death. 60.9% of life-sustaining interventions were a result of delays/omission of prescribed nonmedication treatments and necessary planned procedures.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Rathert 2007[146]	Reporting errors	Cross-sectional study	Survey measuring patient-centered climate, perceived medication error frequency, job satisfaction, comfort reporting own errors and pointing out the errors of others (Level 4)	307 nurses (a 57% response rate) in 3 acute care hospitals in the eastern United States	None	Nurses are more comfortable reporting their own errors in a patient-centered care climate than they are pointing out the errors made by others.
Rudman 2005[112]	Error reporting systems	Cross-sectional study	Comparative description of baseline paper-based medication errors with postintervention Web-based reports; increased medication error reports, increased intercepted medication error threats, and staff access to post error interventions (Level 3)	Hospital reported errors: pre (average = 434.5/mo.) vs. post (average = 79.9/mo.)	Web-based, anonymous medication error reporting system on all personal computers and work stations	Staff accessed reports, noting immediate actions taken. Error reports and intercepted error threats increased. Intercepted nurse, physician, and pharmacist medication errors increased. Errors attributed to physicians increased as nurses' and pharmacists' decreased. Details of cause-of-error reporting.
Schuerer 2006[136]	Error reporting systems	Prospective cohort study	Assessment of error reporting using a prospective analysis following implementation, withdrawal, and then reintroduction of a new error reporting process, specific to the hospital (Level 4)	Nurses, physicians and other health care workers in 1 24-bed surgical ICU	A card-based reporting system (SAFE)	Physician reporting increased from 0.3 to 5.8 reports per 1,000 patient days, and nurses from 18 to 39 reports per 1,000 patient days. When reporting cards were removed, physician reporting decreased to 0 per 1,000 patient days, then increased to 8.1 reports when the cards were reintroduced. A higher proportion of events reported by physicians were for events that caused harm, while the higher proportion of events reported by nurses were for events that did not cause harm to patients.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Stratton 2004[141]	Perceptions on error reporting	Cross-sectional study	Survey of pediatric and adult hospital nurses on their perceptions of the proportion of reported medication errors and why errors are not reported (Level 4)	57 pediatric and 227 adult nurses (a 40% response rate) in 33 acute care units in 11 hospitals (in rural Midwestern States, urban areas in the Rocky Mountain region of the United States)	None	Pediatric nurses estimated that 67% of medication errors were reported; adult nurses estimated 56%. Error rates per 1,000 patient-days were 14.80 in pediatric units and 5.66 in adult units. Medication errors are underreported by pediatric and adult nurses, with more reported on pediatric units. The more strongly nurses on pediatric units agreed with management-related and individual/personal reasons for not reporting errors, the lower the estimates of errors reported. Pediatric nurses agreed that nurses fear consequences from reporting and believe peers will think of the reporters as incompetent.
Throckmorton 2007[140]	Error reporting	Cross-sectional study	Survey about the environment and reasons why nurses do not report errors (Level 4)	435 nurses (a 10% response rate) licensed to practice in Texas	None	Knowledge of the nurse practice act was not associated with intent to report. Nurses providing direct care to patients were more likely to report. Nurses would report both errors that harmed patients and those that did not.
Tuttle 2004[135]	Error reporting system	Prospective cohort study	Implementation of a voluntary, electronic reporting system (ERS) for safety events involving patients or visitors (Level 4)	1 teaching hospital in New York	Implemented new confidential ERS for safety events and provided multifaceted education program to promote safety awareness and how to use the ERS.	Nurses reported 73% of the 2,843 safety events; physicians reported 2%. Of the events reported: - 16% were unsafe conditions or near misses; 22% were adverse events where patient was harmed; and 39% were not reported correctly. - 40% were medication/infusion events, 30% were adverse clinical events, and 24% were falls.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Uribe 2002[149]	Barriers to reporting errors	Cross-sectional study	Survey on perceived barriers to reporting and likelihood they could be modified (Level 4)	56 physicians and 66 nurses (17.3% response rate) in a Midwest academic hospital	None	Major barriers to error reporting were time and work involved in documenting an error; not being able to report anonymously; thinking that errors with no negative outcomes should not be reported; fear of legal actions; and hesitancy to "tell" on someone else. Modifiable barriers were identified as the structure and processes for reporting errors and education. Least modifiable barriers were fear of lawsuits, fear of being blamed, and motivational issues. Physicians identified twice as many barriers to reporting than did nurses; both identified time and extra work involved in documenting an error. Nurses were more concerned about anonymity, "telling" on someone else, fear of lawsuits, and the necessity of reporting errors that did not result in patient harm.
Vojir 2003[145]	Error reporting	Cross-sectional study	Surveyed nurses about their estimates of reported medication administration errors (Level 4)	1,214 nurses in 205 adult patient care units in 26 hospitals	None	Differences in staff definitions of reportable error, occurrence data not widely shared with staff nurses, staff nurses rely on personal experience to estimate unit medication administration errors.
Wakefield 1996[70]	Barriers to reporting medication errors	Cross-sectional study	Survey of medication administration errors and reasons nurses do not report errors, oriented to reporting process (Level 4)	RNs (n = 1,384) in 24 acute care hospitals; nonrandomly selected convenience sample	None	Fear, disagreement over whether an error occurred, administrative responses to medication errors, and effort required to report MAE are reasons nurses may not report errors. Fear inhibits reporting; organizational culture change needed to support reliable, valid, complete error reporting; too much emphasis placed on medication errors as measure of quality nursing care.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Wakefield 1999[150]	Barriers to reporting MAEs Perceived causes of MAEs Estimated MAEs reported	Cross-sectional study	Survey assessing perceived reasons for not reporting MAEs (Level 4)	Staff nurses and supervisors in 29 acute care hospitals in Iowa	None	There was some agreement on fear and administrative response as barriers to error reporting, but the barriers are associated with individual characteristics and management practices. The degree of agreement between staff and their supervisors about why errors are not reported varied considerably. Supervisors were more likely to view fear of administrative response as a barrier to error reporting, whereas staff nurses did view fear as a barrier**.**
Wakefield 2001[151]	Barriers to reporting MAEs	Cross-sectional study	Questionnaire on organizational culture, implementation of clinical quality improvement (CQI), and nurses' perceptions of MAE reporting (Level 4)	292 nurses from 6 Midwest hospitals	None	Hospital culture types varied: smaller institutions tended to have group-oriented cultures, larger institutions tended to be more hierarchal in nature. The extent of CQI implementation increased with bed size of the hospital, and perceived rate of MAE reporting decreased. The greater the number of barriers, the lower the reporting of errors. The presence of a group-oriented culture and higher levels of CQI implementation were positively but not significantly associated with reporting errors. Hierarchical or rational-type cultures were negatively associated with reporting errors.
Wakefield 2005[148] (Note: This includes findings of Wakefield 1996, 1999, 2001[70, 150,151])	Barriers to reporting medication errors	Cross-sectional study	Scale development, content validity (face), construct validity (factorial), concurrent validity; internal consistency, and test-retest reliability (Level 4)	RNs (n =1,384 in 1994, 1,428 in 1996, 862 in 1998, and 295 in 2001) in hospitals (n = 24 in 1994, 29 in 1996, 21 in 1998, and 16 in 2001)	None	The reported reasons why MAEs were not reported were due to disagreement with the definitions, the burden of the reporting effort, fear (e.g., judgment from peers, patients, and their families, physician reprimand, adverse consequences, and being blamed for patient harm), and administrative response (e.g., no positive feedback, individual blame, and response not matching the severity of the error).

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Weingart 2000[36]	Error reporting	Cross-sectional study	Compared house officer reports with incident reports and patients' medical records, using confidential peer interviews to identify errors and substandard quality care (Level 3)	Medical house officers, nurses, social workers, physical therapists, and case managers in 1 hospital in Boston	None	Of the errors verbally reported by the house officer and confirmed in the patient's medical record, only one was recorded in the hospitals' incident reporting system. Nurses recorded the majority of incident reports, whereas only 1 incident report was submitted by a house officer.
Wild 2005[143]	Perceptions and attitudes about error reporting Knowledge and use of error reporting systems	Cross-sectional study	Self-administered survey on the knowledge and use of the hospital error reporting system and attitudes and perceptions about hospital culture regarding error reporting (Level 4).	24 resident physicians (a 96% response rate) and 36 nurses (a 60% response rate) in 1 community hospital in Connecticut	None	54% of residents and 97% of nurses knew of the hospital's error reporting system; 13% of residents and 72% of nurses were likely to use it. Residents were more likely to perceive the culture as more threatening and nonsupportive; 29% of residents and 64% of nurses reported being comfortable discussing mistakes. 42% of residents and 44% of nurses were uncomfortable discussing errors with patients. 64% of nurses were comfortable discussing mistakes with supervisors. 54% of residents and 91% of nurses reported being more likely to report an error, either their own or someone else's. 25% of residents and 1% of nurses were more likely to report an error if they did not like the person who caused the error.
Yamagishi 2003[128]	Reporting adverse events Reporting method	Cross-sectional study	Adverse event data obtained from incident reports, logs, checklists, nurse interviews, medication error questionnaires, urine leucocyte tests, patient interviews, and medical records. Patients were interviewed about the events (Level 3).	Event reports by 115 staff nurses in 6 wards in 1 hospital in Tokyo, Japan	None	Actual events and reported events were similar when using incident reports, checklists, nurse interviews, urine leucocyte tests, and questionnaires of medication errors. Falls were not always reported, depending on whether patients were independent with activities of daily living or under standardized care protocols. Restraint use was usually not documented in patient record.

Chapter 36. Wrong-Site Surgery: A Preventable Medical Error

Deborah F. Mulloy, Ronda G. Hughes

Background

Surgery is one area of health care in which preventable medical errors and near misses can occur. However, until the 1999 Institute of Medicine report, *To Err Is Human,*[1] clinicians were unaware of the number of surgery-associated injuries, deaths, and near misses because there was no process for recognizing, reporting, and tracking these events.[2] Of great concern is wrong-site surgery (WSS), which encompasses surgery performed on the wrong side or site of the body, wrong surgical procedure performed, and surgery performed on the wrong patient.[3] This definition also includes "any invasive procedure that exposes patients to more than minimal risk, including procedures performed in settings other than the OR [operating room], such as a special procedures unit, an endoscopy unit, and an interventional radiology suite"[4] (p. 11). WSS is also defined as a sentinel event (i.e., an unexpected occurrence involving death or serious physical or psychological injures, or the risk thereof) by the Joint Commission (formerly called the Joint Commission on Accreditation of Healthcare Organizations), which found WSSs to be the third-highest-ranking event.[5]

Causes and Consequences of Wrong-Site Surgery

WSS can be a devastating experience for the patient and have a negative impact on the surgical team.[6, 7] State licensure boards are imposing penalties on surgeons for WSS,[8] and some insurers have decided to no longer pay providers for WSS or wrong-person surgery, nor for leaving a foreign object in a patient's body after surgery.[9] Surgery performed on the wrong site or wrong person has also often been held compensable under malpractice claims. Indeed, 79 percent of wrong-site eye surgery and 84 percent of wrong-site orthopedic claims resulted in malpractice awards.[10, 11]

WSSs are rare events, but we are learning more about their prevalence. Because reporting of sentinel events to the Joint Commission is voluntary, it could be that only 10 percent of actual WSSs are reported.[12] Researchers have confirmed that the Joint Commission's numbers are low, finding wide variations in the number of WSSs: 1 out of 27,686 cases,[6] or 1 out of every 112,994 surgeries,[13] or 1 in 5 hand surgeons during their career,[7] or 1 out of 4 orthopedic surgeons with 25 years' experience.[14] Regardless of the exact number of WSSs, they are seen as a preventable medical error if certain steps are taken and standardized procedures are implemented in the perioperative setting.[15, 16]

The incidence of reported WSS has increased in recent years. From the inception of the Joint Commission's Sentinel Event program, the number of WSSs reported has increased from 15 cases in 1998, to a total of 592 cases reported by June 30, 2007.[17] Of these, WSSs most commonly occur in orthopedic or podiatric procedures,[5] general surgery, and urological and neurosurgical procedures.[17] In response to the occurrence of these preventable errors, the Joint

Commission issued two National Patient Safety Goals on January 1, 2003 to target wrong-site surgery:

Goal 1—to improve the accuracy of patient identification by using two patient identifiers and a "time-out" procedure before invasive procedures.

Goal 4—to eliminate wrong-site, wrong-patient, and wrong-procedure surgery using a preoperative verification process to confirm documents, and to implement a process to mark the surgical site and involve the patient/family.[40]

Both of these goals continue to be an ongoing priority for the Joint Commission. Yet with many surgical procedures traditionally performed only in acute care settings now being performed in freestanding surgical centers and physician offices—not necessarily all under the purview of the Joint Commission—surgeons, surgical teams, and patients need to be vigilant with all surgeries, particularly when the level of oversight and scrutiny may not be as high as in hospitals.

WSS is generally caused by a lack of a formal system to verify the site of surgery or a breakdown of the system that verifies the correct site of surgery.[18] In using root-cause analysis, a process that determines the underlying organizational causes or factors that contributed to an event, the Joint Commission found the top root causes of WSS to be communication failure (70 percent), procedural noncompliance (64 percent), and leadership (46 percent).[16] Other system and process causes are listed in Table 1. Risk factors associated with WSS were identified as emergency cases, multiple surgeons, multiple procedures, obesity, deformities, time pressures, unusual equipment or setup, and room changes.[17]

Table 1. Causes of Wrong-Site Surgeries[5, 18, 19, 20]

System Factors	Process Factors
♦ Lack of institutional controls/formal system to verify the correct site of surgery ♦ Lack of a checklist to make sure every check was performed ♦ Exclusion of certain surgical team members ♦ Reliance solely on the surgeon for determining the correct surgical site ♦ Unusual time pressures (e.g., unplanned emergencies or large volume of procedures) ♦ Pressures to reduce preoperative preparation time ♦ Procedures requiring unusual equipment or patient positioning ♦ Team competency and credentialing ♦ Availability of information ♦ Organizational culture ♦ Orientation and training ♦ Staffing ♦ Environmental safety/security ♦ Continuum of care ♦ Patient characteristics, such as obesity or unusual anatomy, that require alterations in the usual positioning of the patient	♦ Inadequate patient assessment ♦ Inadequate care planning ♦ Inadequate medical record review ♦ Miscommunication among members of the surgical team and the patient ♦ More than one surgeon involved in the procedure ♦ Multiple procedures on multiple parts of a patient performed during a single operation ♦ Failure to include the patient and family or significant others when identifying the correct site ♦ Failure to mark or clearly mark the correct operation site ♦ Incomplete or inaccurate communication among members of the surgical team ♦ Noncompliance with procedures ♦ Failure to recheck patient information before starting the operation

Universal Protocol for Preventing Wrong-Site Surgery

Early attempts to address the occurrence of WSS started with the American Academy of Orthopedic Surgeons (AAOS) and the North American Spine Society (NASS). After reviewing of 10 years of malpractice claims and polling its members,[21] AAOS developed an awareness campaign to encourage the marking of the right surgical site, called "Sign Your Site."[22] But in practice, adding an additional warning such as "No" on the incorrect site and having the surgical team work together to verify the correct site helped the Sign Your Site program to be effective.[23] The NASS further refined the Sign Your Site process by adding more detail for the appropriate level and site of the spine in its "Sign, Mark, and X-ray" program, calling for marking the exact site and side of the spine with a radiopaque indicator, and put forth a checklist for patient and procedure verification.[24]

In 2003, the Joint Commission convened a summit, including the AAOS and leaders from 23 other organizations, to address the continued escalation of reported WSS cases (i.e., sentinel events reported to the Joint Commission); and the impact of WSS on patients, their families, and health care professionals; and associated health care costs. The summit was specifically designed to bring health care professionals and others together to address and develop strategies to lessen or eliminate WSS.[14] A major outcome of the summit was creation of a protocol, *The Universal Protocol for Preventing Wrong Site, Wrong Procedure, and Wrong Person Surgery* ™ (see Text Box 1).[20] This protocol was designed to be used in all areas where invasive procedures are performed within health care organizations, including nonoperating-room settings. The goal was to drastically reduce or eliminate completely the incidence of WSS by using a standardized routine and acceptable preoperative process of verifying the patient and the correct site, as well as the physician marking the site with his or her initials before the patient is sedated.

The Universal Protocol for WSS is based on prevention theories that drive safety practice in high-risk industries, such as aviation and development of nuclear weapons. The operating room is complex with "tight coupling" of processes that happen very quickly and cannot be turned off once started; failed parts cannot be isolated from other parts—resulting in an unsafe process. A model most often used to demonstrate this is the one described by Reason[25] as the Swiss cheese model, where error defenses breakdown or are not in place, resulting in patient harm. (See the chapter on human factors for more information on Reason's model.)

By implementing a systems change required by the WSS protocol, the possibility of a WSS should be prevented. The three key elements of the Universal Protocol for WSS are (1) preoperative verification process, (2) marking the operative site, and (3) taking a time out. The Universal Protocol is to be used in ambulatory care, hospitals, critical access hospitals, and office-based settings.[20] Implementing and adhering to this protocol should eliminate WSS errors that can be attributable to interruptions, distractions, and too many forms or procedures. On July 1, 2004, the Joint Commission began to include these three key Universal Protocol elements in its accreditation process for health care organizations and also provided further guidance on its implementation (see Text Box 2).

Text Box 1. The Joint Commission Universal Protocol for Preventing Wrong Site, Wrong Procedure, Wrong Person Surgery™

Wrong site, wrong procedure, wrong person surgery can be prevented. This Universal Protocol is intended to achieve that goal. It is based on the consensus of experts from the relevant clinical specialties and professional disciplines and is endorsed by more than 40 professional medical associations and organizations.

In developing this protocol, consensus was reached on the following principles:

- Wrong site, wrong procedure, wrong person surgery can and must be prevented.
- A robust approach—using multiple, complementary strategies—is necessary to achieve the goal of eliminating wrong site, wrong procedure, wrong person surgery.
- Active involvement and effective communication among all members of the surgical team is important for success.
- To the extent possible, the patient (or legally designated representative) should be involved in the process.
- Consistent implementation of a standardized approach using a universal, consensus-based protocol will be most effective.
- The protocol should be flexible enough to allow for implementation with appropriate adaptation when required to meet specific patient needs.
- A requirement for site marking should focus on cases involving right/left distinction, multiple structures (fingers, toes), or levels (spine).
- The Universal Protocol should be applicable or adaptable to all operative and other invasive procedures that expose patients to harm, including procedures done in settings other than the operating room.

In concert with these principles, the following steps, taken together, comprise the Universal Protocol for eliminating wrong site, wrong procedure, wrong person surgery:

- **Preoperative verification process**
  - **Purpose:** To ensure that all of the relevant documents and studies are available prior to the start of the procedure and that they have been reviewed and are consistent with each other and with the patient's expectations and with the team's understanding of the intended patient, procedure, site, and, as applicable, any implants. Missing information or discrepancies must be addressed before starting the procedure.
  - **Process:** An ongoing process of information gathering and verification, beginning with the determination to do the procedure, continuing through all settings and interventions involved in the preoperative preparation of the patient, up to and including the "time out" just before the start of the procedure.

- **Marking the operative site**
  - **Purpose:** To identify unambiguously the intended site of incision or insertion.
  - **Process:** For procedures involving right/left distinction, multiple structures (such as fingers and toes), or multiple levels (as in spinal procedures), the intended site must be marked such that the mark will be visible after the patient has been prepped and draped.

- **"Time out" immediately before starting the procedure**
  - **Purpose:** To conduct a final verification of the correct patient, procedure, site and, as applicable, implants.
  - **Process:** Active communication among all members of the surgical/procedure team, consistently initiated by a designated member of the team, conducted in a "fail-safe" mode, i.e., the procedure is not started until any questions or concerns are resolved.

[Reprinted with permission from**:** Universal Protocol for Preventing Wrong Site, Wrong Procedure, Wrong Person Surgery. Oakbrook Terrace, IL: Joint Commission on Accreditation of Healthcare Organizations. 2003.[20]]

Text Box 2. Implementation Expectations for the Universal Protocol for Preventing Wrong Site, Wrong Procedure, and Wrong Person Surgery™

These guidelines provide detailed implementation requirements, exemptions, and adaptations for special situations.

Preoperative verification process

- Verification of the correct person, procedure, and site should occur (as applicable):
  - At the time the surgery/procedure is scheduled.
  - At the time of admission or entry into the facility.
  - Anytime the responsibility for care of the patient is transferred to another caregiver.
  - With the patient involved, awake, and aware, if possible.
  - Before the patient leaves the preoperative area or enters the procedure/surgical room.
- A preoperative verification checklist may be helpful to ensure availability and review of the following, prior to the start of the procedure:
  - Relevant documentation (e.g., history and physical, consent).
  - Relevant images, properly labeled and displayed.
  - Any required implants and special equipment.

Marking the operative site

- Make the mark at or near the incision site. Do NOT mark any nonoperative site(s) unless necessary for some other aspect of care.
- The mark must be unambiguous (e.g., use initials or "YES" or a line representing the proposed incision; consider that "X" may be ambiguous).
- The mark must be positioned to be visible after the patient is prepped and draped.
- The mark must be made using a marker that is sufficiently permanent to remain visible after completion of the skin prep. Adhesive site markers should not be used as the sole means of marking the site.
- The method of marking and type of mark should be consistent throughout the organization.
- At a minimum, mark all cases involving laterality, multiple structures (fingers, toes, lesions), or multiple levels (spine). Note: In addition to preoperative skin marking of the general spinal region, special intraoperative radiographic techniques are used for marking the exact vertebral level.
- The person performing the procedure should do the site marking.
- Marking must take place with the patient involved, awake, and aware, if possible.
- Final verification of the site mark must take place during the "time out."
- A defined procedure must be in place for patients who refuse site marking.

Exemptions

- Single organ cases (e.g., Cesarean section, cardiac surgery).
- Interventional cases for which the catheter/instrument insertion site is not predetermined (e.g., cardiac catheterization).
- Teeth–but, indicate operative tooth name(s) on documentation or mark the operative tooth (teeth) on the dental radiographs or dental diagram.
- Premature infants, for whom the mark may cause a permanent tattoo.

"Time out" immediately before starting the procedure
Must be conducted in the location where the procedure will be done, just before starting the procedure. It must involve the entire operative team, use active communication, be briefly documented, such as in a checklist (the organization should determine the type and amount of documentation), and must, at the least, include:

- Correct patient identity.
- Correct side and site.
- Agreement on the procedure to be done.
- Correct patient position.
- Availability of correct implants and any special equipment or special requirements.

The organization should have processes and systems in place for reconciling differences in staff responses during the "time out."

Procedures for non-OR settings, including bedside procedures

- Site marking must be done for any procedure that involves laterality, multiple structures, or levels (even if the procedure takes place outside of an OR).
- Verification, site marking, and "time out" procedures should be as consistent as possible throughout the organization, including the OR and other locations where invasive procedures are done.
- **Exception:** Cases in which the individual doing the procedure is in continuous attendance with the patient from the time of decision to do the procedure and consent from the patient through to the conduct of the procedure may be exempted from the site marking requirement. The requirement for a "time out" final verification still applies.

[Reprinted with permission from**:** Universal Protocol for Preventing Wrong Site, Wrong Procedure, Wrong Person Surgery. Oakbrook Terrace, IL: Joint Commission on Accreditation of Healthcare Organizations. 2003.[20]]

The Association of periOperative Registered Nurses (AORN), realizing the importance of the Universal Protocol for WSS, worked collaboratively with the Joint Commission to develop a Correct Site Surgery Tool Kit. The tool kit, designed to assist health care providers to implement the Universal Protocol for WSS in their facilities, was endorsed by the American College of Surgeons, American Society of Anesthesiologists, American Society for Healthcare Risk Management, American Hospital Association, and the American Association of Ambulatory Surgery Centers.

The AORN Correct Site Surgery Tool Kit contains a variety of resources to educate health care providers about the Universal Protocol for WSS and to assist them with its implementation. The resources include (1) an educational program on CD-ROM; (2) a pocket reference card outlining the steps necessary to promote patient identification, site marking, and the time out; (3) a template to facilitate development of a facility policy to implement the Universal Protocol for WSS; (4) a copy of the Universal Protocol for WSS and Guidelines for Implementing the Universal Protocol; (5) frequently asked questions of the Joint Commission and AORN; (6) letters to nurses, physicians, facility chief executive officers, and health care risk managers encouraging standard implementation of the Universal Protocol across all facilities; and (7) information for patients about the Universal Protocol for WSS and health care safety. This tool kit is available from AORN at http://www.aorn.org/PracticeResources/ToolKits/CorrectSiteSurgeryToolKit. In addition, AORN Standards, Recommended Practices, and Guidelines has a position statement on Correct Site Surgery that has additional information on preventing wrong site surgery.[39]

Several other organizations have set forth tools and policies to prevent WSS. The Veterans Affairs National Center for Patient Safety put forth the Ensuring Correct Surgery and Invasive Procedures directive, based on root-cause analysis, that adds two steps to the Joint Commission's

Universal Protocol: ensuring the consent form is administered and used properly, and having two members of the surgical team review patient information and radiological images prior to the start of the surgery.[26] The OR briefing tool used at Johns Hopkins Hospital expands the time-out part of the Universal Protocol by prompting additional dialogue between the anesthesia care team, nursing, and the surgical team.[27] Additionally, the British National Patient Safety Agency has introduced a risk management tool, setting forth a process for double-checking and identifying who is accountable at each stage for ensuring surgical markings on the right site to avoid WSS.[28]

Research Evidence

There is limited research on wrong-site surgery. The majority of studies have been retrospective, chart reviews, case studies, and surveys of various professional organizations. The evidence table summarizes the most recent evidence related to WSS, specifically the three components of the Universal Protocol.

In two of the retrospective studies that investigated WSS broadly, Meinberg and Stern,[7] in a study relating to the Universal Protocol, found that nearly half of surgeons changed their preoperative practices in response to the Sign Your Site campaign. Since the campaign targeted orthopedic surgeons, they were more knowledgeable about the campaign and were more likely to have changed their practices. Kwaan and colleagues[6] identified 62 percent of WSS cases that could have been prevented had providers adhered to the Universal Protocol. In this study, the authors concluded that the Universal Protocol would not have prevented the remaining one-third of WSS documented cases because of errors initiated in weeks before surgery (e.g., wrong documentation, inaccurate labeling of radiological reports). In an analysis of quality improvement efforts, similar findings also indicated implementation challenges associated with staff nonadherence because the issue of laterality was not addressed in the policy and the process was vulnerable to communication failures during handoffs.[29]

Preoperative Verification

In verifying that the right patient is to have the right surgery in the right location, one study found that when discrepancies occurred among clinicians, a review of the patient's information could resolve the discrepancy.[30] Published guidelines assert the need for a checklist to itemize exactly what should be checked, but do not specify what should happen if a discrepancy occurs.[31]

Marking the Site

Three different studies and one quality improvement project assessed aspects of site marking, included two different approaches in who actually marks the right site. All found challenges in ensuring that each surgical patient had the right site marked, therefore exposing patients to possible WSS. One study that surveyed a small number of surgeons on their site-marking practices following the establishment of national guidelines, found that their practices ranged from no marking to marking every patient, with some relationship to the type of surgery.[32] In approaching site marking from the point of view that it is the patient's responsibility, instead of the surgeon having complete responsibility, DiGiovanni and colleagues[33] sought to have patients

mark the right site after being given a set of instructions. They found that when patients (instead of someone from the surgical team) were asked preoperatively to mark "no" on the wrong foot or ankle, 60 percent of patients marked the site correctly.

The last study and quality improvement project assessed whether marking would cause other errors, because of the permanence of the ink, thereby discouraging site marking. The study found that marking the surgical site with a pen marker did not affect sterility or place a patient at a higher risk for infection.[34] The quality improvement project found that staff were not marking the right site because the ink upset breast cancer patients and was indelible on premature infants, and the policy did not address laterality.[29]

Time Out

Two studies found that the time out component can prevent the majority of WSS, but not all.[6, 13, 35] Another study found that when surgeons, anesthesiologists, and nurses were trained in doing a standardized 2-minute briefing prior to surgery, there were specific improvements in communication on the surgical site and side operated on.[36]

Evidence-Based Practice Implications

In response to continued WSS sentinel event reports, one of the Joint Commission's National Patient Safety Goals continues to be to eliminate wrong-site, wrong-patient, and wrong-procedure surgery. Eliminating WSS errors requires a systems approach, institutionalizing robust systems to verify the correct site that adequately addresses potential causes of breakdowns in the system. Hospital and surgery center leaders and managers should evaluate their policies and procedures regarding WSS and marking the right site to ensure that no WSSs occur under any circumstances.

Adoption of the Universal Protocol standardizes preoperative preparations, improves function of the health care team, and should avert any potential for WSS. All health care personnel must be knowledgeable about the Universal Protocol and consistently adhere to the three key elements—patient identification, site mark, and time out—as outlined in the Universal Protocol to reduce the number of WSSs occurring in the United States.

The Universal Protocol for WSS should be adhered to on all applicable cases, as the operating room and procedural areas are highly coupled and complex areas that would be unlikely to be completely error proof. Measures should be taken that require less reliance on memory. For example, a surgical site mark is a measure to prevent reliance on memory. However, when involving patients in marking the surgical site, one needs to assess their physical, cognitive, and emotional ability.[31]

All health care professionals have an obligation to comply with the Universal Protocol and to speak up if they feel patient safety is being compromised in any way.[37] Nurses, specifically perianesthesia nurses, should function as the patient's advocate and foster procedures that ensure right-site surgery.[38]

Research Implications

There is little empirical evidence regarding prevention of WSS or quantitative evaluation of implementation of strategies to prevent WSS. Part of the problem with research in this area has

been that the medical-error data are not easy to extract, and error data are often transferred to medical claims data and medical liability, further preventing the sharing of such data. Mandatory reporting of these data has just recently been required in some States. Consequently, there are gaps in the current evidence on wrong-site surgery. For example, there were no randomized controlled studies to evaluate the effect of the Universal Protocol on WSS. Research is needed to determine whether the patient's risk for WSS is associated with the organization following the Joint Commission's Universal Protocol or other standardized process, or with the effectiveness of the surgical team in communicating with each other. It is unknown how effective surgical teams are in complying with the protocol on a daily basis, and it is unknown what factors or barriers exist to implementing the Universal Protocol for WSS in facilities across the country.

Conclusion

The reported number of WSS cases continues to increase as health care organizations become more transparent to medical error. Many health care organizations, drawing on error-prevention theories and the experience of the aviation industry, recognize that through such transparencies, systems can change and result in better patient outcomes. However, it is unlikely that WSS will fully be reported because of industrywide report cards, fear of litigation, and difference of opinions. Although absolute numbers of WSS may not be striking, the consequences to the patient on whom it occurs are dire.

Search Strategy

Both PUBMED® and CINAHL® databases between 1990 and March 2007 were searched, using wrong site surgery[keyword] OR wrong site surgery[subject heading]. This identified 239 citations. Citations were excluded for the following reasons: non-English, dealt only with disclosing errors or patient preferences, opinion/editorial pieces, news articles, or announcements. This left 68 articles for consideration in this review, 10 of which were considered as evidence.

Evidence Table. Summary of Evidence Related to Wrong-Site Surgery

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Cronen 2005[34]	Sterility of surgical site marking	Nonrandomized control study	Test the sterility of the site mark after using a surgical marking pen	20 volunteers. The right forearm was used as the experimental (marked) arm, and the left forearm as the control arm. The experimental forearms were marked with a surgical marker as described by the protocol.	Both upper extremities were sterilized from the antecubital fossa to the phalanges with a 7.5% povidone-iodine scrub followed by the application of a 10% povidone-iodine paint. Swabs were used to obtain samples from the experimental and control arms, as well as from the marker. Swabs were sent for microbiological culture and analysis.	No growth was seen in the cultures of the swabs used on the experimental or control arms or on the marking pens. Preoperative marking of surgical sites in accordance with the Universal Protocol did not affect the sterility of the surgical field, a finding that provides support for the safety of surgical site marking.
DiGiovanni 2003[33]	Surgical site marking	Pretest and post-test study	Evaluated the responses of 100 elective patients undergoing foot and ankle surgery to participating in marking the surgical site. (Level 3)	Prospective study. 100 consecutive patients in a private foot-and-ankle practice followed the explicit preoperative instruction, before they underwent elective orthopedic surgery, to mark "NO" on the extremity that was not to be operated on.	Patients were instructed on how to mark the site	59 patients correctly marked the surgical site, 27 made no mark, 4 were considered partially marked, as the mark was different from the “NO” they were instructed to do. 70% of noncompliant patients had a worker compensation claim.
Giles 2006[32]	Surgical site marking	Noncomparative study	Retrospective qualitative semi-structured surveys. (Level 4)	In person or telephone interview of 38 surgeons in 14 hospitals in the U.K.		Surgeon’s practices and methods of site marking varied, as did their value of the need for marking.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
JCAHO 2003[20]	Surgical site identification protocol	Published guidelines based on a consensus report		Universal Protocol is applicable to all JCAHO accredited facilities commencing on July 1, 2004.	Preoperative strategy to verify the correct patient, type of procedure, and site of intervention	3-step Universal Protocol: • Preoperative verification process • Marking the operative site • Time out immediately before starting the procedure
Kwaan 2006[6]	Wrong-site surgery	Case series	Incidence, characteristics, cause of WSS. Characteristics of site verification protocols (Level 2)	Malpractice liability insurer data from 20-year period from one-third of Massachusetts physicians and approximately 30 hospitals. Site verification protocols in 2004 from 28 hospitals covered by 4 malpractice insurers in New England and Texas. Retrospective medical records reviewed on 13 of 24 identified cases of WSS.		Wrong-site surgery is rare as is major injury from WSS. Current protocols for site verification could have prevented only 2/3 of examined cases.
Makary 2007[36]	Communication	Pretest and post-test study	Survey	306 operating room (OR) staff (e.g., surgeons, nurses, and anesthesiologists) at one academic medical center (85% response rate)	Administered a version of the Safety Attitudes Questionnaire before and after initiation of an OR briefing program.	OR briefings reduced perceived risk for WSS, improved perceived collaboration/teamwork among OR staff, and promoted using team discussions.
Mawji 2002[29]	Surgical site identification protocol	Quality improvement project	Root-cause analysis of near misses, for project implementation using the Plan-Do-Study-Act method.	800-bed, 3-site academic hospital and network	Implementation of surgical site policy, marking “yes” on the surgical site and “no” on the other side.	Surgical site marking policy was not being followed. • Handoffs were missing critical information. • Nature of marking was problematic. • Laterality of markings not included in policy.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Meinberg 2003[7]	Incidence of wrong-site surgery in hand surgeons	Noncomparative study	Survey	1,560 active members of the American Society for Surgery of the Hand (ASSH) were polled by mail. Return rate of 67%.	29-question survey to determine incidence of WSS	Estimated number of WSS was 1 in 27,686 hand procedures. 21% hand surgeons reported performing wrong-site surgery at least once during their career; wrong finger occurred 63% of the 242 reported events.
Rogers 2004[31]	Barriers to implementing Wrong Site Surgery Guidelines	Changing practice projects/ research	Observational study of surgical cases at 4 facilities: 2 outpatient surgical units 1 large metropolitan teaching university 1moderate-size Federal facility	October 2001 to February 2002 Field observation and semi-structured interview questions. Total of 40 observational hours.		Surgical process is tightly coupled, complex system that includes multiple layers of interaction. Unlikely to error proof completely the process in such a dynamic environment, but measures can enhance the resiliency, such as having data available to all practitioners that is updated for everyone to see to prevent overreliance on memory. Avoid hidden assumptions, for example, that encourage patients to be involved in site-marking process as it assumes the patient is physically, cognitively, and emotionally able to correct any errors.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Sexton 2006[30]	Teamwork climate in OR – preverification process	Noncomparative study	Safety Attitudes Questionnaire Survey	2,135 OR caregivers in a 60-hospital health system, including surgeons, surgical technicians, anesthesiologists, CRNAs, and OR nurses.		A high level of teamwork was perceived by the attending surgeons (64%) and residents (74%), which was markedly different from the attending anesthesiologists (39%), surgical nurses (28%), anesthesia nurses (25%), and anesthesia residents (10%). When attending surgeons were asked about a fellow, resident, or medical student questioning their decision, 45% of attending surgeons indicated that hierarchical systems should be in place, compared to 94% of airline crew members who preferred no hierarchies (Sexton et al., 2000). When asked the question, "Even when fatigued, I perform effectively during critical times," the surgical team response ranged from 47% to 70% in agreement, compared with 26% of pilots who agreed with this statement (Sexton et al., 2000).

Chapter 37. Medication Administration Safety

Ronda G. Hughes, Mary A. Blegen

Background

The Institute of Medicine's (IOM) first Quality Chasm report, *To Err Is Human: Building a Safer Health System*,[1] stated that medication-related errors (a subset of medical error) were a significant cause of morbidity and mortality; they accounted "for one out of every 131 outpatient deaths, and one out of 854 inpatient deaths"[1] (p. 27). Medication errors were estimated to account for more than 7,000 deaths annually.[1] Building on this work and previous IOM reports, the IOM put forth a report in 2007 on medication safety, *Preventing Medication Errors*.[2] This report emphasized the importance of severely reducing medication errors, improving communication with patients, continually monitoring for errors, providing clinicians with decision-support and information tools, and improving and standardizing medication labeling and drug-related information.

With the growing reliance on medication therapy as the primary intervention for most illnesses, patients receiving medication interventions are exposed to potential harm as well as benefits. Benefits are effective management of the illness/disease, slowed progression of the disease, and improved patient outcomes with few if any errors. Harm from medications can arise from unintended consequences as well as medication error (wrong medication, wrong time, wrong dose, etc.). With inadequate nursing education about patient safety and quality, excessive workloads, staffing inadequacies, fatigue, illegible provider handwriting, flawed dispensing systems, and problems with the labeling of drugs, nurses are continually challenged to ensure that their patients receive the right medication at the right time. The purpose of this chapter is to review the research regarding medication safety in relation to nursing care. We will show that while we have an adequate and consistent knowledge base of medication error reporting and distribution across phases of the medication process, the knowledge base to inform interventions is very weak.

Defining Medication Errors

Shared definitions of several key terms are important to understanding this chapter. Drugs are defined as "a substance intended for use in the diagnosis, cure, mitigation, treatment or prevention of disease; a substance (other than food) intended to affect the structure or any function of the body; and a substance intended for use as a component of a medicine but not a device or a component, part or accessory of a device."[3] Medications include, but are not limited to, any product considered a drug by the Food and Drug Administration (FDA).[3] Given the number and variety of definitions for medication errors, the IOM has recommended that international definitions be adopted for medication error, adverse drug events, and near misses.[2]

Medication Errors

One commonly used definition for a medication error is:

> Any preventable event that may cause or lead to inappropriate medication use or patient harm while the medication is in the control of the health care professional, patient, or consumer. Such events may be related to professional practice, health care products, procedures, and systems, including prescribing; order communication; product labeling, packaging, and nomenclature; compounding; dispensing; distribution; administration; education; monitoring; and use.[4]

Some of the factors associated with medication errors include the following:

- Medications with similar names or similar packaging
- Medications that are not commonly used or prescribed
- Commonly used medications to which many patients are allergic (e.g., antibiotics, opiates, and nonsteroidal anti-inflammatory drugs)
- Medications that require testing to ensure proper (i.e., nontoxic) therapeutic levels are maintained (e.g., lithium, warfarin, theophylline, and digoxin)

Look-alike/sound-alike medication names can result in medication errors. Misreading medication names that look similar is a common mistake. These look-alike medication names may also sound alike and can lead to errors associated with verbal prescriptions. The Joint Commission publishes a list of look-alike/sound-alike drugs that are considered the most problematic medication names across settings. (This list is available at www.jointcommission.org/NR/rdonlyres/C92AAB3F-A9BD-431C-8628-11DD2D1D53CC/0/lasa.pdf.)

Medication errors occur in all settings[5] and may or may not cause an adverse drug event (ADE). Medications with complex dosing regimens and those given in specialty areas (e.g., intensive care units, emergency departments, and diagnostic and interventional areas) are associated with increased risk of ADEs.[6] Phillips and colleagues[7] found that deaths (the most severe ADE) associated with medication errors involved central nervous system agents, antineoplastics, and cardiovascular drugs. Most of the common types of errors resulting in patient death involved the wrong dose (40.9 percent), the wrong drug (16 percent), and the wrong route of administration (9.5 percent). The causes of these deaths were categorized as oral and written miscommunication, name confusion (e.g., names that look or sound alike), similar or misleading container labeling, performance or knowledge deficits, and inappropriate packaging or device design.

Adverse Drug Events and Adverse Drug Reactions

Adverse drug events are defined as injuries that result from medication use, although the causality of this relationship may not be proven.[8] Some ADEs are caused by preventable errors. ADEs that are not preventable are often the result of adverse drug reactions (ADRs), which are defined as "any response to a drug which is noxious and unintended and which occurs at doses normally used for prophylaxis, diagnosis or therapy of disease, or the modification of physiological function, given that this noxious response is not due to medication error."[9] Potential ADEs or near misses/close calls are medication errors that do not cause any harm to the patient because they are intercepted before they reach the patient or because the patient is able to physiologically absorb the error without any harm.

An adverse drug reaction is defined as "an undesirable response associated with use of a drug that either compromises therapeutic efficacy, enhances toxicity, or both."[10] ADRs can be manifested as diarrhea or constipation, rash, headache, or other nonspecific symptoms. One of the challenges presented by ADRs is that prescribers may attribute the adverse effects to the patient's underlying condition and fail to recognize the patient's age or number of medications as a contributing factor.[11] According to Bates and colleagues,[12] more attention needs to be directed to ADEs—including both ADRs and preventable ADEs—which range in severity from insignificant to fatal.

Black Box Warnings and High-Alert Medications

In 1995, the FDA established the black box warning (BBW) system to alert prescribers to drugs with increased risks for patients. These warnings are intended to be the strongest labeling requirement for drugs or drug products that can have serious adverse reactions or potential safety hazards, especially those that may result in death or serious injury.[13] While the FDA does not issue a comprehensive list of drugs with BBWs,[14] some of the BBW drugs are celecoxib (Celebrex), warfarin, rosiglitazone (Avandia), methylphenidate (Ritalin), estrogen-containing contraceptives, and most antidepressants.[15] One study funded by the Agency for Healthcare Research and Quality found 40 percent of patients were taking a medication with a BBW and that many of those patients did not receive the recommended laboratory monitoring. The authors concluded that BBWs did not prevent the inappropriate use of high-risk medications.[16]

Medication errors can be considered a sentinel event when they are associated with high-alert medications. According to the Institute for Safe Medication Practices (ISMP), "High-alert medications are those likely to cause significant harm when used in error." The top five high-alert medications are "insulin, opiates and narcotics, injectable potassium chloride (or phosphate) concentrate, intravenous anticoagulants (heparin), and sodium chloride solutions above 0.9 percent"[17] (p. 339). ISMP's list of high-alert medications is available at: www.ismp.org/tools/highalertmedications.pdf.

The Prevalence and Impact of Medication Errors

In the Harvard Medical Practice Study, Leape and colleagues[18, 19] examined more than 30,000 hospital discharges selected at random from 51 hospitals in the State of New York in 1984. The researchers found that 3.7 percent of hospitalizations involved adverse events that prolonged hospital stay or were manifested as a new disability at the time of discharge. About one in four of these adverse events were judged to be attributable to negligence, and 58 percent were judged to be preventable.

It is difficult to reduce or eliminate medication errors when information on their prevalence is absent, inaccurate, or contradictory. Bates[20] put forth the notion that for every medication error that harms a patient, there are 100, mostly undetected, errors that do not. Most medication errors cause no patient harm or remain undetected by the clinician.[20, 21] The low rate of detected errors makes assessing the effectiveness of strategies to prevent medication errors challenging.

Rates of medication errors vary, depending on the detection method used. For example, among hospitalized patients, studies have shown that errors may be occurring as frequently as one per patient per day.[5, 22] In pediatric intensive care unit (ICU) studies, reported medication error rates have ranged from 5.7[23] and 14.6 per 100 orders[24] to as high as 26 per 100 orders.[25]

The impact of medication errors on morbidity and mortality were assessed in a case-control analysis of ADEs in hospitalized patients during a 3-year period.[26] The investigators found significant increases in (a) the cost of hospitalization from increased length of stay, ranging from $677 to $9,022; (b) patient mortality (odds ratio = 1.88 with a 95% confidence interval); and (c) postdischarge disability. The impact was less in male patients, younger patients, and patients with less severe illnesses and in certain diagnosis-related groups.

Without an infrastructure to capture and assess all medication errors and near misses, the real number is not known. These rates could be expected to be higher once patient safety organizations begin to collect nationwide errors and health care clinicians become more comfortable and skilled in recognizing and reporting all medication errors. The concern raised in *To Err Is Human*[1] about the potential prevalence and impact of ADEs—2 out of every 100 hospitalized patients—was just the beginning of our understanding of the potential magnitude of the rates of medication errors. The concern continues, as is seen in the most recent IOM report, *Preventing Medication Errors*,[2] which states that "a hospital patient is subject to at least one medication error per day, with considerable variation in error rates across facilities" (pp. 1–2). Yet, despite numerous research findings, we cannot estimate the actual rates because they vary by site, organization, and clinician; because not all medication errors are detected; and because not all detected errors are reported.

Error-Prone Processes

There are five stages of the medication process: (a) ordering/prescribing, (b) transcribing and verifying, (c) dispensing and delivering, (d) administering, and (e) monitoring and reporting.[2] Monitoring and reporting is a newly identified stage about which there is little research. Some of the most noted and early work on medication safety found hospitalized patients suffer preventable injury or even death as a result of ADEs associated with errors made during the prescribing, dispensing, and administering of medications to patients,[12, 27–29] although the rates of error in the stages of the medication process vary. A few studies have indicated that one of every three medication errors could be attributed to either a lack of knowledge about the medication or a lack of knowledge about the patient.[30]

Prescribing/ordering. Of the five stages, ordering/prescribing most often initiates a series of errors resulting in a patient receiving the wrong dose or wrong medication. In this stage, the wrong drug, dose, or route can be ordered, as can drugs to which the patient has known allergies. Workload, knowledge about the prescribed drug, and attitude of the prescriber—especially if there is a low perceived importance of prescribing compared with other responsibilities—are significantly associated with ADEs.[31, 32] Furthermore, if nurses or pharmacists question a prescriber about an order, they can be confronted with aggressive behavior, which may inhibit future questioning and seeking clarification.[33] The proportion of medication errors attributable to the ordering/prescribing stage range from 79 percent[29] to 3 percent.[34] Examples of the types of errors committed in this stage include illegible and/or incomplete orders, orders for contraindicated medications, and inappropriate doses. Similar results have been found in mandatory adverse event reporting systems. An analysis of 108 reports associated with significant harm or death reported to the State of New York noted that, when the error occurred during the prescribing stage, written prescriptions accounted for 74 percent of the errors, and verbal orders accounted for 15 percent.[6]

While the preponderance of the research focuses on physician prescribing, there is a brief discussion about the role of advanced practice nurses in prescribing to ensure safety. One

investigation of the occurrence of ADRs in outpatient veterans found no difference in ADR events between physicians and nurse practitioners.[11] Prescribers may make changes in medication therapy (e.g., change the dosage or discontinue the medication) in response to ADRs (e.g., constipation, rash) or other indications communicated to them by nurses or patients.

Transcribing, dispensing, and delivering. In some settings, medication orders are transcribed, dispensed, and then delivered for nurse administration. In certain circumstances and settings, both nurses and pharmacists are involved in transcribing, verifying, dispensing, and delivering medications. Yet errors of these two stages (transcribing and verifying, dispensing and delivering) have been predominately studied for pharmacists. Pharmacists can have an important role in intercepting and preventing prescribing/ordering errors.[35] One study found that while dispensing errors were 14 percent of the total ADEs, pharmacists intercepted 70 percent of all physician ordering errors.[27] Pharmacy dispensing errors have been found to range from 4 percent to 42 percent of errors.[36] Examples of errors that can be initiated at the transcribing, dispensing, and delivering stages include failure to transcribe the order, incorrectly filling the order, and failure to deliver the correct medication for the correct patient.

Medication administration. Nurses are primarily involved in the administration of medications across settings. Nurses can also be involved in both the dispensing and preparation of medications (in a similar role to pharmacists), such as crushing pills and drawing up a measured amount for injections. Early research on medication administration errors (MAEs) reported an error rate of 60 percent,[34] mainly in the form of wrong time, wrong rate, or wrong dose. In other studies, approximately one out of every three ADEs were attributable to nurses administering medications to patients.[21, 28] In a study of deaths caused by medication errors reported to the FDA from 1993 to 1998, injectable drugs were most often the problem;[7] the most common type of error was a drug overdose, and the second most common type of error was administering the wrong drug to a patient. The 583 causes of the 469 deaths were categorized as miscommunication, name confusion, similar or misleading labeling, human factors (e.g., knowledge or performance deficits), and inappropriate packaging or device design. The most common causes were human factors (65.2 percent), followed by miscommunication (15.8 percent).

Nurses are not the only ones to administer medications. Physicians, certified medication technicians, and patients and family members also administer medications. Part of the challenge in understanding the impact of nursing in medication administration is the need for research that clearly differentiates the administrators of medications. Several studies have reported medication administration errors that have included nonnurses.[37, 38] Among many reasons for the prevalence of nurse involvement in medication errors is that nurses may spend as much as 40 percent of their time in medication administration.[39]

A large-scale study by the U.S. National Council of State Boards of Nursing assessed whether there were any identifiable characteristics common to those nurses who committed medication administration errors. The most significant finding was that "the age, educational preparation and employment setting of RNs disciplined for medication administration errors are similar to those of the entire RN population"[40] (p. 12).

The "rights" of medication administration include right patient, right drug, right time, right route, and right dose. These rights are critical for nurses. A survey of patients discharged from the hospital found that about 20 percent were concerned about an error with their medications, and 15 percent of them were concerned about being harmed from mistakes by nurses compared to 10 percent who were concerned about mistakes by physicians.[41] However, the complexity of

the medication process has led to the formulation of the rights of nurses in the area of medication administration. The essential environmental conditions conducive to safe medication practices include (a) the right to complete and clearly written orders that clearly specify the drug, dose, route, and frequency; (b) the right to have the correct drug route and dose dispensed from pharmacies; (c) the right to have access to drug information; (d) the right to have policies on safe medication administration; (e) the right to administer medications safely and to identify problems in the system; and (f) the right to stop, think, and be vigilant when administering medications.[42]

Types of Medication Errors

Leape and colleagues[27] reported more than 15 types of medication errors: wrong dose, wrong choice, wrong drug, known allergy, missed dose, wrong time, wrong frequency, wrong technique, drug-drug interaction, wrong route, extra dose, failure to act on test, equipment failure, inadequate monitoring, preparation error, and other. Of the 130 errors for physicians, the majority were wrong dose, wrong choice of drug, and known allergy. Among the 126 nursing administration errors, the majority were associated with wrong dose, wrong technique, and wrong drug. Each type of error was found to occur at various stages, though some more often during the ordering and administration stages.

Since the study by Leape and colleagues, research has captured some of the types of error identified by Leape and added yet others (e.g., omission due to late transcription,[43] wrong administration technique,[24, 44, 45] and infiltration/extravasation.[46] Reporting incidences by type of error, rather than the stage it was associated with, leads to equivocal implications for nursing practice. The categorization approach used determines whether the implication can be targeted to stage, and therefore discipline, or to types of error. For example, 11 studies reported rates of types of medication errors using institution-specific and national databases, yet not specifying whether the error occurred during the prescribing, dispensing, or administration stage of the medication process or not clearly specifying administration errors associated with nurse administration. One of these studies analyzed deaths associated with medication errors, finding that the majority of deaths were related to overdose and wrong drug[7]—again, not specified by stage. Yet among these, it may be possible to see that wrong dose, dose omission, wrong drug, and wrong time are the most frequent type of medication error. Even then, comparisons and practice implications are challenging due to the lack of standardization among the types of categories used in research.

Working Conditions Can Facilitate Medication Errors

Following the release of *To Err Is Human*,[1] the focus on deaths caused by medication errors targeted system issues, such as high noise levels and excessive workloads,[47] and system interventions, such as the need for computerized order entry, unit dose (e.g., single-dose packaging), and 24-hour pharmacy coverage.[48] The IOM's report, *Crossing the Quality Chasm*,[49] put forth the concept that poor designs set the workforce up to fail, regardless of how hard they try. Thus, if health care institutions want to ensure safer, higher-quality care, they will need to, among other things, redesign systems of care using information technology to support clinical and administrative processes.

We are at the beginning stage of assessing and understanding the potential association between working conditions/environment and medication errors. Early research in this area found a relationship between characteristics of the work environment for nurses and medication

errors.[30, 50, 51] For example, Leape and colleagues[27] found an association between the occurrence of medication errors and the inability to access information and failure to follow policies and guidelines. Also, research has found that health care clinicians should be aware of the repeated patterns of medication errors and near misses to provide insight on how to avoid future errors.[52]

The system approach to safety emphasizes the human condition of fallibility and anticipates that errors will occur, even in the best organizations with the best people working in them. This approach focuses on identifying predisposing factors within the working environment or systems that lead to errors.[53] Reason's[53] model of accident causation describes three conditions that predicate an error:

1. *Latent conditions*—Organizational processes, management decisions, and elements in the system, such as staffing shortages, turnover, and medication administration protocols.
2. *Error-producing conditions*—Environmental, team, individual, or task factors that affect performance, such as distractions and interruptions (e.g., delivering and receiving food trays), transporting patients, and performing ancillary services (e.g., delivery of medical supplies, blood products).[49]
3. *Active failures*—errors involving slips (actions in which there are recognition or selection failures), lapses (failure of memory or attention), and mistakes (incorrect choice of objective, or choice of an incorrect path to achieve it), compared to violation, where rules of correct behavior are consciously ignored.

Threats to medication safety include miscommunication among health care providers, drug information that is not accessible or up to date, confusing directions, poor technique, inadequate patient information, lack of drug knowledge, incomplete patient medication history, lack of redundant safety checks, lack of evidence-based protocols, and staff assuming roles for which they are not prepared. An additional risk is a hospital without 24-hour pharmacy coverage, especially when procedural barriers to offset the risk of accessing high-risk drugs are absent.[6]

Recognizing and Reporting Medication Administration Errors

Error reporting strategies are critical to the implementation of effective system-level approaches to reduce medication errors and ADEs.[54] However, the usefulness of many reporting strategies depends directly on the level of response.[55] To be effective, medication error reporting needs to be ongoing and part of a continuous quality improvement process.[56, 57]

Previous research has found that when nurses voluntarily report medication administration errors, as few as 10 to 25 percent of errors are reported.[28] As discussed in the chapter on error reporting, there were numerous surveys of hospital nurses' perceptions of what constitutes an MAE, why these types of errors occur,[58–61] and what the barriers to reporting are.[58–72] The three most significant barriers to reporting were (a) a hierarchical hospital culture/structure where the nursing staff disagreed about the definition of reportable errors, (b) fear of the response and reaction of hospital management/administrators and peers to a reported error, and (c) the amount of time and effort involved in documenting and reporting an error. Together these studies indicate that the medication errors that are reported do not represent the actual incidence of medication errors.

Without reporting, many errors may not be known. Based on a survey of nurses on barriers to reporting, Wakefield and colleagues[62] suggested several strategies to increase the reporting of MAEs: agreement on the definition of error; supporting and simplifying reporting of errors; institutionalizing a culture that rewards and learns from error reporting (i.e., a culture of safety, where learning is encouraged and blaming discouraged); capitalizing on feedback reports to

determine system factors contributing to error; and ensuring positive incentives for MAE reporting.

Incident reports, retrospective chart reviews, and direct observation are methods that have been used to detect errors. Incident reports, which capture information on recognized errors, can vary by type of unit and management activities;[73] they represent only a few of the actual medication errors, particularly when compared to a patient record review.[74] Chart reviews have been found to be most useful in detecting errors in ordering/prescribing, but not administration.[75, 76] Direct observation of administration with comparison to the medication administration record detects most administration errors; however, it cannot detect ordering errors and, in some systems, transcribing and dispensing errors. There were two studies that compared detection methods. One of these studies of medication administration in 36 hospitals and skilled nursing facilities found 373 errors made on 2,556 doses.[77] The comparison of three detection methods found that chart review detected 7 percent of the observed errors, and incident reports detected only 1 percent. Direct observation was able to detect 80 percent of true administration errors, far more than detected through other means. A second study compared detection methods and found that more administration errors were detected by observation (a 31.1 percent error rate) than were documented in the patients' medical records (a 23.5 percent error rate).[78] Therefore, no one method will do it all. When automated systems that use triggers are not in place, multiple approaches such as incident reports, observation, patient record reviews, and surveillance by pharmacist may be more successful.[79]

The wide variation in reported prevalence and etiology of medication errors is in part attributable to the lack of a national reporting system or systems that collect both errors and near misses. State-based and nationally focused efforts to better determine the incidence of medication errors are also available and expanding (Patient Safety and Quality Improvement Act of 2005). The FDA's Adverse Event Reporting System (AERS), which is part of the FDAs' MedWatch program (www.fda.gov/medwatch), U.S. Pharmacopeia's (USP's) MEDMARX® database (www.medmarx.com), and the USP's Medication Errors Reporting Program (MERP; www.ismp.org/orderforms/reporterrortoISMP.asp), in cooperation with the ISMP, collect voluntary reports on actual and potential medication errors, analyze the information, and publish information on their findings.

Research reported to date clearly reveals that medication errors are a major threat to patient safety, and that these errors can be attributed to all involved disciplines and to all stages of the medication process. Unfortunately, the research also reveals that we have only weak knowledge of the actual incidence of errors. Our information about ADEs (those detected, reported, and treated) is better, but far from complete. With this knowledge of the strengths and limitations of the research, this chapter will consider the evidence regarding nurses' medication administration.

Research Evidence—Medication Administration by Nurses

The research review targeted studies involving medication administration by nurses. This excluded several studies that assessed medication administration errors without differentiating whether the errors were associated with physicians, assistants, or nurses. None of these studies included interventions.

Rates and Types of Medication Administration Errors

Thirteen studies explicitly reported types of MAEs associated with nurses. The incidence of MAEs was detected either formally through incident reports, chart reviews, or direct observation, or informally through anonymous surveys. Two studies conducted retrospective assessments, one using medical records[43] and the other malpractice claims.[80] Seven studies assessed self-reported MAEs from a nationally representative database[44, 81–83] or self-reported errors using a nationally representative sample.[84–86] None of these self-reported MAEs were verified. Eight studies assessed MAEs using direct observation of the medication administration process.[24, 37, 78, 87–91]

The incidence of MAEs varied widely with the different research designs and samples. Using chart reviews, Grasso and colleagues[43] found that 4.7 percent of doses were administered incorrectly. Direct observation studies placed the estimate of total incorrect doses between 19 percent and 27 percent,[87] and when an extra review was done to separate the errors into stages of the medication process, between 6 percent and 8 percent of doses were in error because of administration. The majority of types of MAEs reported were wrong dose, wrong rate, wrong time, and omission. All of the studies reviewed here reported wrong drug and dose, but varied across the other types of MAE categories (see Evidence Table 1); this was dependent upon the study methodology.

Five studies evaluated self-reported MAEs, involving incident reports and informal reports.[38, 44, 81, 82] The most common types of reported errors were wrong dose, omission, and wrong time. Four of these studies[38, 81–83] assessed a large secondary, nationally representative database containing MAEs reported to the MEDMARX database over five years.[38, 81, 82, 44] found in the error reports submitted by nursing students that the majority of MAEs were associated with omission, wrong dose, wrong time, and extra dose. Of the reported contributing factors, 78 percent were due to the inexperience of the nurse. The Beyea and Hicks[81, 82] studies looked at errors associated with the operating room, same-day surgery, and postanesthesia; they found the majority of errors attributable to administration but did not classify them by error type. The other study reviewed 88 incident reports from a long-term care facility submitted during a 21-month period. It found that the majority of MAEs were associated with errors involving interpreting or updating the medication administration record, delayed dose, wrong dose, or wrong drug.[92] A separate component of this study surveyed administrative and clinical nurses and found that they believed the majority of medication errors occurred at either the administration or dispensing stage.

Two other studies assessed the type of MAEs reported by nurses in nationwide surveys.[84, 85] While the majority (57 percent) of errors reported by critical care nurses involved MAEs, an additional 28 percent of reported errors involved near misses. Medication administration errors involving wrong time, omission, and wrong dose accounted for 77.3 percent of errors, while wrong drug and wrong patient accounted for 77.8 percent of near misses. The most frequent types of medication errors were wrong time (33.6 percent), wrong dose (24.1 percent), and wrong drug (17.2 percent), and the three most frequent types of near misses were wrong drug (29.3 percent), wrong dose (21.6 percent), and wrong patient (19.0 percent).[85] Many of the reported MAEs in ICUs involved intravenous medications and fluids.[84] In these surveys, the nurses who reported making errors described between two and five errors during a 14-day period.

At the more advanced stage of incident reports, one study reviewed 68 malpractice cases involving MAEs in Sweden.[80] Among the cases reviewed, the majority of MAEs made by nurses

involved wrong dose. When the nurses delegated the drug administration to subordinate staff, the majority of MAEs involved wrong drug or wrong concentration of a drug. Errors, which were reported to the immediate supervisor, were also reported to the physician in 65 percent of cases. The reported causes of MAEs were lack of administration protocols, failure to check orders, ineffective nurse supervision when delegating administration, and inadequate documentation.

One study assessed medication errors using 31 medical records of patients discharged from a psychiatric hospital and found a total of 2,194 errors.[43] Of these, 997 were classified as MAEs (4.7 percent of all doses, and 66 percent of all errors). Of these, 61.9 percent were due to scheduled doses not documented as administered, 29.1 percent as drugs administered without an order, 8 percent as missed doses because of late transcription, and 3 percent resulting from orders not being correctly entered in the pharmacy computer.

The number of studies using direct observation of medication administration is increasing in response to the concern about the accuracy of other sources of data. Ten studies were found, only three of which were done in the United States. While we attempt to summarize across these studies, it is difficult to determine consistency across studies as each focused on different sets of errors (some only intravenous errors, some included gastrointestinal tube technique) and were conducted in different settings. In many of the non-U.S. studies, nurses dispensed drugs from ward stock and prepared many of the intravenous solutions for administration.

Three observational studies were conducted in pediatric units—one in France,[78] one in Switzerland,[25] and one in the United States.[24] Buckley[24] reported 52 of the 263 doses (19 percent) observed to be in error, but only 15 (6 percent) of those were in the administration stage. Those 15 were nearly evenly divided among wrong dose, wrong time, wrong technique, and extra dose categories. Prot[78] reported nearly 50 percent more MAEs. Of the 1,719 observed doses, 467 (27 percent) were in error, including wrong time; excluding wrong-time errors, the error rate was 13 percent of doses. The categories with the most MAEs in Prot's study were wrong time, wrong route (GI tube versus oral), wrong dose, unordered drug, wrong form, and omissions. Schneider and colleagues[25] reported an overall 26.9 percent error rate with wrong-time errors, and an 18.2 percent rate excluding wrong-time errors. Common errors in addition to wrong time were wrong dose preparation and wrong administration technique.

The incidence of intravenous drug errors was observed in three studies, one in England,[89] one in Germany,[90] and one in both countries.[37] About 50 percent of the doses were determined to contain at least one error. Compared to other studies, this rate is surprisingly high, and it included preparation technique errors (selection of diluent/solvent) as well as administration errors (rate of bolus injection and infusion rate). Part of the explanation may come from institutional (type of pharmacy support available) and professional training factors. (German nurses are not trained to do intravenous medications.)

Three studies focused on medication administration in ICUs in the United States,[45] in France,[91] and in the Netherlands.[94] Kopp and colleagues[45] looked at all medication errors and report that 27 percent of doses were in error; of these 32 percent could be attributed to the administration stage. Within the MAEs, most were omitted medications; the rest were evenly distributed among wrong dose, extra dose, and wrong technique. Few wrong-time errors were noted. Tissot[91] and van den Bernt[94] examined only administration stage errors and reported very different rates. Tissot reported 6.6 percent of the 2,009 observed doses were in error, most from wrong dose, wrong rate, and wrong preparation technique. Excluding wrong-time errors, van den Bernt reported a 33 percent error rate that included preparation errors with diluent/solvent issues, infusion-rate errors, and chemical incompatibility of intravenous drugs. It is likely that the differences in rates across these studies are due to the range of error types observed in each study as well as the varying responsibilities of nurses in the three countries.

The most extensive observation study, by Barker and colleagues,[87] conducted observations of medication administration in 36 randomly selected health care facilities (acute and long-term care) in two States in the United States. Of the 3,216 doses observed, 605 (19 percent) contained at least one error. Nearly half of those errors were wrong-time errors. Other common types of errors included omission, wrong dose, and unauthorized (unordered) drug. In a much smaller study conducted in the Netherlands, Colen, Neef, and Schuring[88] found an MAE rate of 27 percent, with most of these wrong-time errors. The rate of MAEs without wrong time was approximately 7 percent, and most of those were omissions.

Information from these research studies forms a consistent picture of the most common types of MAEs. These are wrong time, omissions, and wrong dose (including extra dose). Rates of error derived from direct observation studies ranged narrowly between 20 and 27 percent including wrong-time errors, and between 6 and 18 percent excluding wrong-time errors. The alarming exception to this was the nearly 50 percent error rate in observation of intravenous medication in ICUs in Europe.

Evidence Table 1. Types of Reported and Observed Medication Administration Errors (MAEs)

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Key Finding(s)
Balas 2004[85]	Type of MAEs	Cross-sectional study	Voluntary, self-reported recording of 14 days of shift work, sleep, and errors using a journal	393 full-time registered nurses (RNs) in hospitals responded to the survey.	37.8% of nurses reported medication errors and near errors; made on average between 2 and 5 errors. Reported top types of medication errors were wrong time (33.6%), wrong dose (24.1%), and wrong drug (17.2%), compared to the top three types of near errors, which were wrong drug (29.3%), wrong dose (21.6%), and wrong patient (19.0%).
Balas 2006[84]	Types of MAEs or near errors	Cross-sectional study	Voluntary, self-reported recording of 14 days of shift work, sleep, and errors using a journal	502 RNs in critical care units throughout the United States	Of the 224 errors and 350 near errors, 56.7% involved medications. Wrong time, omission, and wrong dose accounted for 77.3% of MAEs, and wrong dose, wrong drug, and wrong patient accounted for 77.8% of near misses.
Barker 2002[87]	Types of MAEs	Cross-sectional	Observation of 3,216 doses administered by nurses in 36 randomly selected institutions	12 accredited hospitals, 12 nonaccredited hospitals, and 12 nursing homes	19% of doses were in error including wrong time, 11% excluding wrong time. The most frequent errors besides wrong time were omissions and wrong dose in all three types of institutions.
Buckley 2007[24]	Types of MAEs	Prospective cohort study	Direct observation over 6 months of medication process, determining actual and potential errors. Observers would intervene if error was considered harmful to patient.	In a 16-bed pediatric medical/surgical ICU at a tertiary care academic medical center	263 doses observed and 19% were in error. Only 6% of the doses were affected by an MAE. Common errors during administration were wrong dose, wrong time, extra dose, and wrong technique. Proximal causes of administration errors were slips and memory lapses, lack of drug knowledge, and rule violations.
Colen 2003[88]	Types of MAEs	Prospective cohort study	One phase of a study of the evaluation of a medication distribution system involving direct observation of administration. Observers would intervene if error was considered harmful to patient.	1,077 doses were observed in 1 teaching hospital in the Netherlands	The MAE rate was 27.2% including wrong time, and 7.2% excluding wrong time. The major types of MAEs included wrong time (20.0%) and omissions (3.3%).

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Key Finding(s)
Grasso 2003[43]	Types of MAEs	Retrospective cohort study	Review of patient records for patients discharged from the Augusta Mental Health Institute in Maine, during a period of 14 weeks	2,194 medication errors, of which 1,432 were MAEs, from 31 patient records	MAEs represented 65.3% of all medication errors. 61.9% of MAEs were due to a scheduled dose not documented as administered, 29.1% as drugs administered without an order, 8% as missed dose because of late transcription, and 3% resulting from order not being correctly entered in the pharmacy computer.
Kapborg 1999[80]	Types of MAEs	Retrospective cohort study	Analysis of malpractice cases and small interview survey with 8 nurses working in nursing homes and home care setting using semistructured questions	68 cases of MAEs occurring in several types of home care settings and nursing homes during a 4-year period, reported to a regional supervisory unit of the National Board of Health and Welfare in Sweden	The majority of MAEs made by nurses involved dosing above what was prescribed and when the drug administration was delegated to subordinate staff; the majority of MAEs involved wrong drug or wrong concentration of a drug.
Kopp 2006[45]	Types of MAEs	Prospective cohort study	Direct observation over 6 months by 2 pharmacy residents specializing in critical care pharmacy. Pharmacy residents would intervene if MAE would have resulted in patient harm.	1 16-bed medical/surgical ICU in a tertiary care academic medical center in Arizona	Overall, 27% of doses were in error. Of the 132 ADEs, 42 (32%) were attributed to medication administration. About half of those (48%) were errors of omission. Other common error types were wrong dose, extra dose, and wrong technique. Thirty seven (34%) of ADEs attributed to medication administration were considered potential ADEs, and only 3 of those were intercepted.
McCarthy 2000[86]	Types of MAEs	Cross-sectional study	Voluntary, randomly selected survey of members of the National Association of School Nurses	649 school nurses (64.9% response rate) in the United States	48.5% of respondents reported medication errors, and the majority of the types of errors were missed doses and undocumented doses.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Key Finding(s)
Prot 2005[78]	Types of MAEs	Prospective cohort study	Direct observation of nurses administering medications to patients. Observers would intervene if MAE would have resulted in patient harm.	1,719 doses were observed on 4 units at a pediatric teaching hospital in Paris, France.	27% of doses were in error (538 MAEs). Wrong-time errors were 36% of MAEs, wrong route was 19%, wrong dose was 15%, and unordered drug was 10%. The risk of an MAE increased if the medication was administered by a nurse intern, a temporary staffing agency nurse, or a pool nurse (OR = 1.67, *P* = 0.03) and if the medication had been prepared by the pharmacy (OR = 1.66, *P* = 0.02).
Schneider 1998[25]	Frequency and types of MAEs	Cross-sectional	Direct observation	275 doses were observed on a pediatric ICU in Switzerland	26.9% of the doses were in error including wrong-time errors, 18.2% excluding wrong-time errors. The other common error types were wrong dose preparation and wrong administration technique.
Taxis 2003[89]	Types of MAEs in Intravenous (IV) drug administration	Cross-sectional	Ethnographic—direct observation of nurses administering medications	430 IV drug doses were observed for nurses working in 10 wards in 2 hospitals in the UK.	Overall error rate was 49%; wrong-time errors were not counted. Of the 212 errors observed, 38% involved administering a bolus dose too fast, and preparation errors accounted for 15%. Majority of preparations errors by nurses involved doses requiring multiple-step preparations, specifically preparing the wrong dose or selecting the wrong solvent.
Taxis 2003[90]	Types of MAEs in IV drug administration	Cross-sectional	Ethnographic—direct observation of nurses administering medications	22 staff nurses on 2 units in a German hospital were observed administering 122 IV doses.	Overall error rate was 48%. Wrong-time errors were not counted. Of the errors, the largest proportion occurred during a multiple-step drug preparation procedure, and the second largest was administering incompatible drugs through the same line. Majority of preparations errors by nurses involved preparing the wrong dose or selecting the wrong solvent.
Tissot 2003[91]	Type of MAEs	Prospective cohort study	Direct observation of nurses administering medications to patients by a pharmacist	Medical ICU in France	Of the 2,009 nursing acts observed, 132 (6.6%) were in error. Wrong dose was the most frequent error, followed by wrong rate of administration, errors in preparation, and physicochemical incompatibility.
Ven den Bernt 2002[94]	Frequency and type of MAEs	Cross-sectional	Direct observation of nurses administering medication to patients	233 drug administrations in 2 Dutch hospitals	Overall, 104 doses had errors (44.6%) including wrong time, 77 (33%) excluding wrong time. The most common error types were wrong dose preparation and wrong administration technique.
Wirtz 2003[37]	Types of MAEs in IV drug administration	Cross-sectional	Ethnographic—disguised observation of nurses preparing and administering medications	337 drug preparations and 278 drug administration were observed in 2 German and one UK hospital.	Across the three sites, the rate for preparation errors was 26%, and the rate for administration errors was 34%. The most common errors were wrong administration rate, omissions, and wrong dose. The types of errors varied across the hospitals, which had different pharmacy systems, although nurses prepared and administered IV meds on the wards.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Key Finding(s)
Wolf 2006[44]	Types of MAEs	Retrospective cohort study	Analysis of MAEs reported January 1, 1999, to December 21, 2003, by nursing students during the administration phase	MAEs reported by 1,305 nursing students in the USP MEDMARX program	Majority of MAEs were associated with omission (19%), wrong dose (17%), wrong time (17%), and extra dose (14%). The major causes of MAEs were reported as performance (human) deficit (51%), procedure/protocol not followed (32%), and knowledge deficit (27%). Of the reported contributing factors, 78% were due to the inexperience of staff. When an MAE occurred, 55% of the staff who made the error were informed and 44% received education/training.

Impact of Working Conditions on Medication Errors

Medication safety for patients is dependent upon systems, process, and human factors, which can vary significantly across health care settings. A review of the literature found 34 studies that investigated some aspect of working conditions in relation to medication safety.

Systems factors. Systems factors that can influence medication administration include staffing levels and RN skill mix (proportion of care given by RNs), shift length, patient acuity, and organizational climate. There were 13 articles presenting research findings and three literature reviews. The major systems/organizational factors included nurse staffing, workload, organizational climate/favorable working conditions, policies and procedures, and technologies enabling safety or contributing to MAEs.

Nurse staffing: Medication administration is a key responsibility of nurses in many settings, and three studies assessed the relationship between nurse staffing, hours of nursing care in hospitals, RN skill mix, and medication errors. Two studies associated the total hours of care and the RN skill mix at a patient care unit to reported medication error rates in those units; one study used 42 units in a large Midwestern hospital[95] and the other used 39 units in 11 small hospitals.[96] Rates of MAEs, when the number of doses was the denominator, were highest in medical-surgical and obstetric units; when patient days were the denominator, the highest rate was in ICUs. In both studies the type of unit was controlled and the rate of reported medication errors declined as the RN skill mix increased up to an 87 percent mix. A third study of nurses in ICUs in 10 hospitals found an inverse relationship between rates of medication errors and staffing work hours per patient day in specific settings (e.g., cardiac ICUs and noncardiac intermediate care settings). A little over 30 percent of the variance in medication error rates resulted from the variance in staffing work hours per patient day.[97]

Other studies conducted prior to 1998 did not find a relationship between staffing and medication errors. Three literature reviews,[30, 39, 98] concluded that the direct evidence for a relationship between staffing and MAE rates was inconsistent. Nurses' perceptions of the impact of staffing or workload on medication errors, however, is quite consistent.

Workloads: These findings are consistent with three studies and two literature reviews on the impact of heavy workloads, a component of nurse staffing, on errors. In one survey of nurses in 11 hospitals, both pediatric and adult nurses reported staffing ratios and the number of medications being administered as being the major reasons why medication errors occur.[58] A second survey found that nurses from Taiwan also indicated that workload was a major factor in medication errors.[93] Beyea, Hicks, and Becker[81, 82] and Hicks and colleagues[38] analyzed MEDMARX data for medication errors in the operating room, postanesthesia, and in same-day-surgery units. Most of these errors involved nurses (64–76 percent) and medication administration (59–68 percent). In all three sets of error reports, workload increases and insufficient staffing were noted to be causes of errors.

The effect of heavy workloads and inadequate numbers of nurses can also be manifested as long workdays, providing patient care beyond the point of effective performance. In a national survey by Rogers and colleagues,[99] self-reported errors by nurses found that the likelihood of a medication error increased by three times once the nurse worked more than 12.5 hours providing direct patient care. Among nurses working more than 12.5 hours, the reported errors, 58 percent of actual errors and 56 percent of near misses were associated with medication administration.

Other findings support the importance of adequate nurse staffing and understanding the impact of shift work in decreasing medication errors. A review of incident reports found that the major contributing factors to errors were inexperienced staff, followed by insufficient staffing, agency/temporary staffing, lack of access to patient information, emergency situation, poor lighting, patient transfers, floating staff, no 24-hour pharmacy, and code situations.[44] Certain aspects of shift work can also impact medication safety, as shown in a review of research conducted in the 1980s and early 1990s that indicated that there was a difference in the number of errors by shift, but no difference in the number of hours worked (8 versus 12 hours). However, there were more errors with nurses working rotating shifts.[30]

Organizational climate: Other systems/organizational issues include the presence of favorable working conditions, effective systems, policies and procedures, and technologies that enable safety or contribute to MAEs. An assessment of medication administration behaviors of 176 nurses in rural Australia, using structural equation modeling to test the association between organizational climate and the administration behaviors of nurses, found that the variable "violations" was the only variable with a direct contribution to MAEs, but there was no direct linkage to actual errors. While it was not possible to determine the effect of organizational climate on violations, distress was positively associated with violations, while quality of working life, morale, and organizational climate had a negative association. The organizational climate was found to be linked with safety behavior.[100] Hofmann and Mark[101] did find that the safety climate on patient care units was linked to the rate of harm-producing medication errors in a study using data collected from 82 units in 41 hospitals. Higher overall safety climate was related to lower rates of medication errors and urinary tract infections.

Policies, procedures, and protocols: Lack of appropriate policies, procedures, and protocols can impact medication safety, as seen in a few small studies. In a study of malpractice cases, medication errors were associated with lack of administration protocols and ineffective nurse supervision in delegating administration.[80] However, even when policies are in place, they may not necessarily improve safety. For example, a review of two studies in the literature found that medication errors did not necessarily decrease with two nurses administering medications (e.g., double-checking).[30] In addition, appropriate policies may not be followed. Double-checking policies are commonly used as a strategy to ensure medication safety. When errors occurred under such policies, failure to double-check doses by both pediatric and adult nurses [58] and nurses in a Veterans Affairs (VA) hospital[102] were reported. However, research presented in two literature reviews offers somewhat conflicting information. In the first review of three studies, following double-checking policies did not necessarily prevent errors.[39] Yet in the other review, failure to adhere to policies and procedures was associated with errors.[30]

Process factors. Process factors that influence medication administration include latent failures that can instigate events resulting in errors, such as administrative processes, technological processes, clinical processes, and factors such as interruptions and distractions. These factors reflect the nature of the work, including "competing tasks and interruptions, individual vs. teamwork, physical/cognitive requirements, treatment complexity, workflow."[103] A review of the literature found 18 studies and 2 literature reviews that contained process factors and their association to medication errors by nurses.

Distractions and interruptions: Factors such as distractions and interruptions, during the process of delivering care can have a significant impact on medication safety. Nine studies, four with nationwide samples, and two literature reviews present information on the association between MAEs and distractions and interruptions. One survey of nurses in three hospitals in

Taiwan found that they perceived distractions and interruptions as causes of errors.[93] In three other surveys in the United States, nurses ranked distractions as major causes for the majority of medication errors.[58, 61, 102] In a small, five-site observational study of medication administration among 39 RNs, licensed practical nurses (LPNs) and certified medical technicians/assistants (CMT/As), Scott-Cawiezell and colleagues[104] found an increase in medication errors attributable in part to interruptions, and when wrong-time errors were excluded, the error rate actually increased during medication administration.

These finding are furthered by research concerning self-reported errors from a nationwide sample of nurses.[84] The nurses believed the cause of their reported medication errors and near errors were interruptions and distractions. In a secondary analysis of the MEDMARX® data base, distractions and interruptions were prominent contributing factors to medication errors.[81–83] Furthermore, these findings are supported by three reviews of the literature: one found that distractions and interruptions interfered with preparing and administering medication, potentially causing errors;[30] interruptions were perceived as causing medication errors in the second review;[98] and the third indicated that rapid turnover and changes as well as distractions and interruptions contributed to errors.[39]

Documentation of the medication administration process: One small study investigated nurse adherence to a hospital policy to document medications administered and their effects on patients. From a sample of 12 nurses in one hospital, one-third of progress notes were found to contain information about administered medications, yet only 30 percent of those progress notes included medication name, dose, and time of administration, and only 10 percent documented information about desired or adverse effects of medications. Medication education, outcomes of administered medication, and assessment prior to administering were not documented in any progress note. Only half of withheld medications were documented.[105] In a review of records to detect medication errors, Grasso and colleagues[43] found that 62 percent did not document doses as administered.

Communication: Five studies and one literature review assessed the relationship between communication failures and medication errors. A small observational study of 12 nurses found that they communicated with other nurses about information resources on medications, how to troubleshoot equipment problems, clarification in medication orders, changes in medication regimens, and patient assessment parameters when handing over patients.[106] Nurses communicated with physicians informally to exchange information, about the absence of other physicians, and in both unstructured and structured ward rounds. Nurses also communicated with pharmacists about information on medication administration and organizing medications for patient discharge. Another direct observational study of medication administration found opportunities for errors associated with incomplete or illegible prescriptions.[91] This finding was supported by two related literature reviews that indicated that illegible and poorly written drug prescriptions and breakdowns in communication led to errors.[30, 39] Another survey found that nurses ranked difficult/illegible physician handwriting as a cause of the majority of medication errors, but did not consider withholding a dose because a lab report was late or omitting a medication while the patient was sleeping as something that should have been communicated to physicians or others.[61]

A small survey of 39 nurses in three hospitals in Nova Scotia about communication failures during patient transfers found that more than two-thirds of nurses reported difficulty in obtaining an accurate medication history from patients when they were admitted; 82 percent reported patients were unable to provide accurate medication histories. When patients were transferred

from across units, 85 percent of nurses reported that medication orders were rewritten at transfer, 92 percent that medication orders were checked against electronic medical records, 62 percent that it was time consuming to clarify medication orders, 66 percent that the reasons for medication changes were made at transfer, and 20 percent that blanket orders are often written as transfer orders.[107]

Complexity: Three studies investigated the impact of complexity on medication safety. In a small, five site observational study of medication administration of 39 RNs, LPNs and CMT/As in long-term care settings, Scott-Cawiezell and colleagues[104] found that even though RNs administered fewer medications they had more MAEs, compared to LPNs and CMT/As. The suggested explanation was that the mediations RN must administer in long-term care are those with more complexity. Another survey of 284 RNs in 11 hospitals found that pediatric and adult nurses reported numbers of medications being administered as a major reason on why medication errors occur.[58] Also, another survey of nurses found that they perceived that complicated doctor-initiated orders (24 percent) and complicated prescription were the major causes of MAEs related to the medication administration process.[93]

Equipment failure while administering medication: Three studies found that systems and process factors can interfere with medication administration when equipment used in administration does not perform properly, exposing the nurse and patient to safety risks. In two ICU studies, infusion pump problems were involved in 6.7 percent of 58 MAEs in one study[24] and 12 percent of the 42 MAEs in the other sutdy.[45] Another investigation of smart pumps with integrated decision-support software found that half of the ADEs were considered preventable (2.12 of 100 patient-pump days), and 72 percent of preventable ADEs were serious or life-threatening.[108] Given the number of ADEs, the fact that the drug library was bypassed in 24 percent of the infusions, and the frequency of overriding alerts, the investigators concluded that use of the smart pumps did not reduce the rate of serious medication errors—but possibly could if certain process factors could be modified, such as not allowing overrides.

Monitoring and assessing: An essential component of the medication process related to the administration of medications is monitoring and assessing the patient by the nurse. Only two studies provided information in this area, offering scant evidence. In the first, based on a small sample of nurses in one unit in one hospital, a qualitative analysis of observed medication administration found that participants monitored patients before, during, and after medication administration.[109] Nurses assessed vital signs, lab values, ability to swallow, and patients' self-report of health. They also felt responsible for timing medication administration and providing as-needed (e.g., PRN) medications. In the second study, where ICU nurses were surveyed, no administration errors were found to be associated with inadequate monitoring or lack of patient information.[24]

Effects of Human Factors on Medication Administration Errors

There are a wide range of system-related human factors that can impact medication administration. These factors include characteristics of individual providers (e.g., training, fatigue levels), the nature of the clinical work (e.g., need for attention to detail, time pressures), equipment and technology interfaces (e.g., confusing or straight-forward to operate), the design of the physical environment (e.g., designing rooms to reduce spread of infection and patient falls), and even macro-level factors external to the institution (e.g., evidence base for safe practices, public awareness of patient safety concerns).[103] There were 10 studies that assessed the

association of human factors with MAEs. Four major themes emerged in the review: fatigue, cognitive abilities, experience, and skills.

Effects of fatigue and sleep loss: Five studies assessed the association between fatigue and sleep loss with MAE errors. The first specifically investigated the effects of fatigue and sleep loss on errors using a national sample of nurses over a 2-week period. In this study, the rate of errors increased after working 12.5 hours.[99] A subpopulation of critical care nurses reported forgetfulness, heavy workload, distractions, and high patient acuity as causes for their medication errors or near errors.[84] Fatigue and sleep loss was also a factor in a subpopulation of ICU nurses, who reported errors with high-alert medications (e.g., morphine, chemotherapeautic agents).[85] The other two studies assessed fatigue along with other variables associated with medication errors. In one of these, a survey of 57 nurses, respondents reported that the majority of medication errors were attributable to fatigue.[70] The other study, a survey of 25 nurses in one hospital, found that one of the most frequently perceived causes of medication errors for nurses was being tired and exhausted (33.3 percent).[102]

The thought processes of nurses during medication administration was assessed in two studies. A semistructured, qualitative interview of 40 hospital nurses prior to implementation of a bar-coding system explored the thinking processes of nurses associated with medication administration.[110] Their thought processes involved analyzing situations and seeking validation or a solution when communicating about patients; using knowledge, experience, and understanding of patients' responses to anticipate problems; integrating their knowledge of lab values and patterns of pathophysiological responses to determine possible need to change dosage or administration timing; checking orders for validity and correctness; assessing patients' responses for possible side effects and effectiveness of the drug; using cues from patients or family members about need for explanations about drugs; bypassing protocols or procedures, some taking a risk, to get drugs to patients or use time more efficiently; anticipating needs for future problem solving; and applying professional knowledge during drug administration. The other study of nurses, using direct observation in a medical and surgical unit in Australia, found that participants used hypothetico-deductive reasoning to manage patient problems.[111] Graduate nurses used pattern recognition of patient characteristics and medications during decisionmaking. Intuition and tacit knowledge was used in relation to changes in patients' vital signs and to objectively monitor patients.

Thought process can also be distorted by distractions and interruptions. One study employed direct observation of medication administration to determine the effects of human factors on MAEs.[24] The investigators found that slips and memory lapses were associated with 46.7 percent of MAEs. During both the prescribing and administration of medications, the causes of errors were attributable to slips and memory lapses (23.1 percent during prescribing vs. 46.7 percent during administration), lack of drug knowledge (46.2 percent during prescribing vs. 13.3 percent during administration), and rule violations (30.8 percent during prescribing vs. 13.3 percent during administration). Another study using direct observation found causes associated with MAEs to include slips and memory lapses (40 percent), rule violations (26 percent), infusion pump problems (12 percent), and lack of drug knowledge (10 percent).[45]

Experience and skills also impact thought processes. In one study of 40 student nurses and 6 nurses using a computerized program to assess the impact of dyslexia found that the greater the tendency towards dyslexia, the poorer the potential cognitive ability to effectively provide the skills associated with effective drug administration.[112] Similarly, in two reviews of the literature,

a number of medications errors were found to be caused by poor mathematical skills,[30] especially if mathematical skills were needed to properly administer drugs.[39]

Lack of medication knowledge is a constant problem, and there is a need to continually gain more knowledge about current and new medications.[30] Nurses with more education and experience may have greater knowledge of medications.[39] However, experience has not been found to mitigate the effect of poor mathematical skills nor frequency of MAEs.[30] Those new to a unit or profession may be at risk for errors.[39] In a survey of nurses working in three hospitals in Taiwan, nurses reported causes of MAEs as new staff (37.5 percent), unfamiliarity with medication (31.9 percent), unfamiliarity with patient's condition (22.2 percent), and insufficient training (15.3 percent).[93] Inexperience may also contribute to performance (human) deficit, willingness to follow a procedure/protocol, and knowledge deficit. Of these reported contributing factors, 78 percent were due to the inexperience of staff.[44] Blegen, Vaughn, and Goode[113] found that medication errors rates were inversely related to the proportion of nurses on a unit with greater experience, but were not related to the educational level of the staff on the unit.

Evidence Table 2. Working Conditions Associated With Medication Administration Errors and Adverse Drug Events

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Aitken 2006[105]	*Process Factors*: Documentation of medication administered by nurse	Cross-sectional study	Review of patient medication charts and progress notes for one working shift. Each participant was interviewed.	47 nurses in one urban teaching hospital in Australia	None	34% of progress notes contained information about administered medications. 30% of progress note entries included medication name, dose, and time of administration. Medication education was not documented in any progress note. Outcomes of administered medications were not documented, nor was assessment prior to administering. 10% of progress notes documented information about desired or adverse effects of medications. Only half of withheld medications were documented.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Armitage 2003[39]	*System Factors:* Workload *Process Factors:* Lack of double-checking Failure to follow policies and procedures Distractions and interruptions Communication processes *Human Factors:* Individual characteristics and abilities associated with medication administration errors (MAEs)	Literature review	Expanded upon the O'Shea (1999)[30] review	Literature on drug administration, drug error, and nursing was reviewed.	None	Workload—4 studies indicated equivocal findings on the relationship between workload and errors. Lack of double-checking—3 studies indicated that double-checking did not necessarily prevent errors. Failure to follow policies and procedures—6 studies indicated that failure to adhere to policies has been associated with errors. Distractions and interruptions—6 studies indicated that rapid turnover and changes as well as distractions and interruptions contributed to errors. Communication failures—7 studies indicated that illegible and poorly written drug prescriptions led to errors. Mathematical skills of nurses—5 studies indicated that poor mathematical skills may put nurses at risk for errors, especially if they need complex mathematical skills to administer drugs. 3 additional studies indicated weight-base dosing and mathematical calculations of dosing resulted in potential risk of errors. Knowledge of medications—3 studies indicated that knowledge of medication may be greater in nurses with more education and experience. Length of nursing experience—6 studies indicated that those new to a unit or profession may be at risk for errors.
Balas 2006[84]	*System Factors:* Workload and staffing *Process Factors:* Distractions and interruptions	Cross-sectional	Qualitative 14-day self-reported record of shift work and errors	502 RNs in critical care units	None	Nurses reported forgetfulness, heavy workload, distractions, and high patient acuity as causes for their medication errors or near errors.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Beyea 2003[81]	*System Factors:* Workload and staffing *Process Factors:* Distractions and interruptions *Human Factors:* Experience	Secondary analysis	179 reported medication errors in same-day surgery	MEDMARX® data	None	Workload increase in 11.2% reports, insufficient staffing in 8.4%. Distraction associated with 56.4% of errors. Inexperienced staff with 14.5% of error reports.
Beyea 2003[82]	*System Factors:* Workload and staffing *Process Factors:* Distractions and interruptions *Human Factors:* Experience	Secondary analysis	731 reported medication errors in the operating room	MEDMARX® data	None	Workload increase in 11.5% reports, insufficient staffing in 4.8%. Distraction associated with 48% of errors. Inexperienced staff with 17% of error reports.
Blegen 1998[95]	*System Factors:* Staffing and RN skill mix	Cross-sectional	Administrative data for nurse staffing and medication errors at the patient care unit level	42 units in 1 large tertiary care hospital	None	Rates of medication errors were inversely associated with RN skill mix up to an RN proportion of 87.5%. Rates of medication errors were positively correlated with falls (0.192).
Blegen 1998[96]	*System Factors:* Staffing and RN skill mix	Cross-sectional study	Analysis of event reports and nurse staffing patterns for 10 quarters	39 units in 11 hospitals	None	Rates of MAEs by 10,000 doses were highest in medical-surgical and obstetric units; they were highest by 1,000 days in ICUs. Units with RN proportions greater than 85% had higher rates of MAEs per 10,000 doses.
Blegen 2001[113]	*Human Factors:* RN education and experience	Cross-sectional study	Secondary data analysis	80 units in 12 hospitals	None	MAEs were inversely related to RN experience but were not related to RN education.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Buckley 2007[24]	*Process Factors*: Communication processes Medication administration process *Human Factors:* Individual characteristics associated with MAEs	Prospective cohort study	Anonymous survey of pediatric ICU nurses about the medication process, followed by a direct observation over 6 months of medication process, determining actual and potential errors. Observers of medication administration would intervene if error was considered harmful to patient.	In a 16-bed pediatric medical/surgical ICU at a tertiary care academic medical center	None	Faulty interaction with other services (6.7%) and infusion pump problems (6.7%); no administration errors were found to be associated with drug stocking and delivery, inadequate monitoring, or lack of patient information. Majority of MAEs were associated with slips and memory lapses (46.7%), lack of drug knowledge (13.3%), rule violations (13.3%).
Carlton 2006[98]	*System Factors*: Length of work shift Staff skill mix Patient acuity *Process Factors*: Interruptions Unclear orders Medications received late *Human Factors*: Skill/education/ experience Knowledge of medications	Literature review	Medication administration literature published before 2005		None	5 studies reviewed the association of nurse skill mix with MAEs; found that the research on skill mix is conflicting. 1 study reviewed a neonatal care unit and found increasing number of medication errors (MEs) associated with increasing acuity of newborns. Many MAEs are not recognized as an error. 1 study of a cross-sectional survey of nurses found that nurses perceived MEs to be caused by late arrival of medications from pharmacy, RNs too busy, RNs forgetful or failure in oversight, and unclear medical administration records. 1 study found lack of knowledge and skill/experience, failure to adhere to policies and procedures, and communication failures as active errors by nurses resulting in MEs.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Chevalier 2005[107]	*Process Factors*: Nurse management of the medication administration process	Cross-sectional study	Retrospective survey on safety culture	39 nurses (35% response rate) in 3 hospitals in the Capital Health district of Nova Scotia	None	69% of nurses reported difficulty in obtaining an accurate medication history from patients when they were admitted; 82% reported patients were unable to provide accurate medication histories (e.g., reconciliation). When patients were transferred from another unit, 85% of nurses reported that medication orders were rewritten at transfer, 92% that medication orders were checked against electronic medical records, 62% that it was time consuming to clarify medication orders, 66% that the reasons for medication changes made at transfer, and 20% that "blanket" orders are often written as transfer orders.
Eisenhauer 2007[110]	*Human Factors:* Individual characteristics associated with MAEs	Cross-sectional study	Semistructured, retrospective, qualitative interview of nurses; then used basic content analysis of the narrative data.	40 staff nurses in one northeastern U.S. hospital where bar-coding was being implemented	None	Nurses' thought processes in relation to medication administration included - Analyzed situations and sought validation or a solution when communicating about patients. - Used knowledge, experience, and understanding of patients' responses to anticipate problems. - Integrated their knowledge of lab values and patterns of pathophysiological responses to determine possible need to change dosage or administration timing. - Checked orders for validity and correctness. - Assessed patients' responses, the possible presence of side effects, and effectiveness of drug. - Used cues from patients or family members about need for explanations about drugs. - Bypassed protocols or procedures, some taking a risk, to get drugs to patients or use time more efficiently. - Anticipated need for future problem-solving. - Applied professional knowledge during drug administration.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Fogarty 2006[100]	*System Factors:* Organizational climate	Cross-sectional study	Survey included a 6-item quality of work life, satisfaction with working conditions, positive and negative affect, organizational climate, and a procedure violation scale.	176 nurses in rural Australia working in 11 public sector hospitals	None	"Violations" was the only variable with a direct contribution (24%) to MAEs. Distress was positively associated with violations, while quality of working life, morale, and organizational climate had a negative association. It was not possible to determine if the effect of organizational climate on violations is direct or mediated by stress and morale, but organizational climate is linked with safety behavior.
Hicks 2004[38]	*System Factors:* Workload and staffing *Process Factors:* Distractions and interruptions *Human Factors:* Experience	Retrospective cohort study	645 reported medication errors in postanesthesia care unit	MEDMARX® data	None	Workload increase in 15.5% reports; insufficient staffing in 4.3%. Distraction associated with 47% of errors. Inexperienced staff associated with 14.9% of error reports.
Hofmann 2006[101]	*System Factors:* Safety climate	Cross-sectional study	Survey and administrative data from 82 units in 41 hospitals		None	Increased safety climate scores associated with lower rate of medication errors causing harm.
Kapborg 1999[80]	*Process Factors:* Policies and procedures Supervision Documentation of administration	Retrospective cohort study	Analysis of malpractice cases and small interview survey with 8 nurses working in nursing homes and home care setting using semistructured questions	68 cases of MAEs occurring in several types of home care and nursing home settings	None	Reported causes of MAEs were lack of administration protocols, failure to check orders, ineffective nurse supervision in delegating administration, and inadequate documentation.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Kopp 2006[45]	*Process Factors:* Equipment malfunction during medication administration *Human Factors:* Individual characteristics associated with MAEs	Prospective cohort study	Voluntary survey of nurses on the medication use process followed by direct observation over 6 months by 2 pharmacy residents specializing in critical care pharmacy. Pharmacy residents would intervene if MAE would have resulted in patient harm.	1 16-bed medical/surgical ICU in a tertiary care academic medical center in Arizona	None	12% of the 42 MAEs were caused by infusion pump problems. Causes associated with MAEs included slips and memory lapses (40%), rule violations (26%), lack of drug knowledge (10%).
Manias 2004[109]	*Process Factors:* Medication management and patient monitoring	Prospective cohort study	Qualitative participant observation and questioning of nurses during medication administration	12 graduate nurses in medical and surgical units of a university teaching hospital in Melbourne, Australia	None	To monitor patients before, during, and after medication administration, nurses assessed vital signs, lab values, ability to swallow, and patient self-report of health. Participants felt responsible for timing medication administration and providing as-needed medications.
Manias 2004[111]	*Human Factors:* Cognitive reasoning	Prospective cohort study	Qualitative participant observation of nurses during medication administration	12 graduate nurses in medical and surgical units of a university teaching hospital in Melbourne, Australia	None	Participants used hypothetico-deductive reasoning to manage patient problems. Graduate nurses used pattern recognition of patient characteristics and medications during decisionmaking. Intuition and tacit knowledge was used in relation to changes in patients' vital signs and objective monitoring of patients.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Manias 2005[114]	*Process Factors:* Communication with health care providers	Prospective cohort study	Qualitative participant observation of nurses during medication administration	12 graduate nurses in medical and surgical units of a university teaching hospital in Melbourne, Australia	None	Nurses communicated with other nurses about information resources on medications, how to troubleshoot equipment problems, clarification in medication orders, changes in medication regimens, and patient assessment parameters when handing over patients. Nurses communicated with physicians informally to exchange information, about the absence of other physicians, and in both unstructured and structured ward rounds. Nurses communicated with pharmacist about information on medication administration and organizing medications for patient discharge.
Manias 2005[106]	*Process Factors:* Adhering to protocols for medication administration	Prospective cohort study	Qualitative participant observation of nurses during medication administration	12 graduate nurses in medical and surgical units of a university teaching hospital in Melbourne, Australia	None	Protocols were used to check that practices were acceptable, obtain information on medications, provide patient care without seeking additional information from physicians, and provide key information when working in another unit. Nurses examined the patient's identity 27% of the time before medication administration; double-checked certain medications before administration with another nurse 80% of the time; did not complete incident reports for medication errors (only 2 medication errors were observed); sought information on unfamiliar medications 86% of the time; sought clarity on unclear medication orders 100% of the time; and observed patients taking oral medications 90% of the time.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Mayo 2004[61]	*Process Factors:* Lack of order clarity Communicating missed doses	Cross-sectional study	Random sample of RNs surveyed about perceived causes of medication errors; percentage of medication errors reported to nurse managers; types of reportable incidents; and reporting behaviors, including medication errors scenarios.	983 RNs (a 20% response rate) in the United Nurses Association of California/Union of Health Care Professionals		Nurses ranked difficult/illegible physician handwriting, distractions, and being tired and exhausted as causes for the majority of medication errors. Nurses would not communicate to physicians or others when a routine morning dose of medication was withheld because a lab report was late (91.8%) or a dose omitted while the patient was sleeping (55.5%).
Millward 2005[112]	*Human Factors:* Cognitive skills involved in drug administration	Prospective cohort study	Used a computerized program to assess the presence of dyslexia and its effects on drug administration skills	40 students and 6 qualified nurses	None	The greater the tendency to dyslexia, the poorer the potential cognitive ability to effectively provide skills associated with drug administration.
Osborne 1999[70]	*Process Factors:* Distractions Failure to comply with procedures *Human Factors:* Confusion Fatigue	Cross-sectional study	Self-reported perception of nurses on medication errors, their causes, and how medication errors should be reported	57 full-time and part-time RNs (a 62% response rate) in a medical-surgical unit in a 700-bed community hospital in south Florida		Main cause of medication errors was failure to identify the right patient (35.1%), and 24.6% indicated the effects of fatigue.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
O'Shea 1999[30]	*System Factors:* Workload Nurse staffing Medication delivery systems *Process Factors:* Shift and hours worked Single nurse drug administration Adherence to policy and procedures Distractions and interruptions *Human Factors:* Mathematical skills Knowledge of medications Experience	Literature review	Retrospective review of 97 articles published in 1995 and earlier, involving the definition and contributing factors to MAEs	Studies involving nurses and medication administration	None	Staffing—2 studies indicated contradictory implications on the effect of staffing levels on the incidence of medication errors. Shift and hours worked—3 studies indicated that there was a difference in the number of errors by shift; and 2 studies indicated that there was no difference in the number of hours worked (8 vs. 12), but there were more errors with nurses working rotating shifts. Workload—3 studies indicated that the effect of a heavy workload can be compounded by distractions; use of temporary staff and inadequate skill mix are associated with more errors. Medication delivery systems—1 study indicated that the error rate was higher in units using a medication nurse to administer medications. Single nurse drug administration—2 studies indicated that medication errors did not necessarily decrease with two nurses administering medications (e.g., double-checking). Adherence to policy and procedures—8 studies indicated that MAEs can be caused by failure to adhere to policies. Distractions and interruptions—5 studies indicated that distractions and interruptions interfere with preparing and administering medication, potentially causing errors. Mathematical skills—8 studies indicating that a number of medications errors are caused by poor mathematical skills. Knowledge of medications—8 studies indicated that not only is lack of knowledge a constant problem, but there is a need to continually gain more knowledge about current and new medications.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
O'Shea 1999[30] (cont.)						Length of experience—2 studies indicated that experience did not mitigate the effect of poor mathematical skills nor frequency of MAEs
Rogers 2004[99]	*System Factors:* Nurse staffing Shift work	Cross-sectional study	Qualitative 14-day self-reported record of shift work and errors	Nationwide sample of 393 nurses (a 40% response rate)	None	The risk of medication administration errors was nearly three times higher once a nurse worked more than 12.5 hours during a 24-hour period. In over 80% of shifts, nurses reported leaving after their scheduled shift, working on average 55 minutes longer than scheduled each day. Work duration, overtime, and number of hours worked in a week was directly associated with errors.
Rothschild 2005[108]	*Process Factors:* Using smart pumps to decrease medication administration errors	Randomized clinical trail	Prospective, randomized time-series trial comparing the rate of serious medication errors with and without decision support during 11 months.	1 cardiac surgical intensive care and 2 step-down units in a hospital in Boston	Implementation of new intravenous infusion pumps with decision support (i.e., alerts, reminders, and unit-specific drug rate limits) used during medication administration	During the trial, half of ADEs were preventable (2.12 of 100 patient-pump days); 72% of preventable ADEs were serious or life-threatening. During the intervention, bypassing the drug library (24% of infusions) and overriding alerts were frequent. Use of the smart pumps did not reduce the rate of serious medication errors.
Scott-Cawiezell 2007[104]	*Process Factors:* Distractions and interruptions	Prospective cohort	Naïve, direct observation of medication administration	8 RNs, 12 LPNs, 19 CMT/As in 5 Midwestern nursing homes	None	RNs administered 15.3% of observed doses, LPNs 23.3%, and CMT/As 61.43%. The MAE rate for RNs was 34.6%, LPNs 40.1%, and CMT/As 34.2%. RNs had more interruptions (39.9%), and LPNs had more distractions (41.6%).
Stratton 2004[58]	*System Factors:* Workload *Process Factors:* Distractions and interruptions	Cross-sectional study	Nurses were surveyed to assess the perceived causes of MAEs.	284 RNs (227 adult and 57 pediatric nurses) in 11 hospitals in 2 States (40% response rate)	None	Pediatric and adult nurses reported distractions and interruptions (50% of pediatric nurses and 47% of adult nurses), RN-to-patient ratios (37% and 37%), numbers of medications administered (35% and 31%), and not double-checking doses (28% and 28%) as the most important causes of MAEs.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Tang 2007[93]	*System Factors:* Workload *Process Factors:* Complicated orders Distractions and interruptions *Human Factors:* Experience Knowledge and skills	Cross-sectional study	A semistructured questionnaire was used to assess MAE events, background of the nurse, and perceived contributing factors.	72 female nurses at 3 acute care hospitals (80% response rate)	None	Nurses reported personal neglect (86%), heavy workload (38%), complicated doctor-initiated order (24%), and complicated prescription as the major causes of MAEs related to the medication administration process. Personal neglect included distraction, interruptions, not double-checking, and poor mood. Nurses reported causes of MAEs as new staff (37.5%), unfamiliarity with medication (31.9%), unfamiliarity with patient's condition (22.2%), and insufficient training (15.3%).
Tissot 2003[91]	*System Factors:* Workload *Process Factors:* Incomplete/illegible orders	Prospective cohort study	Direct observation of nurses administering medications to patients by a pharmacist	A geriatric unit and a cardiovascular-thoracic surgery unit within a hospital in France	None	Opportunities for errors were associated with incomplete/illegible prescriptions and nurse workload (OR = 2.44, 95% CI = 1.30–4.60; *P* = 0.006).
Ulanimo 2007[102]	*Process Factors:* Perceived causes of MAEs *Human Factors:* Distractions	Cross-sectional study	Survey on perceived causes of medication errors and percentage of all medication errors that are reported to the nurse manager, completing an incident report.	25 nurses (44% response rate) in a VA hospital in Northern California	None	The most frequent perceived causes of medication errors for nurses were failing to check patient name band with medication administration record (45.8%); being tired and exhausted (33.3%); miscalculating the dose (29.2%); confusion between 2 look-alike drugs (29.2%); distractions (25%); different infusion devices being used (25%); unclear medication labeling/packaging (25%); and wrong infusion device set up/adjustment (24%).
Whitman 2002[97]	*System Factors:* Nurse staffing	Prospective cohort study	Secondary data analysis of a prospective, observational cohort study	95 patient care units in 10 adult acute care hospitals in an integrated health care system in the eastern United States	None	Rates of medication errors were inversely associated to staffing work hours per patient day in cardiac ICU (r = -0.53) and noncardiac intermediate (r = -0.55) care settings. 30.3% of the variance in medication error rates resulted from the variance in staffing work hours per patient day.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Wolf 2006[44]	*Process Factors:* Distractions *Human Factors:* Knowledge deficit Inexperience	Retrospective cohort study	Analysis of MAEs reported January 1, 1999, to December 21, 2003, by nursing students during the administration phase	MAEs reported by 1,305 nursing students in the USP MEDMARX® program; 763 reports included contributing factors.	None	The major contributing factors to MAEs were inexperienced staff (78%) and distractions (20%). The other, significantly fewer causes of errors were insufficient staffing, agency/temporary staffing, lack of access to patient information, emergency situation, poor lighting, patient transfer, floating staff, no 24-hour pharmacy, and code situation. The major causes of MAEs were reported as performance (human) deficit (51%), procedure/protocol not followed (32%), and knowledge deficit (27%).

Strategies To Improve Medication Administration Safety

Strategies to improve medication safety focused on acute care settings. Twenty-six studies and descriptions of quality improvement projects were identified. Strategies used included recommendations from a nationwide voluntary organization to improve safety, education of nurses and other providers in safe practices, and system change and technology.

Nationwide voluntary efforts. Lucian Leape and colleagues[116] reported on a 15-month Institute for Healthcare Improvement Breakthrough Series Collaborative intended to reduce ADEs. Eight types of strategies were successfully used, including documentation of allergies, nonpunitive reporting, and standardizing medication administration times. Effective leadership and appropriateness of intervention were associated with successful change implementation. The converse was associated with failure, as were unclear aims, poorly designed interventions, lack of focus on underlying system failures, unclear measures, too much focus on data collection, involvement from only some stakeholders, opposition from physicians and nurses, and conflicting time demands for team members. The findings were limited by the lack of an analysis of the relationship between established safety policies and practices and the success of implementing new strategies, as well as the relationship between the implementation and the occurrence of ADEs.

A survey of 148 hospitals about the characteristics and barriers associated with adoption of the National Quality Forums' 30 safe practices was done by Rask and colleagues.[117] These practices included unit dosing, adopting computerized physician order entry (CPOE), and having a culture of safety. Of the recommended practices, there was high adoption of standardized labeling and storage of medications (90.5 percent), identification of high-alert medications (81 percent), and use of unit doses (81 percent). For-profit hospitals were more likely than not-for-profit hospitals to have unit-dose medication distribution systems (93.1 percent vs. 78.2 percent) and policies on reading back verbal orders (83.1 percent vs. 58.4 percent). There were greater distractions affecting medication administration in large hospitals. Hospitals with 100–299 beds were more likely to report using pharmacists to review and approve nonemergency orders prior to dispensing; and, 69.4 percent of all hospitals used data analysis to drive patient safety quality improvement efforts.

Nurses' education and training. Educational strategies aimed to improve medication safety and avert unnecessary medication errors. One randomized controlled study used an interactive CD-ROM education program to improve the use of safe medication practices and decrease the rate of MAEs.[118] Direct observation of medication administration was used to assess the impact. After the training, nurses' use of safe administration practices increased, but preparation errors did not decrease. There were too few actual medication errors to analyze pre-post differences. Another approach used an 11 module Web-based educational strategy to improve drug safety with a small sample of nurses.[119] Direct observation of medication administration was used to determine the outcome. After using these modules, rates of nonintravenous MAEs decreased from 6.1 percent to 4.1 percent. Rates of errors in intravenous drug administration did not decline as expected. Dennison[120] reported the results of a medication safety training program for nurses. Knowledge scores improved in this pre-post test study, but there was no significant change in safety climate scores, labeling of intravenous infusion setups, or the number of self-reported errors.

Attempts to improve basic and continuing education in medication safety have been reported, but they have not assessed the impact on actual error rates. In a small pilot study, a problem-

based learning approach was found to enable students to use findings from topic-specific research to develop and apply solutions for clinical problems. Papastrat and Wallace[121] proposed using problem-based learning and a systems approach to teach students how to prevent medication errors and suggested content, but their approach was not compared to other teaching methods. Another proposed educational strategy for practicing nurses was to use simulation of medication administration and errors in a controlled setting to improve medication safety, "duplicate the complexity of the nurse-patient interaction and related cognitive thought"[122] (p. 249). Simulations could be used to prepare nurses to recognize and manage medication errors when and if they occur.

System change. Several attempts to change the system have been tested. Some of the strategies addressed the thoroughness of error reporting, some the processes and events surrounding medication administration, and some focused directly on reducing errors. Using a hospitalwide performance improvement project that emphasized system factors, not individual blame, error reporting increased from a rate of 14.3 percent to 72.5 percent.[123] To address intravenous infusion problems, a medication safety education program and medication calculation worksheets were introduced, followed by ongoing Plan-Do-Study-Act cycles.[124] Multiple system changes were also used to improve safety of intravenous drug infusion. These included removing 90 to 95 percent of potassium chloride ampoules from the bedside; developing preprinted labels for five common drug infusions; removing four-channel infusion pumps the unit and replacing them with double-channel infusion pumps with a simple interface design; standardizing administration of drugs given by bolus dose using a syringe pump; decreasing missed doses of immunosupression drugs for transplant patients from 25 percent to 9 percent by incorporating them into the main drug chart; implementing standardized prefilter and heparin-lock central venous catheters and heparin infusions into ICU protocol; redesigning drug infusion administration practices throughout the hospital; eliminating burettes for IV drug infusion; preparing standardized drug infusions for 36 drugs; and providing Intranet-based up-to-date drug information.

A time study and focus groups were used to compare nurse efficiency during medication administration using either medication carts with unit doses or a locked wall-mounted cupboard in each patient room.[125] After 12 weeks, the wall-mounted units were found to have decreased medication administration time for nurses an average 23 minutes per 12-hour shift. Time saved by not having to search for missing medications saved 0.38 full-time equivalent (FTE) annually. Pharmacists spent an additional 0.05 FTE in stocking room cupboards. Nurses reported more contact time with patients when using room cupboards and fewer interruptions by colleagues during medication preparation and administration. Two small experimental studies attempted to reduce distractions that frequently interrupt nurses during medication administration and thereby introduce the potential for error.[126, 127] In both studies a standardized protocol for safe administration of medications was introduced to the nursing staff in the experimental group and signage was used to remind others (physicians, patients, other staff) to not interrupt. The signage in the first study was a vest that the nurse administering medication wore; in the second it was a sign above the preparation area. Direct observation of the number and types of distractions provided the outcome measures in the first study; a questionnaire completed by each nurse administering medications provided the measure of distractions for the second. In both studies, the number of distractions was significantly reduced. Medication error rates were not captured.

One randomized controlled trial compared the use of a dedicated nurse for medication administration to nurses providing comprehensive care, including administering medications, to

their patients in two hospitals.[128] MAEs were then assessed using direct observation. The investigators found the error rates to be 15.7 percent at the intervention hospital and 14.9 percent in the control hospital. The rate of MAEs was not significantly different between control and experimental groups.

Involving patients in the administration of medications while in the hospital is another system strategy that has been assessed. With this intervention, hospitalized patients have the responsibility for administering their own medication under the supervision of nursing staff. A literature review reported on 12 studies that described and evaluated a patient self-administration program.[129] This review found that the patients' knowledge about their medications and the prescribed dosing increased, but knowledge about the potential side effects of their medications did not. Given the body of the reviewed literature, it appeared as though patients and families make as many or more MAEs than do health care providers.

System change with technology. Another rapid-cycle implementation project over 6 months used continuous quality improvement data before and after implementing a modular, computerized, integrated infusion system.[130] Most infusion error warnings occurred between 3 p.m. and 9 p.m., peaking at 6 p.m. Nurses responded to 12 percent of the infusion error warnings by altering the setting and averting errors. The nature of the 88 percent of warnings not responded to was not discussed. Risk scores associated with heparin infusion rates decreased almost fourfold. Almost all nurses used the new software correctly.

Two studies focused on documentation of medication administration. One study introduced a charting system with decision support and used a quasi-experimental design to determine the effects.[131] Researchers collected medication charting data for 8 weeks in both the control and study units. Staff in the study unit received an educational intervention about error avoidance through real-time bedside charting, followed by 12 weeks of monitoring and performance feedback. After the 12 weeks, medication charting rates increased from 59 percent to 72 percent in the intervention group. The second study used a computer-based "unreported meds followup" to remind nurse staff about scheduled medications omitted or not documented.[132] After charts were prospectively reviewed, a mandatory medication error prevention seminar was given to nurses, and a medication review report was created for nurses. Reported medication errors and documentation of medication administration were reviewed, medication administration policies were developed, and focus changed to the potential causes of errors. Documentation errors decreased over the 3 years of the study, and reported error rates increased by 0.5 percent each year.

Bar-coded medication administration (BCMA) is promoted as the most effective way to reduce administration errors and is being implemented widely. Conceptually this technology should catch nearly all errors, but rigorous evaluation of the impact of technology on error rates has lagged behind implementation. The biggest challenge to determining the effectiveness of BCMA or other interventions is the lack of valid measures of MAEs. Data from voluntary self-reported medication errors are known to capture only a small portion (5 percent to 50 percent) of actual errors, and the BCMA system itself greatly alters nurses' awareness of errors, thereby systematically affecting reported error rates. Many studies reporting analysis of the impact of BCMA have used data collected by the system only after implementation.[133–136] From these we learn the types of errors intercepted by the system. Three other studies of the impact of BCMA on administration errors reported very large reductions: 59–70 percent decrease,[137] 71 percent and 79 percent drops.[138] However, the sources of the data for determining these decreases are not known.

Direct observation of medication administration, a resource- and time-intensive approach to data collection, is the only way to gather unbiased data to evaluate the impact of BCMA on medication administration errors. Three studies have used direct observation; however, each evaluated the implementation of a different set of technology. Franklin and colleagues[139] reported a decline in MAE rates from 8.6 percent to 4.4 percent when a new system was implemented in a teaching hospital in England. The system included BCMA, computerized order entry, automated dispensing, and electronic medication administration record. Prescription errors also declined from 3.8 to 2 percent. It is noteworthy that the rate of both administration and prescribing errors by direct observation was much lower than other direct observation studies have reported. Paoletti and colleagues[140] used direct observation to determine the impact of BCMA and an electronic medication record in a hospital in the United States. They reported that the rate of MAEs declined from 13.5 percent to 3 percent. Finally, the implementation of only the electronic medication administration record led to a decline in MAEs from 10.5 percent to 6.1 percent using direct observation.[141] Health-related technology designed to increase medication safety has great promise, but more study using valid outcome measures and controlled interventions needs to be done to demonstrate the potential benefits.

Evidence Table 3. Strategies To Reduce Medication Administration Errors

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Anderson 2004[137]	Bar-coded technology	Quality improvement project		One hospital	Bar-coded point-of-care medication administration	59%–70% reduction in MAEs. Positive effect on nurses' satisfaction.
Bennett 2006[125]	Dispensing mechanisms to improve medication administration	Quality improvement project	Time study and focus groups to compare nurse efficiency using medication carts or a unit dose to locked wall-mounted cupboards in each patient room	Nurses in 2 units and pharmacists in one hospital	Wall-mounted cupboards in patient rooms	Wall-mounted units decreased medication administration time for nurses an average 23 minutes per 12-hour shift. Time saved not searching for missing medications saved 0.38 FTE annually. Pharmacist spent an additional 0.05 FTE in stocking room cupboards. Nurses reported more contact time with patients when using room cupboards. Nurses reported fewer interruptions during medication preparation and administration.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Burdeu 2006[124]	Improving safety of intravenous medication administration	Quality improvement project	Plan, do, study, act (PSDA) cycle was used to assess deviations in safe practice of drug infusions, using regular audits by ICU nursing management.	Began with 1 25-bed ICU, then applied lessons learned throughout one acute care teaching hospital in Melbourne, Australia	Provided a medication safety education program and medication calculation worksheets, followed by ongoing PDSA cycles.	Improved drug infusion labeling practices. 90 to 95% of potassium chloride ampoules were removed from the bedside. Preprinted labels were developed for the 5 drug infusions most commonly used. 4-channel infusion pumps were removed from the unit and replaced by double-channel infusion pumps with a simple interface design. Standardized administration of drugs given by bolus dose using a syringe pump. Decreased missed doses of immunosupression drugs for transplant patients from 25% to 9% by incorporating them into the main drug chart. Implemented standardized prefilter and heparin-lock central venous catheters. Eliminated burettes for IV drug infusion. Standardized drug infusion protocols for 36 drugs and provided Intranet-based up-to-date drug information.
Coyle 2005[133]	BCMA	Quality improvement project	Assessed process	161 medical centers in the Veterans Health System	Systemwide change to BCMA and electronic documentation	Acceptance of nurses and “marked decrease” in errors (data for this decrease not described).

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Dennison 2007[120]	Medication safety education program	Pre-post test Evaluation study of education program	Technology-enhanced education program	One coronary care unit in one hospital	Two computer-based education modules on medication error reduction and intravenous infusion of high-alert meds.	Nurses knowledge increased from pre- to post-test. Safety climate scores did not change. Labeling of infusion did not change. Number of reported errors did not change.
Fields 2005[130]	Improving safety of intravenous medication administration	Quality improvement project	Rapid-cycle implementation over 6 months, using continuous quality improvement data before and after implementation	100 new systems in 1 hospital in Georgia	Implemented a modular, computerized, integrated infusion system	Most infusion error warnings occurred between 3 p.m. and 9 p.m., and peaked at 6 p.m. 12% of warnings led to changes in pump settings. Risk score associated with heparin infusion rates decreased almost fourfold. Almost all nurses used the new software correctly.
Force 2006[123]	Medication error reporting	Quality improvement project	Used focus groups to gather information on the medication process and process failures to improve error and near-error reporting by pharmacists and nurses	1 hospital in Illinois	Implemented a hospitalwide performance improvement project, emphasizing identifying system factors, not individual blame.	After 1 year of implementation, error reporting increased from a rate of 14.3% to 72.5%.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Franklin 2006[119]	Drug safety education Types of MAEs	Pretest and post-test study	Conducted a drug safety program for nurses and assessed possible improvements in drug safety. Medication administration processes were observed before and after the program.	19 nurses in one hospital ward (63% completed all educational modules).	Web-based drug safety program with 11 modules	The most common types of MAEs were omission, wrong dose, extra dose, and fast intravenous bolus. Rates of nonintravenous MAEs decreased from 6.1% to 4.1%. While nurses used the drug safety program and there was a decrease in nonintravenous MAEs after implementation, there was no significant difference in total MAEs after implementation of the drug safety program.
Franklin 2007[139]	Health technology implementation	Before-and-after study	Reviewed records for prescribing errors, direct observation of nurse med administration	Surgical ward in one hospital in UK	CPOE, BCMA, automated dispensing, electronic medication administration record	MAEs declined from 8.6% to 4.4%. Prescribing errors declined from 3.8% to 2%. Ward pharmacist time increased, prescription time increased, nursing time on medication tasks declined.
Greengold 2003[128]	Medication administration nurses	Randomized controlled trial	Compared using a dedicated nurse for medication administration to nurses administering medications to their patients	2 hospitals	Using a dedicated nurse for medication administration	Generally, there were no significant differences in MAEs between the 2 types of interventions, but MAEs were lower in surgical units and higher in mixed medical and surgical units that used dedicated nurse medication administers.
Larrabee 2003[136]	BCMA	Quality improvement	Descriptive—process and experiences	1 hospital	BCMA	Occurrence reports increased, analysis of systems data for prevented errors found prevalence of “not-due,” wrong-dose, and wrong-patient errors. No omitted and missed doses errors were captured.

Leape 2000[116]	Interventions for reducing adverse drug events	Quality improvement	15-month period of rapid-cycle changes.	36 hospitals participating in an Institute for Healthcare Improvement (IHI) collaborative on reducing adverse drug events.	Education on IHI's method for rapid-cycle change and evaluation	Successful change strategies included nonpunitive reporting; standardized prescribing to reduce illegible handwriting and eliminate leading or trailing zeros; heparin protocols; removal of concentrated potassium chloride from nursing units; improved documentation of allergy information; standardized medication administration time; standardized protocols for chemotherapy; and implementation of insulin-ordering protocols. Of these, removing concentrated potassium chloride from nursing units was 100% successful, and implementing nonpunitive reporting and insulin-ordering protocols were the least successful (50% and 43%, respectively). Success of change strategy was associated with the commitment of the collaborative team (i.e., leadership), effective processes, and appropriate choice of interventions. Failure was attributed to lack of leadership support; ineffective team leadership; unclear aims; poorly designed interventions; lack of focus on underlying system failures; unclear measures; too much focus on data collection; involvement from only some stakeholders; opposition from physicians and nurses; and conflicting time demands for team members.

Mahoney 2007[134]	Integrated clinical information technology	Quality improvement—measures only after implementation	Examined medication errors, turnaround time, decision-support overrides.	Multihospital system	Included CPOE, electronic record, BCMA, decision support, and drug dispensing	System decreased prescribing errors, increased pharmacist interventions, improved monitoring. 73 administration errors for every 100,000 doses were intercepted after implementation.
Meadows 2002[138]	BCMA	Review of BCMA system and effects	Relates briefly the results of two system interventions	2 hospitals	BCMA	The two hospitals had reductions in medication error rates of 71% and 79%. Data used to measure these not described.
Nelson 2005[131]	Decision support to improve medication administration	Pretest and post-test	Collected medication charting data for 8 weeks in both the control and study units. Staff in the study unit received an educational intervention about error avoidance through real-time bedside charting, 12 weeks of monitoring, and performance feedback.	Two 40-bed surgical units in one hospital in Utah	Educational intervention followed up with real-time feedback on documentation.	Medication charting rate increased from 59% to 72% in the intervention group.
Paoletti 2007[140]	BCMA and electronic medication administration record (MAR)	Evaluation study—before and after	Used direct observation to determine MAEs.	3 units in one hospital: 1 control, 2 intervention	BCMA and electronic MAR	Accuracy rate 86.5% before and 97% after.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Paparella 2004[122]	Educational interventions	Quality improvement	Medication safety education, using the NLN Medication Proficiency examination, a medication calculation test, an ongoing continuing educational program on medication safety, and tested medication administration safety simulation models to supplement education.	235-bed community hospital in Pennsylvania	Required medication safety education and calculation testing of all new RNs and LPNs, ongoing medication safety education for current staff, using simulation models "What's Wrong With This Patient."	The educational component for new nurses was used prior to matching with a preceptor during medication administration. The simulation program engaged nursing staff in identifying unsafe medication administration practices.
Papastrat 2003[121]	Educational interventions	Changing practice project	Pilot testing of problem-based learning and systems analysis methods for medication administration to undergraduate nurses.	First-semester baccalaureate nursing students at Thomas Jefferson University	New teaching method	Problem-based learning enabled students to use findings from topic-specific research to develop solutions for clinical problems. Students applied knowledge to clinical settings.
Pape 2003[126]	Reducing distractions during medication administration	Quasi-experiment	Three groups: one control, one used protocol, one used protocol and signage. Outcomes measured by observing medication rounds for distractions.	One medical/surgical unit in one hospital, 24 nurses	Protocol for safe medication administration. Signage—nurse administering medications wore vest asking others not to interrupt.	Distractions were statistically significantly less in the intervention groups, particularly the intervention group using both protocol and signage.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Pape 2005[127]	Reducing distractions during medication administration	Process Improvement	Interventions introduced after observation of distractions. Measured distractions with self-report tool.	5 units in one hospital, 20 nurses	Protocol and checklist for safe medication administration introduced to all nurses. Signage "STOP do not disturb" placed above med prep area.	Self-report of distractions from before and after signage was placed showed decline in distractions from other nurses, other personnel, external conversation, and loud noises.
Rask 2007[117]	Medication safety practices	Cross-sectional study	Survey of hospitals about adoption of National Quality Forum's safe practices and culture of safety	148 hospitals in the United States	None	There was high adoption of standardized labeling and storage of medications (90.5%), identification of high-alert medications (81%), and use of unit doses (81%). For-profit hospitals were more likely than not-for-profit hospitals to have unit-dose medication distribution systems (93.1% vs. 78.2%) and policies on reading back verbal orders (83.1% vs. 58.4%). There were greater distractions affecting medication administration in large hospitals. Hospitals having 100–229 beds were more likely to report using pharmacists to review and approve nonemergency orders prior to dispensing. 69.4% of hospitals use data analysis to drive patient safety quality improvement efforts.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Sakowski 2005[135]	BCMA system	Evaluation study	Effect of implementing BCMA using a retrospective audit of warning and error reports generated by the BCMA system	6 hospitals in a multihospital system.	BCMA	Of 7,120 alerts and warnings, 5,606 actionable warning identified. Users overrode 78%. 25% of items listed as preventable errors and 70% of those labeled as possible errors were noise. Most common types of errors were early doses, wrong dose, doses without order, doses after order discontinued.
Schaubhut2000[132]	Expanding error reporting system Concurrent chart review process	Quality improvement	Reviewed reported medication errors, documentation of medication administration, identified need for medication administration policies, and focus on potential causes of errors	1 hospital in a suburb of New Orleans, LA	A computer-based "unreported meds followup" was created to remind nursing staff about scheduled medications omitted or not documented. Charts were prospectively reviewed, a mandatory medication error prevention seminar was given to nurses, and a medication review report was created for nurses.	Reported error rates increased by 0.5% each year over 3 years. Documentation errors decreased over time.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Schneider2006[118]	Educational interventions	Randomized controlled trial	Nurses were randomly assigned to use an interactive educational tool on medication administration. Direct observation of medication administration before and after the educational tool.	30 nurses (10 at each site) with at least 1 year experience, working full-time for at least 6 months, at 3 community hospitals in the Midwest within a large nonprofit health system	Interactive medication administration program	Errors in administrative practices decreased at a statistically significant level, errors in preparation increased slightly, and there were too few adverse drug events to analyze.
van Gijssel-Wiersma 2005[141]	Computerized medication charts	Before-after study	Compared prescription errors by review and administration errors by direct observation before and after	1 internal medicine unit	Computerized medication chart, updated daily, compared to handwritten 5-day medication record	Prescribing errors increased, mostly omitted name and date. Administration errors decreased from 10.5% to 6.1%.
Wright 2006[129]	Inpatient self-administration	Literature review	12 studies that measured patient compliance with self-administration programs (SAPs)	Retrieved 455 citations that involved patient SAPs, predominately in hospitals.	None	Even though SAPs varied widely in their structure and content, some SAPs reported that the patients' knowledge of their drug regimen (including the names and dosing frequency of their drugs) improved, but the patients' knowledge of possible side effects of their medications did not increase.

Evidence-Based Practice Implications

Medication safety is a significant issue in hospitals and throughout health care. Great improvements are needed, and hospitals are engaged in many efforts to reduce errors and increase this aspect of patient safety. Unfortunately, there is little evidence on which to base interventions. Based on the research literature, we can have confidence in only two aspects of our knowledge. First, data from voluntary self-reports of medication errors is neither reliable nor valid. Yet, this is the evidence most available for evaluating quality improvement. Interventions to improve the quality of voluntary self-report data include changing the culture to focus on system issues rather than individual deficiencies and having explicit and visible quality management system responses to these data. Staff who do not fear the response to an error report and see that the reports are used to improve quality are much more likely to take the time to report.

The second area about which there is some consensus in the literature is the rate and types of medication administration errors that commonly occur. Using the more reliable and valid data from direct observation studies, we see that the proportion of doses in error is between 20 and 27 percent counting wrong-time errors and between 7 and 18 percent without the wrong-time errors. MAEs are most likely to be wrong time, omissions, and wrong dose (wrong or extra dose). Because the nurse is often the last health care provider in the medication-use process, no one, except the patient, is in a position to intercept those errors. Given the number of medication doses administered each day in U.S. hospitals, the probable number of errors is truly staggering. If hospital patients get 10 doses of medication each day, at least 1 and possibly 3 of those will be wrong.

While the research base for practice interventions is growing, it is still weak for most of the strategies currently recommended to improve medication safety. System-focused strategies include increasing nurse staffing levels, otherwise decreasing workloads, improving the safety climate, and instituting policy and procedures such as RN independent double-checks. There are few research studies describing nurses' perceptions of the impact of these system features and even fewer assessing the actual impact, and none that have implemented and rigorously evaluated the effects of system strategies. Instituting new technological systems is most highly recommended. Given the emphasis, there have been surprisingly few studies actually assessing the impact on error rates of bar-coded medication administration and other medication safety technologies.

Process-focused factors include minimizing distractions and interruptions during medication administration, using equipment correctly, and assessing and monitoring the patients' responses to the medications. Again, a few small, single-site studies have assessed the effects of implementing protocols addressing these issues; but overall, the evidence is weak.

The human factors of knowledge and skills (e.g., mathematical) have been studied for decades, and changes in basic education and nurses' orientation and continuing education have been instituted. Studies linking these strategies to outcomes such as the rate of medication errors have not been completed. The impact of fatigue on MAEs is currently of great interest. But with only one descriptive study available and no interventions tested, it is difficult to know how to approach this issue.

Based on this review of the literature, it is clear that medication errors are an immense problem. When implementing interventions to improve medication safety, use the most reliable

and valid data available, and share the results through publications to make the knowledge available to all.

Research Implications

The implications for research follow directly on the discussion of practice implications. Research in this area is constrained by the need to carry out these projects "in the field." Secondary analysis of existing data sets cannot be used for most of the pertinent questions in this area. Laboratory studies are equally impossible. The situations at the heart of medication safety are complex, multifaceted, and multidisciplinary; knowledge about them must be produced with studies conducted within that complex environment. This requires health care institutions to simultaneously attempt to implement changes that will reduce the problem and evaluate the impact. Essentially, this is quality improvement (QI) work.

The question is, should the results of QI projects be considered evidence and used as part of the knowledge foundation for future evidence-based practice projects?[142] QI is a set of activities intended to improve some aspect of health care processes,[143] a dynamic and changing package of interventions,[144] and identification of ways to implement effective change.[145] For the most part, definitions of QI do not include assessing the effectiveness of these activities or producing knowledge. And yet, reports of QI projects are increasingly used as evidence for practice and organizational change.

Health care institutions are responding to the crisis in quality and safety with frenetic activities designed to bring about improvement. They desperately want evidence that will assist them in knowing which of these activities to focus on. Massive amounts of money are being invested in organizational changes to improve quality and safety with mostly expert advice and hunches to go on. There is little doubt that these projects are well intentioned; many of them suggest changes that are intuitive or reflect common sense. To move beyond the current state of multiple projects targeting similar changes, the industry needs evidence of the effects of specific changes: the direct and indirect effects, the intended and unintended effects, and the cost effectiveness.

By their nature, QI efforts are local, attempt to minimize disruption to the organization, and try to constrain costs of implementation. To justify the organization's investment in the project, there is a desire to show that the project had the intended effect. Further, the directors of the project often want to capitalize on the QI activities by reporting the results publicly, preferably through respected journals or presentations at professional meetings. As a result of these multiple goals, the project usually has only low-cost, superficial evaluation efforts that are then reported as evidence with an emphasis on outcomes supporting the intervention and omission of those that did not. Many current QI studies have significant bias and can cause harm by disseminating results that lead health care institutions to invest in activities that may not improve quality, while ignoring others that could.[146] But, there is no consensus on standards that can be applied to improve this situation. As Mosser and Kane[147] asked recently, What level of proof should we require to conclude that improvement has been achieved? What level of proof is there that the intervention was the cause of improvement?

The problem of bias inherent in local efforts to improve quality is crucial. When organizations make decisions to invest large amounts of money in a QI project, there is understandable reluctance to hear, let alone share, results that show no systematic effects on the outcomes of care. Yet, to produce the science required for future QI efforts, reports of activities

that were ineffective and those that resulted in unintended and disruptive side effects must also be shared with others. Most QI activities cannot be tested with rigorous and controlled research, and we therefore need to develop a QI science to enhance the internal and external validity of the results. We cannot accept poorly conducted studies of efforts to improve quality and safety—it is too crucial to the future of health care. At the same time, we must recognize that the complexity of projects taking place in the real world cannot be simplified and that analytic methods must substitute for experimental controls in this work.[148] Both the practitioners' distrust of research and its accompanying statistics and the researchers' disdain of the messiness of QI activities must be tempered with a better understanding.

Despite concerns about the rigor of QI, it is crucial that these activities be reported to promote learning about implementation methods that worked and those that did not, and the types of projects that produced desired results and those that did not. To maximize learning, these reports must be thorough and include both the intended and unintended outcomes, descriptions of the intervention and implementation must be candid, the robustness of the measures must be clear, and the description of the organizational context must be adequate. Recent guidelines for the publication of QI projects may assist in achieving this thoroughness and transparency.[149] Collaboration between the principals involved in the QI project and health systems researchers would maximize the potential for producing evidence from these field studies. It is unlikely that science will ever develop methods to study implementation and evaluation of QI projects in their natural setting with a level of rigor similar to experiments or clinical trials, and that makes the results of QI projects even more valuable. It is crucial that we learn which QI activities work in which settings and which outcomes can most likely be improved with organizational changes.

The specific issues most in need of research (QI activities) at this time are as follows:

- Bar-coding and other medication safety technology—widely recommended but little or no valid research using before-and-after designs.
- Independent RN double-checks—logical and widely recommended, but no research has been done describing, let alone testing, the effects of this policy.
- Relationship between nurse staffing and medication errors—a few descriptive studies and studies asking RN perceptions of the problem suggest that staffing and workload are major factors, but there are no research studies using valid and reliable data.
- Techniques to reduce distractions, interruptions, other risk factors for medication error need to be tested.
- Methods of effective education in medication safety for nurses and all providers.
- Effectiveness of implementing new checklists, policies, and procedures.
- Understanding work-arounds.
- Methods and techniques for successful implementation of system and process change.

Despite the national emphasis on patient safety and quality care, very little is known about effective medication safety strategies for nurses. The recent IOM report on medication safety [2] identified several areas needing future research, including the following:

- What are the most effective mechanisms to improve communication between patients and clinicians regarding the safe use of medications?
- What are the most effective mechanisms to improve patient education about the safe use of medications?
- Which self-management support strategies are effective in improving patient outcomes?

- How can information about specific medications be effectively used by patients? What is the impact of that information on patients' adherence and communication with clinicians?
- How can patient-centered approaches to medication safety decrease errors associated with medications and improve patient outcomes?
- How can medication-related competencies become a core competency among the current workforce?
- What is the impact of free samples on patient adherence and health outcomes?

Conclusion

There is a large and growing body of research addressing medication safety in health care. This literature covers the extent of the problem of medication errors and adverse drug events, the phases of the medication-use process vulnerable to error, and the threats all of this poses for patients. As this body of literature is evaluated, the fact that there are crucial areas about which we know little becomes apparent. Nurses are most involved at the medication administration phase, although they provide a vital function in detecting and preventing errors that occurred in the prescribing, transcribing, and dispensing stages. Administration errors comprise a significant proportion of all errors and yet, beyond that fact, there isn't much known about the causes or about the effectiveness of proposed solutions. Research addressing the complex process of medication use in hospitals is badly needed and requires a new approach to produce valid knowledge from studies done in the field with few controls of confounding factors.

Search Strategy

A search of the literature was conducted using PubMed® and CINAL®. The key words employed in the search included "adverse drug events," "drug administration," "medication administration," "medication administration errors," "medication error reporting," "medication safety," "nursing," "patient safety," and "work(ing) conditions." This resulted in 1,400 abstracts, which were narrowed as follows. Literature that addressed topics covered in this book on health information technology, specifically computerized provider order entry with clinical decision-support systems (for nurses and/or physicians) and bar-code medication administration systems, children, and medication reconciliation were excluded from this review, as were studies with only physicians and pharmacists as study subjects, those in home health care settings, and those related only to prescribing medications or patient compliance. Additional exclusion criteria included research not differentiating the nursing role in medication administration, administration of medications to reverse adverse drug reactions (e.g., naloxone for opioid overdose), prescribing and dispensing process of medications, and unique specifications regarding specific medications. Reviewed articles were searched for references that we did not already have, and PubMed® links were checked as additional articles were found. The final review also excluded editorials, newsletters, single-case studies, medication safety outside institutional settings (if dealing with patient self-management or adherence), and studies with critically flawed methodology and inadequate reporting. The literature was then also limited to reports written in English and research published in 1997 or later. A total of 70 articles were identified as having met the inclusion criteria as evidence and were discussed in this chapter.

Chapter 38. Medication Reconciliation

Jane H. Barnsteiner

Background

According to the Institute of Medicine's *Preventing Medication Errors* report,[1] the average hospitalized patient is subject to at least one medication error per day. This confirms previous research findings that medication errors represent the most common patient safety error.[2] More than 40 percent of medication errors are believed to result from inadequate reconciliation in handoffs during admission, transfer, and discharge of patients.[3] Of these errors, about 20 percent are believed to result in harm.[3, 4] Many of these errors would be averted if medication reconciliation processes were in place.

Medication reconciliation is a formal process for creating the most complete and accurate list possible of a patient's current medications and comparing the list to those in the patient record or medication orders. According to the Joint Commission[5] (p. 1),

> Medication reconciliation is the process of comparing a patient's medication orders to all of the medications that the patient has been taking. This reconciliation is done to avoid medication errors such as omissions, duplications, dosing errors, or drug interactions. It should be done at every transition of care in which new medications are ordered or existing orders are rewritten. Transitions in care include changes in setting, service, practitioner, or level of care. This process comprises five steps: (1) develop a list of current medications; (2) develop a list of medications to be prescribed; (3) compare the medications on the two lists; (4) make clinical decisions based on the comparison; and (5) communicate the new list to appropriate caregivers and to the patient.

Recognizing vulnerabilities for medication errors, numerous efforts are underway to encourage all health care providers and organizations to perform a medication reconciliation process at various patient care transitions. The intent is to avoid errors of omission, duplication, incorrect doses or timing, and adverse drug-drug or drug-disease interactions. The Joint Commission added medication reconciliation across the care continuum as a National Patient Safety Goal in 2005.[6] The Institute for Healthcare Improvement (IHI) has medication reconciliation as part of its 100,000 Lives Campaign. This chapter reviews the evidence for medication reconciliation and makes recommendations for nursing practice.

Medication Reconciliation

A comprehensive list of medications should include all prescription medications, herbals, vitamins, nutritional supplements, over-the-counter drugs, vaccines, diagnostic and contrast agents, radioactive medications, parenteral nutrition, blood derivatives, and intravenous solutions (hereafter referred to collectively as medications).[6] Over-the-counter drugs and dietary supplements are not currently considered by many clinicians to be medications, and thus are often not included in the medication record. As interactions can occur between prescribed medication, over-the-counter medications, or dietary supplements, all medications and

supplements should be part of a patient's medication history and included in the reconciliation process.

The steps in medication reconciliation are seemingly straightforward.[7] For a newly hospitalized patient, the steps include obtaining and verifying the patient's medication history, documenting the patient's medication history, writing orders for the hospital medication regimen, and creating a medication administration record. At discharge, the steps include determining the postdischarge medication regimen, developing discharge instructions for the patient for home medications, educating the patient, and transmitting the medication list to the followup physician. For patients in ambulatory settings, the main steps include documenting a complete list of the current medications and then updating the list whenever medications are added or changed.

However, the process of gathering, organizing, and communicating medication information across the continuum of care is not straightforward. First, there is tremendous variation in the process for gathering a patient's medication history. Second, there are at least three disciplines generally involved in the process—medicine, pharmacy, and nursing—with little agreement on each profession's role and responsibility for the reconciliation process. Third, there is often duplication of data gathering with both nurses and physicians taking medication histories, documenting them in different places in the chart, and rarely comparing and resolving any discrepancies between the two histories.

Additionally, patient acuity may influence the process of reconciliation. For example, a patient admitted for trauma may result in cursory data gathering about the medication history. Alternatively, a patient with numerous comorbidities may stimulate gathering a more complete list of current medications. In general, there is no standardization of the process of medication reconciliation, which results in tremendous variation in the historical information gathered, sources of information used, comprehensiveness of medication orders, and how information is communicated to various providers across the continuum of care.[7]

Safety Vulnerabilities Necessitate Medication Reconciliation

A multitude of factors—such as patients' lack of knowledge of their medications, physician and nurse workflows, and lack of integration of patient health records across the continuum of care—all contribute to a lack of a complete medication reconciliation, which in turn creates the potential for error.

Physician and nurse workflows have not traditionally included making a regular inventory of all medications a patient is taking (including prescription medications, over-the-counter drugs, herbals, and other complementary drugs such as vitamins) or verifying these lists with the patient. There has been no standard regarding what constitutes a comprehensive medication history or where medication information is kept in the paper or electronic health record. A patient's medication history may be found in the nursing admission database, the medication administration record, the physician history, and/or the pharmacy profile. When health care information is not integrated across settings, organizations, and among clinicians, it is not easy to validate or fill in the gaps from patient-reported information. Patients and family members may not be good historians of a medication record, and due to limited access to pharmacy records, only an incomplete recording of current medications may be obtained. Lau and colleagues[8] compared community pharmacy drug lists with hospitalized patients and found 25 percent of prescription drugs in use at home were not recorded on the hospital admission record.

In inpatient facilities, there are several situations where medication reconciliation is needed. Generally, patients are admitted to the hospital for a specific procedure, such as surgery, or on an urgent basis. When specialty health care providers are focused on the one component of care related to the specific encounter and do not take a holistic view to other aspects of the patients' health care needs and practices, it is easy to overlook medications that may cause an adverse event when combined with new medications or different dosages. Some of the patient's daily medications may be discontinued during a hospital stay, and when there is a lack of a formal reconciliation process on discharge, the need to restart medications upon discharge may be overlooked. One example would be discontinuing an anticoagulant during a hospital stay and neglecting to restart it upon discharge. Another example is when orders from one unit of care (such as intensive care) are discontinued and new orders are written when the patient moves to another unit of care (such as a general care unit). The policy necessitating the rewriting of orders makes it easy for the prescriber to overlook medications that may need to be reordered when no formal medication reconciliation process is in place. These factors combine to create an unsafe medication environment in acute care settings.

Research Evidence

Medication reconciliation studies have focused on the accuracy of the medication history during various transitions: ambulatory to acute care inpatient setting, skilled nursing facility to acute care inpatient setting, inpatient acute care setting to skilled nursing facility, inpatient acute care setting to discharge, inpatient floor to the intensive care unit (ICU), and ICU to discharge. Little research has focused on outcomes related to the prevalence of errors resulting from a lack of or an incomplete patient medication list.

Reconciliation in the Ambulatory Setting

Medication discrepancies in outpatient records were addressed in three studies. Ernst and colleagues[9] found discrepancies in 26.3 percent of charts of patients requesting prescription renewal. Of the charts with discrepancies, 59 percent omitted medications from the electronic medical record medication list. Miller and colleagues,[10] upon examining patient records of an ambulatory family practice, found that while 76 percent of patients had prescribed medications, 87 percent of charts had incomplete or no documentation of those medications. Three years following institution of a reconciliation process, which included a form on the chart listing all medications ordered for a patient, 82 percent of charts had complete prescription medication documentation. Similar findings were noted in a study of cardiology and internal medicine practices[11] and in a group of patients receiving dialysis.[12] Whether patients used the prescribed medications as originally prescribed or if their medications were changed by another physician was not reported. The reconciliation process requires verification with the patient regarding their use of the prescribed medications.

Reconciliation in Acute Inpatient Settings

Nine studies examined medication reconciliation in acute inpatient settings. Bayley and colleagues[7] identified that the common discrepancies in medication history from ambulatory to inpatient care were omitted medication orders, altered doses, or incomplete allergy histories.

Vira and colleagues[13] found a 38 percent discrepancy rate in their study of newly hospitalized patients. Gleason and colleagues[4] found more than half of the patients they studied had discrepancies in medication histories or admission medication orders.

Among the most common medication discrepancies between what is in the patient's history and what is ordered upon admission to the hospital was omission of a medication that patients reported taking prior to admission.[13] These discrepancies result from incomplete documentation of the patient's medication history and a lack of time to search for the information. Nursing staff have been noted spending in excess of an hour per patient admission or transfer trying to accurately identify medications a patient has been receiving,[3] including getting a list of preadmission medications from the patient and filling in gaps through the pharmacy and primary care physician.

Chevalier and colleagues[14] examined nurses' perceptions of medication reconciliation practices. More than 60 percent of nurses reported that determining the medications a patient was taking at home, clarifying medication orders at transfer, and ensuring accurate discharge medication orders was a time-consuming process. Time requirements and staffing resources were identified as a barrier to completing the process. Although implementing a medication reconciliation process will likely consume more health care provider time initially, the process may become more efficient once in place. A standardized reconciliation process has been reported to reduce work and the rework associated with the management of medication orders. Rozich and colleagues[15] reported that implementing a systematic approach to reconciling medications was found to decrease nursing time at transfer from the coronary care unit by 20 minutes per patient, and pharmacy time at hospital discharge by more than 40 minutes. Stover and Somers[16] reported that case managers performing the reconciliation process spent 5 to 10 minutes per day completing the process with new admissions, and each case manager typically reviewed eight new admissions each day.

One challenge to having an accurate patient medication history is the lack of a standardized location in the patient chart where the information may be found. A nurse may need to check the nursing admission database, the medication administration record, the physician patient history and progress notes, and the pharmacy database. Rozich and Resar[15] found that prior to initiation of a reconciliation process, details of the current medications in the inpatient chart were nonexistent or incorrect 85 percent of the time. Similar findings were found in family practice.[17] Nickerson and colleagues[18] found that of the medication history discrepancies they identified, 83 percent had the potential for harm. Others reported that when a medication reconciliation process was instituted, it reduced discrepancies from 70 percent to 15 percent.[3, 19] Vira and colleagues[13] reported that a medication reconciliation process prevented the potential for harm in 75 percent of cases.

Transfers From Inpatient Floor to ICU and Discharge From the ICU

Two studies by Pronovost and colleagues[20, 21] examined medication reconciliation in the ICU. Examining discrepancies between medications a patient was receiving in the ICU and the discharge orders from the surgical ICU resulted in 94 percent of discharge orders needing to be changed. Following implementation of a paper-based medication tracking system, the error rate of discharge medication orders was reduced to zero.[20] Following implementation of a reconciliation process using an electronic form at discharge from a surgical ICU, only 21 percent of orders required changing.

Admissions Between Skilled Nursing Facilities and Hospitals

A study of medication changes during transfer from nursing home to hospital and hospital to nursing home found inaccurate and incomplete reconciliation of medication regimens.[22] The mean number of medication orders altered per patient on admission to the hospital from a nursing home was 3.1, and from the hospital to the nursing home was 1.4. Sixty-five percent of the medication changes were discontinuations, 19 percent were dose changes, and 10 percent were substitutions for medications with the same indications. The investigators estimated that 20 percent of the medication changes led to an adverse drug event.

Inpatient to Discharge

Four studies looked at the process of discharge from the hospital to home. Bayley and colleagues,[7] in a qualitative study including nurse, physician, and pharmacist informants, reported that reconciliation failures at discharge stemmed from not resuming medications held during the hospital stay, and insufficient patient education at discharge. These failures resulted from incomplete gathering of the home medication regimen at admission and rushed discharges.

Moore and colleagues[23] found that 42 percent of the patients they studied had one or more errors in the discharge medication orders. Most often medications that should have been restarted were not. The medications commonly involved were cardiovascular (36.4 percent), gastrointestinal (27.3 percent), and pulmonary (13.6 percent). Sullivan and colleagues[24] found that 59 percent of discrepancies not corrected at discharge could have resulted in patient harm.

The use of a multipart paper prescription form for discharge medications was found to improve accuracy. The form integrates admission medications, in-hospital changes, and discharge medications. One part of the form is used as the prescription, the second is placed in the chart, the third is given to the patient with instructions for home management, and the fourth is sent to the primary care physician. Accuracy of medication prescriptions with the use of a multipart form was 82 percent, as compared to 40 percent without the use of an integrated process.[25]

Medication History Accuracy With Electronic Health Records

The electronic health record is generally believed to contain more accurate information and facilitate easier retrieval of information than paper-based medical records. Studies of medication lists in electronic health records have found the data are only as accurate as what has been entered. Wagner and Hogan[26] found discrepancies between the number of medications patients reported taking (5.67) and that listed in the electronic record (4.69). Data entry errors accounted for 28 percent of the discrepancies, while 26 percent were related to failure of the clinician to enter medication changes into the electronic record.

DeCarolis and colleagues[27] found that a computerized medication profile was inaccurate in 71 percent of the patients they studied. They demonstrated that implementation of a standardized medication reconciliation process reduced the number of patients with unintended discrepancies by 43 percent, thereby significantly decreasing the potential for medication errors. However, developing and implementing an electronic reconciliation process requires technical support. Kramer and colleagues[28] reported needing grant funding with hospital matching funds for development and programming. Reprogramming is required anytime there are system upgrades.

Use of a computer order entry system can reduce errors at the time of discharge by generating a list of medications used before and during the hospital admission. The medication list with instructions can be printed and used for education and review with the patient.[7] The utility of such a system depends upon the prior implementation of an admission medication reconciliation system. Some electronic discharge medication ordering systems allow for direct transfer of the orders to the community pharmacy and to the primary care physician, as well as keeping a permanent record on the electronic health record.

Clearly there is a need for patients, families, health care providers, and pharmacies to have a single electronic medication record with everyone working from the same record and all medications being reconciled against this record. Electronic systems make it easier to access medication histories, but they need to be kept up to date, and information must be correlated with patients' actual medication use.

Electronic prescribing network systems are being developed that can instantaneously provide a patient's medication history to pharmacists, consumers, and health care providers, while protecting patient privacy. Additionally, electronic prescribing allows for key fields such as drug name, dose, route, and frequency. Electronic prescribing also allows for decision support such as checking for allergies, double prescribing, and counteracting medications.

Evidence-Based Practice Implications

There are numerous areas for nurse involvement in the area of medication reconciliation. The following are generally consensus recommendations; they have not been subjected to systematic study for effectiveness unless noted.

Define the Steps in the Reconciliation Process

A first step in having an accurate listing of medications is defining the steps in obtaining a complete medication history. IHI suggests three steps to the process: (1) verify by collecting the list of medications, vitamins, nutritional supplements, over-the-counter drugs, and vaccines; (2) clarify that the medications and dosages are appropriate; and (3) reconcile and document any changes.[29] Each health care setting needs to develop standards for who is responsible and how the process will be completed. Whittington and Cohen reported that the accuracy of medication lists went from 45 percent to 95 percent with the implementation of reconciliation standards.[30]

Clearly Identify Responsibilities for the Process

Health care professionals need to clearly identify team roles and responsibilities for medication reconciliation. This needs to include evaluating existing processes; identifying a standard location in the patient chart where the medication history is kept; and determining who will put the medication history onto the agreed upon place in the chart, the time frame for resolving variances, and how to document medication changes.[31] These processes would eliminate the duplication of history taking and documentation that currently exists in many settings.

Consider Use of a Standardized Form

Many settings have found the use of a standardized medication form facilitates an accurate list that is accessible and visible.[32] Numerous examples are available on the IHI and Joint Commission Web sites.

Have an Explicit Time Frame for Completion

Many organizations have a process in place that calls for reviewing the patients' medication list at every primary care visit and within 24 hours of an inpatient admission. High-risk medications such as antihypertensives, antiseizures, and antibiotics may need to be reconciled sooner, for example, within 4 hours of admission.

Design Education Programs for Health Care Professionals

Medication reconciliation is a complex process. Education programs need to include the research about medication reconciliation and the steps being put into place to make a safer system for patients.

Design and Implement a Monitoring Process

Implement a reconciliation review of open and/or closed patient records. Assess adherence to the process and identify the potential for and any actual harm associated with unreconciled medications. Auditing tools such as the Improvement Tracker on the IHI Web site may assist health care settings in tracking their findings over time. Share results with providers so they are able to note progress over time.

Educate Patients and Family Members To Serve as Advocates

Patient education needs to be a major focus in medication reconciliation. Patients may not be accurate historians.[32] Recognition that information is being gathered from laypeople needs to be acknowledged and assistance needs to be offered to make the information as accurate as possible. A number of approaches have been identified to assist patients and families—for example, reconcile the medication list at every ambulatory visit.[9] Establish a process where patients bring their medications, including all over-the-counter preparations, to every health care encounter.[9, 33] Use of a universal patient medication form has shown promise in North Carolina; the form can be found at www.scha.org. In addition, educating patients about their medications allows them to keep better track of the medications they are taking.

Challenges

There are many challenges associated with implementation of effective medication reconciliation programs across the continuum of care. First, developing and implementing effective programs is very complex considering the various sites of care, the need for standardization in the process, and the importance of including the patient in the process.

Garnering executive leadership and support, obtaining physician and nurse understanding of the need for medication reconciliation, and actively participating in the design and implementation of programs may be difficult in many organizations where providers already feel burdened. There is a time commitment in both obtaining the medication history and completing the reconciliation process.

Research Implications

Research is needed on all aspects of the medication reconciliation process to provide an evidence base for impacting the prevention of adverse drug events. The Institute of Medicine report *Preventing Medication Errors*[1] found that currently most of the studies reported in the literature have small sample sizes and are single-site quality improvement projects. Multisite studies across the continuum of care are needed to assess the scope of the problem. Intervention studies using a variety of approaches, both paper based and electronic, are needed to determine the accuracy, feasibility, and simplicity of maintaining accurate lists of a patient's medication history.

The medication reconciliation process takes time, initially an additional 30 to 60 minutes per admission.[15] If an inpatient unit has multiple discharges and admissions, this can translate to the need for additional full-time staff. If nurses are responsible for the process, nursing hours per patient day may need to increase. Study of how medication reconciliation processes change the workflow and time associated with it are needed.

Busy clinicians are resistant to changing their workflow. Designing and testing streamlined processes that will work across the continuum of care, from the ambulatory to the inpatient setting, and having all stakeholders involved in the design will facilitate the process.

Studies of the sustainability of medication reconciliation processes need to be carried out. What does it look like at 6, 12, and 24 months? Are improvements being maintained?

Patients need to be full partners and self-advocates in the medication reconciliation process. Studies on systematic, multifaceted education programs regarding how to best maintain a current and complete listing of all medications need to be undertaken, as recommended in *Preventing Medication Errors*.[1] Studies should also address what techniques (e.g., the use of a medication card) work best to maintain an accurate list of medications.

Conclusion

There is some evidence to demonstrate how a medication reconciliation process is effective at preventing adverse drug events. Few studies have been published demonstrating how to do the process effectively or outlining the costs associated with design and implementation of programs. Nonetheless, an effective medication reconciliation process across care settings—where medications a patient is taking are compared to what is being ordered—is believed to reduce errors. Comparing what is being taken in one setting with what is being prescribed in another will avoid errors of omission, drug-drug interactions, drug-disease interactions, and other discrepancies. Medication reconciliation is a major component of safe patient care in any environment.

Search Strategy

Searches were carried out using the terms "medication reconciliation," "medication verification," "medication safety" "medication systems," and "medication errors." OVID databases for CINAHL®, MEDLINE®, and Google databases were searched. English-language health care literature from 1965 through March 2007 was reviewed. Additional searches were carried out on numerous patient safety Web sites, such as the Institute for Safe Medication Practices, the National Patient Safety Foundation, the Joint Commission, and the Institute for Healthcare Improvement. Reference lists from articles on medication reconciliation were also used to identify additional publications.

Articles that describe various components of the reconciliation process were found. Studies tended to be about one of the steps in the handoff process, such as admission from home to an acute care facility. No studies were identified that described the reconciliation process along the entire continuum of care from admission to an acute care facility, transfer from one level of care to another (such as critical care to general care), and discharge back to the community to the primary care practitioner or skilled care facility. The majority of articles were descriptive, and published studies were primarily quality improvement projects with small sample sizes limited to single clinical sites.

Evidence Table. Medication Reconciliation

Study	Aim	Design & Sample	Site	Outcome
Bates 1999[34]	Assess strength of patient risk factors for adverse drug events (ADEs)	Nested case control 4,108 admissions	11 medical and surgical units in 2 tertiary care hospitals	Adverse drug events more frequent in sicker patients with longer hospital stay. Few risk factors emerged when controlling for level of care and pre-event length of stay. Prevention strategies should focus on improving medications systems.
Bayley 2005[7]	Enhance understanding of how patient handoffs are related to risk of adverse medical events before and after implementation of an information technology solution	Informant interviews	One primary care practice and four inpatient facilities (one academic medical center and three community hospitals)	Based on thematic analysis of qualitative data, identified information barriers due to work processes, role definitions, and individual discretion which can assist in designing effective technology solutions.
Bedell 2000[11]	Examine frequency of discrepancy between medications prescribed and those taken and associated causal factors. Compare medication containers and reported use of medication with medical records	Descriptive design 312 medical records in ambulatory setting	5 cardiology and 3 internal medicine practices	545 discrepancies among 239 patients (76%) 278 (51%) taking meds not recorded in chart 158 (29%) not taking recorded meds 109 (20%) taking different dosage than in chart. Predictors of discrepancy: age of pt, number of meds and multiple physicians
Boockvar 2004[22]	Identify medication changes during transfer between hospital and nursing home and ADEs caused by these changes	Descriptive study of residents of 4 nursing homes admitted to 2 academic hospitals. Nursing home and hospital records reviewed to identify changes in medication regimens between sites. Medications matched and compared regarding dosage, route, and frequency of administration	4 nursing homes	During 122 admissions, the mean numbers of medications altered during transfer from nursing home to hospital and hospital to nursing home were 3.1 and 1.4, respectively (p<.001). Changes in drug use were discontinuations, dose changes and class substitutions. Of 71 bidirectional transfers, ADEs attributable to medication changes occurred during 14 (20%). Overall risk of ADE per drug alteration (n=320) was 4.4% Most medication changes (8/14) implicated in causing ADEs occurred in the hospital, most ADEs (12/14) occurred in the nursing home after nursing home readmission.

Study	Aim	Design & Sample	Site	Outcome
Chevalier 2006[14]	Measure nurses' perceptions of patient safety, medication safety and current medication reconciliation practice at transition points in a patient's hospital stay	Descriptive survey of 111 nursing staff	Three general medicine units	Inconsistent medication reconciliation completion due to insufficient time and lack of communication among heath care professionals.
DeCarolis 2005[27]	Compare usual process of obtaining medication history to systematic reconciliation process	Comparison of pharmacist obtained medication history to inpatient medical record and computerized outpatient medical profile.	1 VA medical center	71% of patients had inaccurate computerized profile. Unintended order discrepancies in 58% of patients. Medication reconciliation system reduced unintended order discrepancy to 43%
Ernst 2001[9]	Assess accuracy of data in the EMR and document frequency and types of discrepancies that occurred.	Compared prescription renewal requests with electronic medical record data. 950 prescription-renewal requests for 134 medications over 3 month period.	Family Medicine Outpatient Clinic	Medication discrepancies were noted for 250 (26.3%) requests. 58.8% of the discrepancies were for prescriptions patient was taking but that were not ordered in the EMR medication list.
Gleason 2004[4]	Identify type, frequency, and severity of medication discrepancies in admission orders. Assess whether pharmacist obtained admission med histories decreased number of med errors.	Convenience sample compared 204 pharmacist conducted medication histories from patients to medication and allergy history documented in patient charts	725 bed tertiary care academic medical center. Direct admissions to 12 adult medical-surgical units	Interviews took on average 13.4 minutes. Discrepancies in medication histories and admission medication orders identified in more than 50% of patients. 22% could have been harmful if no intervention.
Kramer 2007[28]	Establish feasibility of electronic system for pharmacist and RN admission and discharge medication reconciliation and assess effect on patient safety, cost, satisfaction among providers and nurses	Pre-post electronic reconciliation process	283 patients on general medicine unit, 147 in preimplementation phase and 136 in postimplementation phase.	Preimplementation RNs identified more incomplete medication orders and dosage changes Post implementation greater numbers of allergies were identified, pharmacists completed significantly more dosage changes and patients reported higher level of agreement re discharge medication instructions. Lack of MD participation, 25% did not complete electronic discharge report

Study	Aim	Design & Sample	Site	Outcome
Lau 2000[8]	Compare medication history in hospital medical record with community pharmacy records prior to admission	Prospective observational study of 304 patients	General medical units of 2 acute care hospitals	61% of patients had discrepancy from community pharmacy records to inpatient medication history. 26% of prescription medications in use prior to admission were not listed in hospital medical records.
Manley 2003[12]	Determine rate of drug record discrepancies in a hemodialysis population	Prospective observational study of 63 patients	Outpatient hemodialysis center	60% of patients had drug record discrepancies.
Miller 1992[10]	Improve family practice office chart documentation of prescribed medications through use of duplicate prescription forms	Descriptive study of implementation of duplicate prescription forms Baseline chart review – 67 charts Duplicate prescription form: 1 week = 50 charts; 40 months = 60 charts	Ambulatory family practice	Baseline: 51 patients (76%) had prescribed medications with 87% of charts with incomplete or no documentation 1 week: 83% of charts had complete prescription medication documentation 40 Months: 82% of charts had complete prescription medication documentation
Moore 2003[23]	Determine prevalence of medical errors from inpatient to outpatient setting	Descriptive study of 86 patients inpatient and ambulatory medical records	950 bed urban teaching hospital and affiliated primary care practice	42% of patients had at least 1 medication continuity error
Nickerson 2005[18]	Determine clinical impact on drug therapy problems (DTP) of pharmacist review of discharge medications at discharge	Randomized clinical trial with 6 month followup of 253 patients	2 inpatient family practice units	Pharmacist intervened in 481DTP with average per patient of 3.49. Control group retrospective chart review found 56% had DTP
Paquette-Lamontagne 2002[25]	Improve accuracy of patient profile information in community pharmacies with use of discharge prescription forms	Quasi experimental intervention with 89 patients	Medical units in 3 teaching hospitals	82% of medication profiles in experimental group were complete as compared to 40% in control group
Pronovost 2003[20]	Reduce medication errors with a reconciliation process using paper form at discharge fro surgical ICU	Intervention using paper medication discharge form for ICU discharges	Surgical ICU	At baseline 94% of discharge orders were changed due to discrepancies. At Week 24 discharge error rate was 0
Pronovost 2004[21]	Reduce medication errors with a reconciliation process using an electronic form at discharge from surgical ICU	Intervention using electronic medication discharge form for ICU discharges	1,455 patients in surgical ICU over 1 year period	21% of patients required medication order change. 6% due to allergy discrepancy

Study	Aim	Design & Sample	Site	Outcome
Rozich 2001[15] Rozich 2004[3]	Reduce medication discrepancies at health care transition points through the implementation of a medication reconciliation process on admission, during transfer and at discharge from the hospital	Descriptive study of implementation of medication reconciliation process	Acute care inpatient units Baseline 20 charts per week for 6 weeks the ongoing chart review	Baseline medication discrepancy rate 213 per 100 admissions. 7 month post introduction of reconciliation process rate was 42 per 100 admissions.
Vira 2006[13]	Describe potential impact of medication reconciliation process to identify and rectify errors at time of hospital admission and discharge	60 randomly selected patients. Compared admission medication orders with patient medication vials and interviews with patients, caregivers and outpatient health care providers. At discharge, pre-admission and in patient medications compared with discharge orders and written instructions.	Inpatient community hospital	60% of patients had minimum of 1 unintended variance with 18% having minimum of 1 clinically important variance. None were detected outside of reconciliation process
Wagner 1996[26]	Assess correspondence between medications the patient taking and documentation in EMR	Descriptive comparison of patient report and chart review study of 312 medical records	Outpatient geriatric center	Mean number of medications per patient: 5.67 Mean number of medications listed in EMR: 4.69 Missing medication recording attributed to patient misreport (36%) and MD/NP failure to note medication changes in EMR (26%)
Whittington 2004[30]	Reduce percentage of admission ADEs caused by errors in reconciliation through use of admission reconciliation form as hospital medication record and discharge prescription form	Descriptive study of implementation of medication reconciliation process Number of patients enrolled not reported	4 hospitals	Change from 45% to 95% accuracy of medication list on implementation of reconciliation process.
Winterstein 2006[35]	Evaluate medication safety infrastructure of critical-access hospitals in Florida	Qualitative assessments using self-administered survey and site visits of 7 hospitals.	7 critical access hospitals in Florida	Characteristics targeted for quality improvement included medication reconciliation. Admission medications infrequently reviewed, and readmissions were associated with higher prevalence of medication errors

Chapter 39. Personal Safety for Nurses

Alison M. Trinkoff, Jeanne M. Geiger-Brown, Claire C. Caruso, Jane A. Lipscomb, Meg Johantgen, Audrey L. Nelson, Barbara A. Sattler, Victoria L. Selby

Background

The safety of nurses from workplace-induced injuries and illnesses is important to nurses themselves as well as to the patients they serve. The presence of healthy and well-rested nurses is critical to providing vigilant monitoring, empathic patient care, and vigorous advocacy. Many workplace stressors that can produce diseases and injuries are present in nursing work environments. These stressors include factors related to the immediate work context, characteristics of the organization, and changes that are occurring external to the organization but throughout the health care industry.[1] Nurses experience significant physical and psychological demands during their day, as well as a work safety climate that can be adverse. Pressures within organizations to downsize, use nurses employed under alternative arrangements (pool and traveling staff), and the turnaround time for patient care (early discharge, higher patient loads) are examples of factors that are determined at an organizational level. The external context within which nurses practice includes lean managed care contracts, increasing use of complex technological innovations, an older nurse workforce, and increasing numbers of very sick elderly patients (aging population). Factors at each of these levels can produce threats to nurses' safety while on the job.

The hazards of nursing work can impair health both acutely and in the long term. These health outcomes include musculoskeletal injuries/disorders, other injuries, infections, changes in mental health, and in the longer term, cardiovascular, metabolic, and neoplastic diseases. In this chapter we will present major research findings that link common work stressors and hazards to selected health outcomes. These stressors include aspects of the way work is organized in nursing (e.g., shift work, long hours, and overtime) and psychological job demands, such as work pace. In addition, aspects of direct care work that influence nurse safety will be discussed, including the impact of physical job demands such as patient lifting and awkward postures, protective devices to prevent needlesticks, chemical occupational exposures, and potential for violence. Where possible, interventions that have demonstrated effectiveness to reduce the risk of illness and injury will be presented, as well as gaps in knowledge that can spur new lines of research inquiry.

Research Evidence

Shift Work and Long Work Hours

The relationship between work schedules and health and safety is complex and is influenced by characteristics of the work schedule (time of shift, direction and speed of rotation, pattern of days off, shift length, rest breaks), as well as characteristics of the job, the worker, and the work environment.[2] While the focus is on potential negative aspects, some workers experience benefits

from shift work and prefer it (e.g., incentive pay, reduced volume of activities and personnel when compared with day shift).

Researchers theorize that shift work exerts adverse effects by disturbing circadian rhythms, sleep, and family and social life.[2, 3] Disturbances in circadian rhythms may lead to reductions in the length and quality of sleep and may increase fatigue and sleepiness, as well as gastrointestinal, psychological, and cardiovascular symptoms. In addition, working at unusual times may make it difficult to interact with family and maintain other social contacts.[4] Similarly, long work hours may reduce the time available for sleep, leading to sleep deprivation or disturbed sleep and incomplete recovery from work.[5–7] This may adversely affect nervous, cardiovascular, metabolic, and immune functioning. Family and social contacts may also be reduced, which in turn may lead to physiological responses associated with stress. Long hours may also increase exposure times to workplace hazards such as chemicals; infectious agents; and physical, mental, and emotional demands. Long hours also may reduce time available for exercise or nutritious meals, and added job stress can increase smoking, alcohol consumption, and caffeine use.

Risks Associated With Shift Work

Sleep, sleepiness, performance, safety. Drake and coworkers[8] indicated that 32 percent of night workers (majority of shift hours between 9 p.m. and 8 a.m.) and 26 percent of rotating shift workers (shifts that change periodically from days to evenings or nights) experienced long-term insomnia and excessive sleepiness and were unable to adapt their sleep adequately on these shifts. Sleep loss makes people sleepier while awake, which may affect the shift worker's ability to perform activities safely and efficiently, both on and off the job. Increased sleepiness (or decreased alertness) in shift workers on the job has been demonstrated with subjective reports,[9] objective performance testing,[10] and EEG recordings showing brief, on-the-job sleep episodes.[11] Sleepiness is most apparent during the night shift, and poor daytime sleep appears to be a contributing factor.[12] A meta-analysis combining injury data from several studies indicated that injury risk increased by 18 percent during the afternoon/evening shift and 34 percent during the night shift compared to morning/day shift.[13] These results are consistent with worksite observations of increased subjective sleepiness and decreased reaction time during night shifts, and progressive decreases in total sleep time from early to late in the workweek.[14]

Social and familial disruptions. Because shift workers often work in the evening and sleep during the day, they frequently sacrifice participation in social and family activities. Furthermore, shift workers in continuously operating organizations such as hospitals are regularly required to work weekends and holidays, when much social and family interaction occurs.[15, 16] Consequently, too little time with family and friends is the most frequent and most negatively rated complaint among shift workers. The extent to which such disruptions occur depends both on the worker's schedule, type of family, gender, presence of children, and the degree of flexibility in the worker's social contacts and leisure pursuits.[15–17] For families, shift work often conflicts with school activities and the times when formal child care services are available, making arranging for the care of children more challenging,[17] affecting both the worker and the family's social adjustments.

Long-term effects and vulnerable groups. Although the specific contribution of shift work to other illnesses is not clear, several diseases have been associated with these work schedules. Gastrointestinal (GI) complaints are common in shift workers and could be due to changes in

circadian rhythms of GI function, sleep deprivation leading to stress response and changes in immune function, or the types of foods that are available during these shifts.[18, 19] Schernhammer and colleagues[20] reported an increased risk of colon cancer in nurses working 3 or more nights per month for 15 or more years.

Psychological complaints are frequently reported, including depression and other mood disturbances, personality changes, and relationship difficulties.[21] A review of 17 studies suggests that shift work increases risk for cardiovascular disease by 40 percent compared with day workers.[22] Possible mechanisms include decreased glucose tolerance, insulin resistance, elevated cortisol levels, and increased sympathetic activity. A systematic review of reproductive outcome studies concluded that shift work was associated with a modest increase in spontaneous abortion, preterm birth, and reduced fertility in women.[23] The effect on reproduction in men was not analyzed due to an inadequate number of studies. A meta-analysis of 13 studies examining night work and breast cancer reported that night work was associated with a moderately elevated risk among women.[24] The authors hypothesized that exposure to light at night reduces melatonin levels, increasing risks for cancer.

Shift work also may exacerbate preexisting chronic diseases, making it difficult to control symptoms and disease progression. Shift work interferes with treatment regimens that involve regular sleep times, avoiding sleep deprivation, controlling amounts and times of meals and exercise, or careful timing of medications that have circadian variations in effectiveness. Sood[25] suggests several conditions that may be exacerbated by shift work: unstable angina or history of myocardial infarction, hypertension, insulin-dependent diabetes, asthma, psychiatric illnesses, substance abuse, GI diseases, sleep disorders, and epilepsy requiring medication. Costa[26] adds to this list chronic renal impairment, thyroid and suprarenal pathologies, malignant tumors, and pregnancy. Aging is also associated with less tolerance of shift work, which may be due to age-related changes in sleep that may make it more difficult for older people to initiate and maintain sleep at different times of the day.[27] These sleep changes may begin as early as the 30s and 40s, so some workers who initially adapted well to shift work during their younger years may show more symptoms as they grow older.

Risks Associated With Long Work Hours

The number of studies examining long work hours is less extensive, but a growing number of findings suggest possible adverse effects. A meta-analysis by Sparks and colleagues[5] reports that overtime was associated with small but significant increases in adverse physical and psychological outcomes. A review by Spurgeon and colleagues[6] concluded that the adverse overtime effects were associated with greater than 50 hours of work per week, but little data are available about schedules with fewer than 50 hours. An integrative review by Caruso and colleagues[28] reported that overtime was associated with poorer perceived general health, increased injury rates, more illnesses, or increased mortality in 16 of 22 recently published studies. Dembe and colleagues,[29] examining data from the National Longitudinal Survey of Youth, found a dose-response relationship, such that as the number of work hours increased, injury rates increased correspondingly. Trinkoff and colleagues[30, 31] found that long work hours were related to the incidence of musculoskeletal injuries and needlesticks in nurses. Overall, these studies indicate that caution is needed in implementing schedules with extended work hours. Determining the number of work hours critically associated with risk for a specific job would require examining how extended hours interact with other factors contributing to fatigue,

such as work load, competing responsibilities, and opportunities for rest and recovery. Additional information on the effect of long work hours can be found elsewhere in this book.

Coping Strategies

Efforts to promote adaptation to (or ease the difficulties of coping with) shift work and long work hours include strategies for employers and strategies for workers. Most suggestions to date were written for shift work, but they may also be relevant for long work hours. A sampling of strategies suggested in the literature for shift work include designing new work schedules and rest breaks during work, altering circadian rhythms with bright light or blue light, optimally timing physical activity or other work demands, improving physical conditioning, using caffeine, planning dietary regimens, stress reduction, support groups, and family counseling.[32–39] Caldwell and Caldwell[36] suggest using behavioral and administrative strategies fully before considering pharmacologic aids since these stimulants and sedatives can be addictive and questions remain about the safety and effectiveness of long-term use. Taking naps during work is another intervention that has been associated with improvements in alertness[40, 41] and is an accepted practice in some Asian countries. More research is needed to determine the optimum length and timing of the nap and a practical environment at work to take a nap. Empirical evaluations and applications of the other techniques have begun and will be useful for some workers, but more research is needed to develop strategies that can be easily applied by workers in a wide range of demanding work schedule situations. Another type of strategy are work hour limits such as the recent Institute of Medicine recommendation[42] (p. 13) that work hours for nurses be limited to 60 hours per 7-day period and 12 hours per day.

Nurse Injury and Disease Outcomes

Musculoskeletal Injuries

Few industries in the United States have undergone more sweeping changes over the past decade than the health care industry. Changes in health care, including restructuring and redesign, have led to increasingly heavy demands on nurses and other health care workers. Extended schedules and increased work pace, along with increased physical and psychological demands, have been related to musculoskeletal injuries and disorders (MSD).[43] These demands have been found in laboratory and worker studies to increase the risk of musculoskeletal pain/disorders.[44–47]

Definitions for MSD vary, though most include pain in the affected body region (e.g., back or neck) for a specified duration or frequency,[48] along with other related symptoms such numbness and tingling.[49] Measurement of MSD also varies from study to study, with many studies relying on self-report and others requiring seeking care or obtaining testing or clarification/diagnosis by a clinician.[48] Researchers are careful to rule out nonwork-related MSD from their studies.

Health care workers are at extremely high risk of MSD, especially for back injuries. Health care workers are also overrepresented for upper extremity MSDs among workers' compensation (WC) claims.[50] In 2001, U.S. registered nurses (RNs) had 108,000 work-related MSDs involving lost work time, a rate similar to construction workers.[51] In 2003, the incidence rate for nonfatal

occupational injuries, many of which were MSDs, was 7.9 per 100 full time equivalents (FTEs) for hospital workers.[52]

Studies have shown that MSDs lead to sick days, disability, and turnover. In a survey of more than 43,000 nursing personnel in five countries, 17–39 percent planned to leave their job in the next year due to physical and psychological demands.[53] In previous research, the percentage of nurses reporting job change due to MSD ranged from 6 percent to 11 percent, depending on the body part injured (neck, shoulder, or back).[54] Staffing has also been related to MSD, with lower staffing complements related to increased injuries. Between 1990 and 1994, the Minnesota Nurses Association collected injury and illness data from 12 hospitals in the Minneapolis-St. Paul area. The researchers found that when RN positions in the hospitals decreased by 9.2 percent, the number of work-related injuries or illnesses among RNs increased by 65.2 percent. Lower staffing ratios for nurses and higher patient loads have both been shown to result in increased exposure to hazardous conditions and insufficient recovery time.[55] In a review of evidence, the Institute of Medicine indicated that there was strong relationship between nursing home staffing and back injuries.[56] In a recent study of the relationship of health care worker injuries to staffing in nursing homes, researchers indicated that staffing levels were significantly related to health care worker injury rates in nursing homes across three States.[57]

Physical/postural risk factors and MSD. Health care work is highly physically/posturally demanding,[54, 58, 59] and tasks requiring heavy lifting, bending and twisting, and other manual handling have been implicated in health care worker back injuries.[60] In one study, nurses were found to be at particular risk of back injury during patient transfers, which require sudden movements in nonneutral postures.[61, 62] Patient transfers also require flexion and rotation, increasing the injury risk due to a combination of compression, rotation, and shear forces.[63–65] Highly demanding physical work was associated with 9–12 times the odds of having a neck, shoulder, or back MSD among nurses.[54] Hoogendoorn and colleagues,[66] using video observations and questionnaires in a 3-year study of health care workers, found that extreme flexion and frequent heavy lifting had a strong impact on worker low-back pain. Other analyses found that physical/postural risk factors were related to impaired sleep, pain medication use, and absenteeism.[59]

Fewer studies have examined physical/postural risk factors in relation to health care worker neck and shoulder MSDs. Risk factors related to neck and shoulder pain include body placement in awkward postures that need to be maintained for long periods of time. Using direct observation, Kant and colleagues[58] found that surgeons had extensive static postures, along with operating room nurses who were required to maintain tension on instruments, leading to substantial musculoskeletal stress of the head, neck, and back. Lifting and stooping were significantly associated with health care worker arm and neck complaints,[67] whereas shoulder complaints were associated with pushing and pulling motions.[68, 69] Heavy lifting and actions with arms above shoulder height were associated with shoulder pain or injury in health care workers and in other occupational groups.[70–72] The evidence indicates that preventive interventions for MSD need to address physical/postural risk factors.

Work schedules and MSD. The work schedule can affect the sleep–wake cycle, and working extended hours, such as 12+ hour shifts, can lead to MSD due to extended exposure to physical/postural risk factors and insufficient recovery time.[73, 74] As physical/postural demands on the job increased for nurses, the likelihood of inadequate sleep also significantly increased.[59] Workers on schedules requiring frequent shift rotation and long hours may also be at higher risk for MSD.[75–78] In a survey of 1,428 RNs, more than one-third had extended work schedules, and

such schedules were associated with an increased likelihood of MSD.[79] A later study found that long work hours were related to incident musculoskeletal injuries in nurses.[30]

In workers with employment-related myalgia, symptoms increased with each successive workday, and remitted only by the second day off.[80] These workers had shorter periods of muscle rest, suggesting that continuous muscle tension was associated with musculoskeletal symptoms. In a British study of doctors-in-training, the fewer hours they slept and the more hours they worked, the more somatic symptoms, including MSD, they reported.[81]

Schedule components significantly related to MSD include long work hours, mandatory overtime, working while sick or on days off, and having fewer than 10 hours between shifts.[30] The new Institute of Medicine report, *Keeping Patients Safe*: *Transforming the Work Environment of Nurses*,[42] incorporated Wave 1 findings on nurse scheduling. More than one-third of staff nurses typically worked 12 or more hours per day. Among those working 12+ hours, 37 percent rotated shifts. On-call requirements were also very common (41 percent of the sample). Despite the long hours, few nurses took breaks; two-thirds typically took one or no breaks during their shift.

Mitigating MSD risks. Although two decades of research have demonstrated the work-relatedness of MSD, use of single-approach intervention methods to reduce MSD exposures (e.g., engineering controls, administrative changes, or worker training only) has shown inconsistent outcomes.[82] This is likely due to the combination of factors related to MSD and the need for broad organizational involvement to mitigate MSD problems.[83] Despite these concerns, important evidence-based successes have been demonstrated in reducing MSD, especially during patient lifting and transfer.[84, 85] Interventions incorporating participatory ergonomics have been found to improve upon previous approaches by allowing for extensive worker input into the design and adoption of preventive practices.[86, 87] In a participatory ergonomics approach, employees participate in the identification of ergonomic risk factors, brainstorm alternatives and solutions, handle implementation of controls, and assess control effectiveness along with symptom identification, ultimately becoming champions for ergonomics change.[86] Participatory ergonomics also has the potential for changing the culture of health care organizations, as employees begin to use ergonomic principles to improve jobs and the workplace. Because participatory interventions incorporate both management commitments to reducing injuries, along with workers who are involved in developing solutions, positive and effective workplace changes can occur.[88]

Interventions for MSD. Three common interventions used to prevent work-related musculoskeletal injuries associated with patient handling are (1) classes in body mechanics, (2) training in safe lifting techniques, and (3) back belts. Despite their wide spread use, these strategies are based on tradition rather than scientific evidence; there is in fact strong evidence these strategies are not effective.[85, 89] Recently there has been a major paradigm shift away from these approaches toward the following evidence-based practices: (1) patient handling equipment/devices, (2) no-lift policies, (3) training on proper use of patient handling equipment/devices, and (4) patient lift teams. Table 1 describes interventions and identifies challenges that have been associated with their implementation.

Table 1. Evidence-Based Interventions for Safe Patient Handling

Proposed Intervention	Description	Challenges to Implementation
Patient handling equipment and devices	Patient handling technologies include height-adjustable electric beds,[90–92] mobile mechanical patient lifts,[93–97] ceiling-mounted lifts,[98–100] friction-reducing devices/lateral transfer aids,[101–104] bed repositioning,[105–107] etc. More complete listings of patient handling equipment and devices are available.[108–110]	▪ Cost ▪ Assuring competency of all staff in its use ▪ Integrating multiple technologies ▪ Selecting the best technology to address the specific risks identified ▪ Technology often takes more time than performing the task manually
No-lift policies	Regardless of the title, these policies focus on minimizing manual patient handling.[84,111,112] No-lift policies have been developed through legislation or facility-based policies. National policies have been enacted in Europe and Canada. In the United States, State legislation related to manual patient lifting was recently passed in Texas and Washington. Facility-based policies are known as "no-lift policy," "zero lift," "minimal lift," "lift-free," or "safe patient handling and movement."	▪ Necessary equipment needs to be in place before the policy is implemented. ▪ Nonpunitive approach is necessary for success.
Training on proper use of equipment/ devices	While traditional classes in body mechanics and lifting techniques are not effective, evidence supports the need for ongoing training in use of equipment and devices.[84, 109, 113–115]	▪ Training all staff, across shifts ▪ Training on units with high staff turnover ▪ Need to reinforce training over time ▪ Need for "just-in-time" training when equipment is needed sporadically, such as bariatric device.
Patient lift teams	A lifting team is defined as "two physically fit people, competent in lifting techniques, working together to accomplish high-risk patient transfers."[116] This term is sometimes also referred to as "patient transfer team", "lift team" or a combination of these phrases.[116–125]	▪ Logistics of providing lift team services 24 hours a day/ seven days a week ▪ Cost ▪ Managing workload and logistics of "unscheduled lifts" that emerge during typical workday ▪ Addresses only patient lifts, ignoring other high-risk tasks such as repositioning, toileting, or bathing

Promising new interventions that are still being tested include use of unit-based peer leaders, clinical tools (algorithms and patient assessment protocols), and after-action reviews. Table 2 describes each intervention and identifies challenges associated with implementation.

Table 2. Interventions for Safe Patient Handling With Emerging Evidence

Proposed Intervention	Description	Challenges to Implementation
Peer leader education	Traditional education approaches (didactic classes in risk, body mechanics, and training in lifting techniques) have not been effective in sustaining changes over time. Newer approaches to education and training have emerged, demonstrating early success with a need to study these trends over time. One new model that shows promise is use of local peer leaders. A peer leader is a nurse designated on each unit (or shift) who receives special training to work on site with colleagues to make practice changes to improve safety. Their roles include ongoing hazard evaluation of the work environment, assure competency in use of patient handling equipment and devices, help sustain the unit-based ergonomic program over time.[109, 126] In the United States, peer safety leaders have been called Back Injury Resource Nurses (BIRNs),[109] and Ergo Rangers,[84] while in the Netherlands they are called Ergo Coaches.	▪ Selecting the "right" peer leader who is effective in coaching peers to change behaviors ▪ Incentives for peer leaders ▪ Support and timely response by management to issues raised by peer leader
Clinical tools (algorithms and patient assessment tools)	Unfortunately, nurses have become accustomed to using whatever limited lifting aids are available, if they are available, rather than carefully matching equipment to specific patient characteristics. Cognitive aids can assist clinicians to apply research to practice, thereby reducing unnecessary variation in practice. Use of patient assessment protocols and algorithms can provide a standardized way to assess patients and make appropriate decisions about how to safely perform high-risk tasks.[108, 109, 112, 127–129]	▪ Training all staff, across shifts ▪ Training on units with high staff turnover ▪ Need to reinforce training over time ▪ Integrating these clinical tools into routine processes, e.g., patient admission ▪ Timely and effective communication of the assessment and plan to all staff
After-action reviews (AAR)	After-action review is a way for nurses to learn not only from their own mistakes and near misses, but also from the mishaps experienced by their coworkers. It is not unusual for many nurses on a unit to identify a hazard and work around it, only to have another nurse fall prey to this risk in the environment. Immediately after an accident or near miss, staff will meet informally to evaluate what happened and how to prevent its reoccurrence on the unit. In AARs, staff should feel free to share knowledge without fear of embarrassment or recrimination. AAR is compatible with established mechanisms for dealing with errors and near misses such as incident reporting and root-cause analysis.[130, 131]	▪ Time constraints ▪ Support and timely response by management to issues raised by peer leader

Given the complexity of this high-risk, high-volume, high-cost problem, multifaceted programs are more likely to be effective than any single intervention, indicating the need to build a culture/climate of safety into the organization and employ more than one evidence-based approach. A culture of safety in terms of worker injury prevention is defined somewhat differently from patient safety culture, though there is some overlap between the terms. Safety culture is considered to be the product of multiple goal-directed actions to improve safety in an organization.[132] Nonetheless, empirical data supporting the impact of culture alone on reducing worker injuries are limited.

Needlesticks

Health care workers continue to be exposed to the serious and sometimes life-threatening risk of blood-borne infections in a wide variety of occupations and health care settings. An estimated 600,000 to 800,000 needlestick injuries occur annually,[133, 134] about half of which go unreported.[133, 135] It is estimated that each year more than 1,000 health care workers will contract a serious infection, such as hepatitis B or C virus or HIV, from a needlestick injury. An estimated 50 to 247 health care workers are infected with hepatitis C virus (HCV) each year from work-related needlesticks.[136] At an average hospital, workers incur approximately 30 needlestick injuries per 100 beds per year.[133] Nursing staff incur most needlesticks—54 percent of reported needlestick and sharp object injuries involve nurses.[137]

After a needlestick injury, the risk of developing occupationally acquired hepatitis B virus (HBV) infection for the nonimmune health care worker ranges from 6 percent to 30 percent, depending on the hepatitis B antigen status of the source patient. The risk of transmission from a positive source for hepatitis C is between 0.4 percent and 1.8 percent, and the average risk of transmission of HIV is 0.3 percent.[138] Risk of transmission increases if one is injured by a device visibly contaminated with blood, if the device is used to puncture the vascular system, or if the stick causes a deep injury. Health care workers, laundry workers, and housekeeping workers are often engaged in duties that expose them to high-risk needlestick injuries.

The number of occupationally acquired HIV infections is underestimated by the national case surveillance system. This is related to the Centers for Disease Control and Prevention's (CDC's) strict definition of a documented HIV seroconversion temporally associated with an occupational HIV exposure and the fact that these are voluntary reports. CDC U.S. surveillance data over 20 years include 57 health care workers with documented occupationally acquired HIV infection.[139] A total of 88 percent of these infections resulted from percutaneous injuries. Of these infections, 41 percent occurred after the procedure, 35 percent during a procedure, and 20 percent during disposal.[139] Recent State-based surveillance programs in California and Massachusetts will provide more complete estimates of the incidents, devices involved, and circumstances surrounding sharp exposures.[140]

Despite the promulgation of the original bloodborne pathogen (BBP) standard in 1991 by the Occupational Safety and Health Administration (OSHA), percutaneous injuries continue to occur in unacceptably high numbers in health care workers. The requirement under the BBP standard that HBV vaccine be made available free of charge to health care workers has greatly reduced the consequences of exposure to this pathogen. Advances in the treatment of HIV infection with prophylaxis has improved the prognosis for those health care workers infected with HIV-contaminated blood. Tragically, there is no vaccine or treatment for HCV, so nurses and other health care workers exposed to HCV-contaminated blood suffer from the potential of contracting a life-threatening illness. As such, it is imperative that all health care workers, not only those working in the acute care setting or those who traditionally handle needles on a regular basis, receive every available protection from occupational exposure to blood and body fluids.

The passage of the Federal Needlestick Safety and Prevention Act in 2000 has begun to afford health care workers better protection from this unnecessary and deadly hazard. Not only does the act amend the 1991 BBP standard to require that safer needles be made available, it also requires employers to solicit the input of front-line health care workers when making safe needle purchasing decisions.

Use of conventional needles in health care today has been compared with the use of unguarded machinery decades ago in the industrial workplace. Safer needle devices have integrated safety features designed into the product to prevent needlestick injuries. The term "safer needle device" is broad and includes many different devices, from those with a protective shield over the needle to those that are completely needle-free. Safer devices are categorized from passive to active, with passive devices offering the greatest protection because the safety feature is automatically triggered after use, without the need for health care workers to take any additional steps. An example of a passive device is a spring-loaded retractable syringe or self-blunting blood collection device. An example of an active safety mechanism is a sheathing needle that requires the worker to manually engage the safety sheath, frequently using their second hand and potentially resulting in more injuries.

A comparison of 1993 and 2001 percutaneous injury rates for nurses documented a 51 percent reduction in needlestick injuries, supporting the use of new technology in reducing percutaneous injury risk.[141] More recently, results from a number of intervention studies have found the use of safer needles systems reduced injury.[142–146] A study of safety needles at a tertiary-care hospital in Manhattan found a statistically significant reduction in the mean annual incidence of percutaneous injuries from 34.08 to14.25 per 1,000 FTE pre- versus postintervention. The reductions were observed across occupations, activities, times of injury, and devices.[146] Other factors related to working conditions also may need to be addressed to prevent and reduce needlesticks.[31]

While there has been widespread conversion to safer phlebotomy needles and intravenous catheters, for other devices such as laboratory equipment and surgical instruments, relatively small numbers of safer devices are in use.

Chemical Occupational Exposures

There are thousands of chemicals and other toxic substances to which nurses are exposed in practice. Hazardous chemical exposures can occur in a variety of forms—including aerosols, gases, and skin contaminants—from medications used in practice. Exposures can occur on an acute basis, up to chronic long-term exposures, depending upon practice sites and compounds administered; primary exposure routes are pulmonary and dermal.[147] Substances commonly used in the health care setting can cause asthma or trigger asthma attacks, according to a recent report.[148] The report explores the scientific evidence linking 11 substances to asthma, including cleaners and disinfectants, sterilants, latex, pesticides, volatile organic compounds (including formaldehyde), and pharmaceuticals. An important criterion for the selection of the substances in the report was the presence of safer alternative products or processes. The evidence is derived from an array of peer-reviewed sources of scientific information, such as the National Academy of Science Institute of Medicine. In this section, we will discuss some of the hazardous substances currently in use and provide references to obtain evidence on others, as well as for identifying safer alternatives.

Volatile organic compounds. Volatile organic compounds (VOCs) are chemicals that readily evaporate at room temperature, thus allowing the chemicals to be easily inhaled. Formaldehyde and artificial fragrances are two such sources that have a ubiquitous presence in hospitals. A study of occupational exposure to artificial fragrances found that health care workers had the highest rate of allergic sensitivity.[149] The fragrances are typically contained in devices that either aerosolize the chemicals into rooms or evaporate the fragrances from a solid form,

thus producing VOCs. Although the Food and Drug Administration is responsible for regulating fragrances and other chemicals in personal care products, the majority of these compounds have not been tested for potential toxic human health effects.[150] Strong odors, fumes, and perfumes are also potent triggers of asthma.[151] Formaldehyde, a known carcinogen,[152] is used in pathology and lab settings and is contained in bedding, drapes, carpets, acoustic ceiling tiles, and fabricated furniture. Artificial fragrances are used to address unpleasant odors. Purchasing low- and no-VOC products, which are readily available (e.g., no-VOC paint), is a key to addressing this problem. Also ensuring adequate indoor air circulation, which can decrease the concentration of VOCs in the air, effectively decreases the "dose" of the chemicals being inhaled.

Sterilants. As an example, ethylene oxide (EtO) and glutaraldehyde are commonly used in medical settings for sterilization. Nurses and other medical staff are exposed while cleaning equipment and work surfaces. Although both of these chemicals are powerful and effective, they are associated with serious human health risks. Glutaraldehyde is associated with respiratory irritation including asthma, skin irritation and dermatitis, and eye irritation and conjunctivitis.[153] In fact, in a review of health effects of glutaraldehyde exposure, almost all case reports of occupational asthma were of endoscopy nurses.[154]

The National Institute for Environmental Health Sciences[152] produces a report on carcinogens that summarizes the latest scientific evidence on the cancer-causing properties of many chemicals, including EtO,[155] formaldehyde, and others that are present in health care. In this report, EtO is also listed as a known human carcinogen. EtO has been associated with increased incidence of certain types of cancer in workers with long-term exposures.[156] Additionally, EtO is an eye and skin irritant and also may damage the central nervous system, liver, and kidneys.[157]

Medications. Many medications and compounds in use in personal care products have known toxic effects. These have been comprehensively reviewed with a detailed summary of the evidence of environmental and personal hazards associated with these compounds by Daughton and Ternes.[149] Although many medications can be hazardous to workers, those most commonly identified as hazardous to health care workers include antineoplastics and anesthesia. Anesthetic gases have been identified as particularly problematic, as gases escape into the air and can be inhaled by workers. Methods of induction have been studied in terms of worker exposure,[158] with findings indicating that such exposures (measured by urinary metabolites) frequently exceed National Institute for Occupational Safety and Health (NIOSH) recommended limits.[159] Hasei and colleagues[160] found that intravenous induction posed a far lower risk of exposure to health care workers.

There are also data to support the deleterious effects of exposure to antineoplastic drugs, especially an increased risk of spontaneous abortions among health care workers.[161] Cytotoxicity, genotoxicity, terotogenicity, and carcinogenicity are associated with such exposures.[152] For the past few decades, awareness of the risk of antineoplastic agents has been available, including guidelines for handling them published by the Occupational Safety and Health Administration.[162] Nursing functions of particular risk, according to NIOSH, include medication administration, handling contaminated linens, exposure to human wastes, handling drug containers, cleaning drug preparation areas, being involved with special procedures, and disposal of containers and other wastes.[163] Other research indicates that antineoplastics and cytostatics have been found in locations beyond the confines of the designated handling areas such as air vents, desks, countertops, and floors.[164, 165]

Pesticides. Pesticide use, both inside and outside of hospitals and health facilities, is another cause for concern. Because of the special vulnerabilities of children and pregnant women to pesticide exposures, control of pesticide use in health care settings is particularly important. In a survey conducted by Health Care Without Harm, all hospitals surveyed reported some regular applications of pesticides inside the hospital building, outside on the grounds, or both.[166] This report, *Healthy Hospitals: Controlling Pests Without Harmful Pesticides,* offers guidance on reducing pesticides and implementing safer integrated pest management techniques. Integrated pest management is a comprehensive approach to pest management that employs nontoxic and least-toxic products and processes to control pests. Beyond Pesticides, a 25-year-old organization that has been working with Health Care Without Harm on pesticide issues in the United States, is currently orchestrating several hospital-based pilot programs in Maryland.[167] They are working with hospital environmental services to implement an integrated pest management approach that will work for hospitals. These collaborations will result in a set of best practices for a range of facility types—small community hospitals, inner-city university health centers, and others.

Latex exposure. Latex allergy due to exposure to natural proteins in rubber latex is also a serious problem in health care workers. Diepgen[168] estimated that the annual incidence rate among all workers is 0.5 to 1.9 cases per 1,000 full-time workers per year. Symptoms may start with contact dermatitis located in the glove area, and symptoms can become more severe, such as asthma or anaphylaxis. The course of latex allergy as described by Amr and Bollinger[169] involves progressive impairment of nurses from continued exposure to latex, leading to an inability to continue working as nurses. In fact, the hazard from aerosolizing of latex particles attached to powder in latex gloves or from latex balloons bursting is of great concern, as these exposures can lead to occupational asthma.[170] The American Nurses Association has issued a position statement to suggest actions to protect patients and nurses from latex allergy in all health care settings. These include use of low-allergen powder-free gloves and removal of latex-containing products from the worksite throughout the facility to reduce the exposure at that institution.[171] Hospital environments that have gone latex-free need to ensure that they are not allowing balloons into the facility. As balloons break they can contribute latex into the air that remains for up to 5 hours.[172]

Summary of Key Issues Regarding Harmful Exposures

An awareness of the repercussions of exposure to chemicals and toxins has prompted action to reduce such exposures in health care settings. Promotion of the availability of safer alternatives has gained momentum as a means to reduce exposures. There are resources available to assist advocates and decisionmakers. The *Green Guide for Health Care* is an extensive toolkit providing recommendations for design, construction, renovation, operations, and management of sustainable (causing reduced occupational and environmental effects) and healthier buildings.[173] Also, a clearinghouse of nontoxic alternatives to various medical and health care products is available from the Sustainable Hospitals Project.[174] *Green Link,* a recently inaugurated newsletter, promotes healthier buildings and sustainable hospitals for patients and health care workers.[175] In addition, the American Hospital Association and the Environmental Protection Agency have partnered, forming Hospitals for a Healthy Environment, promoting purchasing of environmentally preferable products.[176] The focus on reducing chemical exposures will be increasingly important over the next decade, especially as the benefits for patient and worker health continue to be recognized.

Mental Health Effects of Nursing Work

Working in nursing increases the risk of experiencing both minor and major psychiatric morbidity[177, 178] with job strain contributing to this outcome.[179–183] Minor psychiatric morbidities include feelings of tension, anger, anxiety, depressed mood, mental fatigue, and sleep disturbance;[184] these are classified variously as burnout, subthreshold depression, or adjustment disorders. Mental disorders such as major depression, anxiety disorders, and psychotic disorders are less common, but they can be induced or exacerbated by work stress.[184] A variety of exposure types are associated with psychiatric morbidity. These fall into two categories: the overall allostatic load demanded by the work, and the organization of the work, including schedule and such job demands as the emotional toll when caring for patients.

Allostatic load is a theoretical concept whereby excessive demands and a persistent sympathetic (adrenergic) load on the body produce changes in neuronal, immune, and cardiovascular system structure and function, thus having a detrimental impact on bodily processes.[183, 185–188] Changes in neuronal function are associated with anxiety and depression.[185] Several types of psychosocial risk factors can contribute to this overall allostatic burden. High physical demands, fast-paced work, adverse work schedules, role stressors, career insecurity, difficult interpersonal relationships, nonstimulating jobs, and lack of autonomy have been associated with symptoms of anxiety and depression, several psychoses, and with substance use disorders.[183, 189, 190] Some studies have even provided longitudinal evidence linking job demands, lack of autonomy, and monotony at work to affective and substance use disorders.[183, 191, 193] Mental disorders in the workplace—depression in particular—have important consequences for quality of life, the costs and utilization of health care, safety, and productivity.[190, 194]

Extended work schedules have been associated with a variety of mental health indicators in nursing and in other occupations where these schedules are common. Proctor and colleagues[195] found that both the number of overtime hours and the number of cumulative days worked by automotive workers were associated with changes in mood States such as depression and tension. Hospital interns reported subjective deterioration in mood after long shifts.[196] Japanese managers reported decreased quality of life (validated by comparison to a measure of psychiatric distress) when working more than 10 hours per day consistently.[197] French customs workers used antidepressants at a higher rate when assigned to shift schedules with rapid rotation.[198] Shift work has been associated with more mental stress[199] and higher levels of burnout[200] among health care workers. Depression and anxiety have also been shown to vary with the level of work pace, variety, control, social support, and conflicting demands made on workers.[191, 201] Thus with both unfavorable work conditions and extended work hours, the effect on mental health may be multiplied. Fatigue is thought to be a central nervous system stressor.[195]

Nursing is emotionally demanding, with both emotional labor and the need to witness and bear with suffering taking its toll. Emotional labor is necessary to display socially appropriate emotions that are congruent with the job requirements in face-to-face interactions with patients. The more frequent and intense the interpersonal interactions are with others (staff, visitors, patients), requiring the nurse to expend emotional effort, the more likely the nurse will experience symptoms of burnout, including depersonalization and emotional exhaustion.[202, 203] Witnessing the suffering of others occurs in a variety of nursing care settings, but is common when end-of-life suffering is unrelieved.[205] Intense feelings of emotional pain can result and, if unresolved, can affect both physical health and family life.[204, 205]

Interventions to reduce work-related mental changes have focused on either changing the organization of work to reduce the stressors, or changing the workers' ability to cope with stress by providing cognitive-behavioral interventions, relaxation techniques of various types, or multimodal strategies.[184, 206] Although several nationwide initiatives on the prevention of mental disorders have emphasized the importance of addressing work organization factors,[190, 194] only a small number of studies have evaluated this approach, and results have not shown an overall strong relationship.[185] In nursing, Mimura and Griffiths[206] conducted a systematic review of interventions for nurses to reduce their work stress. Two of the reviewed studies used organizational interventions (changing to individualized nursing care and primary nursing), and only one of the two was deemed "potentially effective." Seven studies of strategies to help nurses manage their stress were presented; music, relaxation, exercise, humor, role-playing assertiveness, social support education, and cognitive techniques were among the stress-reducing strategies studied. The authors stated that no recommendations on the most effective approach were possible due to the small number of studies. In a larger meta-analysis of both nurses and other workers,[183] a moderate effect for cognitive-behavioral interventions and multimodal interventions was found, along with a small but significant overall effect for relaxation techniques. Organizational interventions were not significant; however, the authors posit that combining individual-level skills (e.g., cognitive-behavioral) with organizational changes may be a fruitful area for future research.

Violence

From 1993 to1999, 1.7 million incidents of workplace violence occurred annually in the United States, with 12 percent of all victims reporting physical injuries.[207] Six percent of the workplace crimes resulted in injury that required medical treatment. Yet, only about half (46 percent) of all incidents were reported to the police. The health care sector leads all other industries, with 45 percent of all nonfatal assaults against workers resulting in lost workdays in the United States, according to the U.S. Bureau of Labor Statistics (BLS).[208] The BLS rate of nonfatal assaults to workers in "nursing and personal care facilities" was 31.1 per 10,000, vs. only 2.8 per 10,000 in the private sector as a whole.[208] In two Washington State psychiatric forensic facilities, 73 percent of staff surveyed had reported at least a minor injury related to an assault by a patient during the previous year; only 43 percent of those reporting moderate, severe, or disabling injuries related to such assaults had filed for WC. In these two facilities, the survey found an assault incidence rate of 415 per 100 employees per year, compared to hospital incident report rates of only 35 per 100.[219]

Environmental and organizational factors have been associated with patient and family assaults on health care workers, including understaffing (especially during times of increased activity such as meal times), poor workplace security, unrestricted movement by the public around the facility, and transporting patients. The presence of security personnel reduces the rate of assaults, while increased risk is associated with the perception that administrators consider assaults to be part of the job, receiving assault prevention training, a high patient/personnel ratio, working primarily with mental health patients, and working with patients who have long hospital stays.

Emergency department personnel also face a significant risk of injuries from assaults by patients or their families. Those carrying weapons in emergency departments create the opportunity for severe or fatal injuries. California and Washington State have enacted standards

requiring safeguards for emergency department workers. Although mental health and emergency departments have been the focus of attention and research on the subject, no department within a health care setting is immune from workplace violence. Consequently, violence prevention programs would be useful for all departments.

The first report to the Nation on workplace violence underscores the lack of systematic national data collection on workplace assaults, the paucity of data evaluating violence prevention strategies, and the methodological flaws in published intervention research to date.[210] As background to this report, Runyan and colleagues[211] reviewed the violence prevention intervention literature and found five studies that evaluated violence prevention training interventions,[212–216] two that examined postincident psychological debriefing programs,[217, 218] and two that evaluated administrative controls to prevent violence.[220-221] Findings from the studies were mixed, with six reporting a positive impact and three reporting no or a negative impact. All were quasi-experimental and without a formal control group. Runyan and colleagues criticized the design of published violence prevention interventions to date because of their lack of systematic rigor in the evaluation. She calls for greater reliance on conceptual and theoretical models to guide research as well as stronger evaluation designs. She further suggests that studies must evaluate "process, impact and outcome measures."[211]

Since Runyan's review paper, Arnetz and Arnetz[219] reported on a randomized controlled trial of 47 health care workplaces examining a violence prevention intervention involving "continuous registration" of violent events for 1 year with "structured feedback" from supervisors. This study found that the intervention hospitals reported significantly more violence incidents than the control hospitals. The authors attributed this finding to increased awareness of the violence and improved supervisory support at the intervention facilities.

There is no Federal standard that requires workplace violence protections. California and Washington State both have legislation addressing workplace violence in health care settings. In 1996, OSHA published *Guidelines for Preventing Workplace Violence for Health Care and Social Service Workers*.[222] The 1996 Federal guidelines provide a framework for addressing the problem of workplace violence and include the basic elements of any proactive health and safety program: management commitment and employee involvement, worksite analysis, hazard prevention and control, and training and education. The OSHA guidelines provide an outline for developing a violence prevention program, but since they are "performance based," the challenge of developing a specific process for implementing the guidelines in a manner that will yield results is left to the employer.

Between 2000 and 2004, Lipscomb and colleagues[223] conducted an intervention effectiveness study to describe a comprehensive process for implementing the OSHA Violence Prevention Guidelines and evaluate its impact in the mental health setting. Program impact was evaluated by a combination of quantitative and qualitative assessments. A comparison of pre- and postintervention survey data indicated an improvement in staff perception of the quality of the facility's violence prevention program as defined by the OSHA elements in both intervention and comparison facilities over the course of the project. Results of the comparison of the change in staff-reported physical assaults were equivocal.

Many psychiatric settings now require that all patient care providers receive annual training in the management of aggressive patients, but few studies have examined the effectiveness of such training. Those investigators that have done so have generally found improvement in nurses' knowledge, confidence, and safety after taking an aggressive behavior management program. However, implementation of comprehensive violence prevention programs that go

beyond staff training will improve safety of the health care workplace for all workers. These advanced programs include the use of currently available engineering and administrative controls such as security alarm systems, adequate staffing, and training.

Research Implications

Challenges in Measuring Nursing Working Conditions and Nurse Safety Outcomes

While there is increasing evidence linking nursing work environments to nurse health, much more effort has focused on understanding how work influences satisfaction and performance. Improving data and measures will allow better comparisons across studies and build evidence of which relationships are most important. Varied approaches are used to compile data about the nursing work environment. Measures of work characteristics have varied considerably and are most often related to the particular discipline and study objectives. In occupational health, the traditional assessments of exposure have expanded from obvious physical and chemical exposures to include psychosocial demands, physical demands, and leadership quality.[224] These measures are used in individual studies or translated to a job exposure matrix where estimated levels of exposure to an agent or stressor are assigned to an occupation or group of occupations.[225, 226] These approaches are more fully developed and utilized in Scandinavia and Europe, although the O*NET database describes job requirements, worker attributes, and the context of work (www.onetcenter.org).

A self-administered paper-and-pencil or electronic questionnaire is probably the most common approach to gathering information from nurses. The advantages over observation or interviews are obvious: they are generally less costly, can be administered over a broader population, are more uniform and standardized, and confidentiality and anonymity can be more efficiently assured. Yet, these same advantages can also be disadvantages: nurses have varying motivations to respond, leading to response bias; questionnaires are often developed by researchers based on particular study goals, limiting comparison across studies; and there is no opportunity to clarify questions or solicit rich detail. The level of the data may also be unclear. Some items may explicitly reflect the work group or organization, while others may reflect both. Clarity is needed about how many respondents is optimum to represent a particular level of analysis. Where multiple nurses' perceptions are solicited, all responses may be used to form an index or an average score.

Nurse Health Outcomes

Worker outcome data may be solicited from an individual through self-report interviews or questionnaires. These data are subject to the same limitations noted above, although nurse reports are more likely to yield detailed information about potential factors contributing to their health. Measuring nurse health outcomes also is challenging. No matter how data are collected, there can be some measurement error in assessing adverse health outcomes—and attributing them to the work environment. Many of these issues have been discussed in the sections on adverse health outcomes. For example, musculoskeletal injuries become chronic conditions and may not be attributed to the work. Likewise, mental health and substance abuse may be considered in isolation from the individual's work experience.

Another source that is rarely used is administrative data (e.g., incident reports, OSHA logs, WC data).[227] The Occupational Safety and Health Act (1970) requires employers to maintain records of serious workplace injuries and illnesses (29 USC section 657 c[2]). Unfortunately, these statistics may not reflect minor injuries requiring only first aid or injuries that can be episodic and remitting, such as back injuries, majors concerns for nurses. Data sources include logs maintained at the organizational level (OSHA Form 300), first reports of injury (FROI) documenting details of the injury (OSHA Form 301), and WC claims, when filed. The FROI may be used as the baseline data for entry into a WC system, although the two reports may be distinct. The FROIs serve as a more complete source of potentially claimable injuries to health care workers than WC data[228] as they represent all reported injuries, even those that do not lead to lost work time or a medical claim. Relying on WC claims data without using FROI data may introduce systematic selection biases because studies have shown that WC claims are more likely to be filed by workers who are unionized, working for a company too small to be self-insured, or who are more severely injured.[229] FROI data have been used to study injury in a population of home health workers[230] and to find that staffing was related to injuries in nursing home staff.[57] Yet FROI data are often unavailable to researchers or may contain injuries of limited severity.

Somewhat distinct from the OSHA reporting requirements, employers are required to comply with State WC regulations. WC is concerned with compensating injured or ill workers, while the OSHA Occupational Injury and Illness Recording and Reporting Requirements Act is designed to develop a database that can improve understanding of injury and illness, with the intent to prevent them. Thus, certain injuries and illnesses may be reportable under both systems, while others will be reportable under State WC law or under the OSHA recordkeeping rule. State WC benefit requirements also vary, with some States not requiring lost time, but requiring that the employee sought medical care. Other States require a certain number of days of lost time before filing a FROI. Unfortunately, ascertainment of nursing health outcomes varies across these data. Even when analyzing WC claims or FROI data with presumably broader inclusion, some injuries will be missed. For example, injured workers may seek care from their regular health provider and fail to mention the work-relatedness of the injury. In a cross-sectional study of unionized autoworkers diagnosed with work-related MSDs, only 25 percent filed WC claims.[231] In a population-based telephone survey, only 10.6 percent of workers reporting work-related MSDs had filed a WC claim.[232]

The need for standardization in data collection and measuring both work environment and worker outcomes is not new. As noted by NIOSH,[233] insufficient job data to link work factors to health outcomes is a barrier to research. An international conference on linked employer-employee data was held in 1998 to address issues of confidentiality, levels of analysis, and the need for coordination across Federal and State agencies.[234] The work in Europe and Scandinavia builds upon international work and could become a model across many countries. Unfortunately, data policy changes at the Federal and local levels are often slow to occur, as modifications to existing systems require long and arduous lobbying, legislation, and procedure and policy development before implementation. Moreover, the WC regulations are primarily State driven, and this is unlikely to change.

Researchers are encouraged to use established instruments and items, with established reliability and validity. If they are developing their own instruments, psychometric testing is essential. Findings benchmarked with other similar populations are useful to determine variation and explore sources of measurement error. When assessing work environments, the level of

analysis for the measure must be explicit (e.g., work group, organization, or system). Analytical strategies should be used to account for the multilevel nature of the data.

Administrative data for worker injuries can be very useful. Many health care organizations are implementing programs that are likely to affect both patient and worker safety, yet it may be difficult to efficiently evaluate the effectiveness of these programs. Ohio, for example, has used the claims data to support issuance and evaluation of safety grants used in lifting and other mechanical equipment purchases to reduce employee injuries.[235]

Conclusion

In this chapter, we have focused on the major injury and safety issues for working nurses. Some of these issues have been thoroughly researched, with extensive evidence-based findings available for epidemiology and prevention, whereas others remain to be studied and explained. As indicated, there is great potential for preventing nurse injury, even though many risk factors have yet to be addressed. The benefits of improvements to nurse safety are great, both for retaining nurses and attracting new nurses into the profession. For example, work hours that are excessive adversely affect nurses' health and thus can in turn adversely impact patient care. As many facilities are making important financial investments and system-level improvements to promote patient safety, it is important to leverage these efforts to improve worker safety as well. In the long run, these improvements will also benefit patients, as measures that are taken to improve safety for nurses should lead to a healthier and more effective workforce.

Search Strategy

Relevant papers for this review were identified from Pubmed,® CINHAL,® as well as from cited literature, and from NIOSH publications up through 2007. Searches were also performed examining journals such as the *American Journal of Industrial Medicine, American Journal of Public Health,* and *Scandinavian Journal of Work and Environmental Health.* As our chapter encompassed multiple outcomes, search terms varied depending on the category, and included but were not limited to, e.g., occupational health, organization of work, shiftwork, back injuries, musculoskeletal disorders, chemical exposures, mental health, work stress, and workplace violence.

The

Evidence Table

Author, year	Safety issue	Design type	Outcome measure	Setting population	Intervention	Findings reported by authors
Shift work and long work hours						
Caldwell 2005[36]	Shift work, long work hours	Review	Fatigue		Medications	Provides a short overview of hypnotics such as temazepam, zolpidem, or zaleplon and alertness-enhancing compounds such as caffeine, modafinil, or dextroamphetaminethese compounds as well as factors to be considered before choosing one or more to help manage fatigue.
Caruso 2004[28]	Long work hours	Review	Health disorders, safety, health behaviors			In 16 of 22 studies, overtime was associated with poorer perceived general health, increased injury rates, more illnesses, or increased mortality. One meta-analysis of long work hours suggested a possible weak relationship with preterm birth. Overtime was associated with unhealthy weight gain in two studies, increased alcohol use in two of three studies, increased smoking in one of two studies, and poorer neuropsychological test performance in one study.
Costa 2003[26]	Shift work	Review	Health disorders			Organization of shift schedules according to ergonomic criteria and on specific medical surveillance are required to mitigate the adverse effects and ensure that the worker can cope satisfactorily. Consider very carefully psycho-physiological, pathological, and social factors that can influence tolerance and/or maladaptation.
Folkard 2005[13]	Shift work, long shifts	Review	Safety			Three main trends in risk are discussed: (i) risk is higher on the night shift, and to a lesser extent the afternoon shift, than on the morning shift; (ii) risk increases over a span of shifts, especially so if they are night shifts; and (iii) risk increases with increasing shift length over 8 hours.

Author, year	Safety issue	Design type	Outcome measure	Setting population	Intervention	Findings reported by authors
Knauth 2003[34]	Shift work	Review	Health, safety		Prevention, compensatory measures	Discusses measures that can be taken to optimize the well-being of shift workers and to identify ill-health at an early stage: the design of shift systems, taking account of variation in the views and circumstances of employees, and strategies to combat sleepiness at work and elsewhere.
Knutsson 2003[18]	Shift work	Review	Health disorders			The strongest evidence exists for an association of shift work with peptic ulcer disease, coronary heart disease, and compromised pregnancy outcome.
Megdal 2005[24]	Night work	Meta-analysis	Breast cancer	13 studies		Studies on night shift work and breast cancer risk collectively show a modest increased breast cancer risk among women (aggregate estimate 1.48, 95% CI = 1.36–1.61).
Revell 2005[35]	Shift work, long work hours	Review	Circadian adaptation		Light treatment	Reviews studies in which bright light and melatonin were administered to try to counteract jet lag or to produce circadian adaptation to night work. Demonstrates how jet lag could be prevented entirely if rhythms are shifted before the flight using their preflight plan and discusses the combination of interventions that they now recommend for night shift workers.
MSD epidemiology						
Ariens 2002[44]	Work-related neck musculoskeletal problems	Longitudinal cohort study	Frequency of sickness absence due to neck pain x3 days or more	758 workers		Found “work-related neck flexion, neck rotation, low decision authority, and medium discretion over work activities” as measured by the Job Content Questionnaire to be significant risk factors for absence from work due to neck pain.

Author, year	Safety issue	Design type	Outcome measure	Setting population	Intervention	Findings reported by authors
Fredriksson 2002[236]	Work environment	Population-based case control study	Persons seeking health care for neck or shoulder pain	17,000 men and women ages 20–59, living in Norrtalje district, central Sweden		There were associations between seeking care and the physical and psychosocial factors in the work environment. In women, "long term perceived high workload, long term exposure to frequent hand or finger work, and frequent bending and twisting and hindrance at work was associated with seeking care for neck or shoulder pain," whereas, in men long-term exposure to vibrating tools was found. For women, high perceived workload and hindrance (risk of injury, risk to work quality or of extra work) combined to increase risk of seeking care.
Maul 2003[237]	Course of work-related low-back pain over up to 8 years of followup	Longitudinal study	Low-back pain occurring in the past 12 months. 1–7 days = mild 8+ days = mod/severe pain	Nurses working at a university hospital in Switzerland		The prevalence of low-back pain was 73–76% over the 8-year period. Over the 8-year period, about half reported the same number of days of back pain at followup, with about half of those remaining experiencing more days of back pain, and rest fewer days with back pain.
Bernard 1997[48]	Work activities related to musculoskeletal problems	An extensive review of over 600 epidemiologic studies	Neck, shoulder, upper extremity (wrist, arm, hand) and back MSDs	Variety of occupations		Summarized evidence for work relatedness of MSD. Findings include strong causal evidence for awkward and static work postures related to back MSD and posture related to neck MSD. Tendinitis, hand, elbow/wrist MSD strongly related to repetition, force, and posture combined. There is evidence for a causal relationship between highly repetitive work and neck and neck/shoulder MSDs, and for forceful exertion and repetition in relation to shoulder MSD.

Author, year	Safety issue	Design type	Outcome measure	Setting population	Intervention	Findings reported by authors
Punnett and Wegman 2004 [238]	Work-related MSDs	Review of studies with 94 article citations	MSDs	Variety of occupations		Despite numerous studies on the relationship between MSD and occupation, there continues to be debate. From a review of the epidemiologic literature, the authors, along with the Institute of Medicine and others internationally, conclude there are adequate data to support the impact of physical work demands on MSD. Risk factors for MSD with sufficient evidentiary support include repetitive motion, forceful exertions, nonneutral postures, and vibration. Nursing is noted as one of the "high-risk sectors" for MSDs "with rates up to 3–4 times higher than the overall frequency."
Rogers 2005[239]	Work-related injuries	Literature review Best practices Focus groups with hospital nurses Observation of hospital ergonomic hazards	Nurse MSD	Hospital nurses in North Carolina		Evidence on MSD epidemiology and prevention summarized, along with best practices for addressing many ergonomic hazards that lead to nurse MSD. Preventive interventions proposed and recommendations provided.
Trinkoff 2006[30]	Work schedule including work hours, mandatory overtime and on-call	Three-wave longitudinal study	Reported neck, shoulder, and back MSD cases Nordic questionnaire	2,617 registered nurses working in nursing in the past year		Hours/days per week were significantly related to increased MSD; working 13+ hours/day, on days off/vacation days, mandatory overtime, on-call, with <10 hrs between shifts all significantly related to increased MSD. This was largely due to exposure to physical demands of the work.
Needlesticks and sharps						
Dement 2004[240]	Sharps exposure	Surveillance	Blood and body fluids	24,000 health care workers employed in a university-based tertiary care hospital		2,730 BBF exposures between 1998 and 2002, resulting in an overall annual rate of 5.5 events/100 FTEs and a rate of 3.9 for percutaneous exposures. Much higher rates were observed for house staff, nurse anesthetists, inpatient nurses, phlebotomists, and surgical/operating room technicians. Rates of percutaneous exposures from hollow needles were found to decrease over the study period; however, exposure rates from suture needles appear to be increasing.

Author, year	Safety issue	Design type	Outcome measure	Setting population	Intervention	Findings reported by authors
Sohn 2004[145, 146]	Sharps exposure	Research report	Percutaneous injuries	New York City tertiary care hospital	Safer needle system composed of various safety-engineered devices	A statistically significant reduction in the mean annual number of percutaneous injuries from 34.08 to 14.25 per 1,000 FTE pre- verses postintervention.
Trinkoff 2007[31]	Needlestick injuries and consequences, sharps exposure by positions specialty and work setting, work schedule	Three-wave longitudinal study	Reported prevalent (past year) and incident needlesticks (measured longitudinally)	2,273 registered nurses working in nursing in the past year		Specialties with highest percentage of past year needlesticks: emergency, critical care, OR, and cath lab/diagnostics (≥ 21%). Working increased hours/day, weekends/month, and nonday shifts significantly increased the risk of needlesticks.
Vaughn 2004[241]	Sharps exposure	Research report	Adherence to safe needle precautions	Non-Federal general hospitals in Iowa		Survey of infection control professionals and health care workers found that positive predictors of consistent adherence included infection control hours/FTE (OR = 1.03), frequency of standard precaution education (OR = 1.11), providing personal protective equipment (OR = 1.82), use of needleless IV systems (OR = 1.42), and management support for safety (OR = 1.05).
Mental health						
Van der Klink 2001[184]	Stress-related psychological problems; intervention studies		Outcomes include quality of worklife, psychologic resources, physiologic responses, complaints, absenteeism	48 experimental studies	Cognitive-behavioral interventions, multimodal interventions, relaxation techniques, organization-focused interventions	Moderate effect for cognitive-behavioral and multimodal interventions. Small effect for relaxation techniques. No significant effect for organization-focused intervention.

Author, year	Safety issue	Design type	Outcome measure	Setting population	Intervention	Findings reported by authors
Violence						
Duhart 2001[207]	Violence	Survey report	Workplace violent crime	National survey		Department of Justice, National Crime Victimization Survey, a population-based survey assessing the incidents of criminal acts of workplace violence, reported 1.7 million incidents per year. Rates are reported by occupation, demographic variables, as well as the relationship of victim to perpetrator.
Gerberich 2004[242]	Violence in health care	Nested case-control study	Assault	MN RNs		Incidence of physical assault was 13.2 per 100 persons per year. Among 310 cases and 946 control subjects, odds ratios for assault were increased in nursing homes or long-term care facilities (2.6; 95% confidence interval [CI] = 1.9–3.6), emergency departments (4.2; 95% CI = 1.3–12.8), and psychiatric departments (2.0; 95% CI = 1.1–3.7); in environments not "bright as daylight" (2.2; 95% CI = 1.6–2.8); and for each additional hour of shift duration (1.05; 95% CI = 0.99–1.11). Risks were decreased when carrying cellular telephones or personal alarms (0.3; 95% CI = 0.2–0.7).
Runyan, 2000 [211]	Violence	Review	Workplace assault			Literature search and review of workplace violence intervention studies yielded 137 articles including the term intervention, while only 9 studies involving the evaluation of interventions. Results of intervention studies were equivocal. Research employing rigorous methods studying interventions to prevent workplace violence are needed
Chemical exposures						
Buckley 2002[149]	Fragrance exposures	Physiological assessment	Allergic reactions	Multiple occupations		Health care workers had the highest prevalence of allergic sensitivity to fragrances.
Daughton 1999[150]	Exposure to pharmaceuticals and personal care products	Review	Adverse effects			Review of toxic pharmaceuticals and personal care products in the environment. This includes various drugs, disinfectants, fragrances, sun screen, nutritional supplements, etc.

Author, year	Safety issue	Design type	Outcome measure	Setting population	Intervention	Findings reported by authors
Dranitsaris 2005[161]	Cytotoxic drug exposure	Meta-analysis	Adverse health effects Spontaneous abortion, congenital malformations, stillbirths	Health care workers		Risk of spontaneous abortions for workers handling cytotoxic drugs was elevated.
Sattler 2007[243]	Hospital environment	Literature review	Adverse health effects, compromise of the environment	Patients, health care workers, and the community		Review of products used in the hospital setting and their adverse health effects. Explores alternative product selection.
Takigawa 2006[154]	Exposure to glutaraldehyde	Review	Adverse health effects	Multiple occupations		Review of toxicity of glutaraldehyde and workplace exposure. Includes case series for asthma and skin reactions that incorporate many findings from exposed nurses.

Chapter 40. The Effects of Fatigue and Sleepiness on Nurse Performance and Patient Safety

Ann E. Rogers

Background

Although the words “fatigue” and “sleepiness” are often used interchangeably, they are distinct phenomena. Sleepiness refers to a tendency to fall asleep, whereas fatigue refers to an overwhelming sense of tiredness, lack of energy, and a feeling of exhaustion associated with impaired physical and/or cognitive functioning.[1] Sleepiness and fatigue often coexist as a consequence of sleep deprivation.

Even though fatigue can be due to a variety of causes (e.g., illness, a vigorous workout, or a period of prolonged concentration), this chapter will focus on the effects of fatigue associated with insufficient sleep (see Key Terms and Definitions). The impact of extended work shifts and the relationship of these work schedules to nurse and patient safety will also be explored. Several practices that show demonstrable potential for reducing the adverse effects of fatigue on patient safety will be reviewed at the end of the chapter.

Insufficient Sleep

Studies suggest that average sleep durations have decreased from 9 hours in 1910 to as little as 6.9 hours on workdays in 2002.[2–6] Objective measurements, however, suggest that mean sleep times may actually be somewhat lower than are typically reported in surveys. For example, 273 randomly selected middle-aged residents of San Diego (40 to 64 years) reported sleeping approximately 7 hours, an amount that appeared to correspond to their time in bed. Mean sleep times obtained from wrist actigraphy, however, revealed that participants slept on average 6.22 hours, approximately 43 minutes less than their subjective reports.[7]

Sleeping longer on weekends and nonworkdays is also common,[4, 6] suggesting that individuals are obtaining insufficient sleep on workdays, then attempting to “catch up” on weekends. Americans slept on average 36 minutes more on weekends in 2002,[4] which is somewhat longer than the 23 minutes reported by British adults.[6] American nurses who participated in a recent survey, however, obtained on average 84 minutes more sleep on nonworkdays than work days (8.2 hours on nonworkdays compared to 6.8 hours on workdays),[8] which is more than triple the amount reported by British adults and more than double that of other Americans.

Individuals working nights and rotating shifts rarely obtain optimal amounts of sleep. In fact, an early objective study showed that night shift workers obtain 1 to 4 hours less sleep than normal when they were working nights.[9] Sleep loss is cumulative and by the end of the workweek, the sleep debt (sleep loss) may be significant enough to impair decisionmaking, initiative, integration of information, planning and plan execution, and vigilance.[10, 11] The effects of sleep loss are insidious and until severe, are not usually recognized by the sleep-deprived individual.[12, 13]

Finally, it is not uncommon for nurses and other shift workers to acknowledge falling asleep when working nights.[8, 14, 15] Almost one-fifth of the nurses working permanent night shifts reported struggling to stay awake while taking care of a patient at least once during the previous month.[15] Another survey found that the occurrence of falling asleep during the night shift occurred at least once a week among 35.3 percent of the nurses who rotated shifts, 32.4 percent of the nurses who worked nights, and 20.7 percent of the day/evening shift nurses who worked occasional nights.[16] Objective recordings using ambulatory polysomnographic recorders and actigraphy have verified that nurses, air traffic controllers, and even commercial truck drivers regularly fall asleep for brief periods during the night shift.[17–19]

Effects of Insufficient Sleep

Although the exact amount of sleep needed by healthy adults has not been determined, the effects of insufficient sleep have been well documented. A review of the relevant literature over the past 15 years reveals that insufficient sleep (or partial sleep deprivation) has a variety of adverse effects. Despite the wide range of research methodologies (e.g., qualitative studies, surveys and clinical trials, instruments) and settings (e.g., field studies, and time-isolation laboratories, and sample sizes), the results are quite similar: insufficient sleep has been associated with cognitive problems, mood alterations, reduced job performance, reduced motivation, increased safety risks, and physiological changes. Results from laboratory studies of total sleep deprivation (one or more nights without sleep) were not included in this review, since the focus of this section is on insufficient sleep (partial sleep deprivation) and not on total sleep deprivation.

It is important to note that none of the several hundred studies reviewed for this paper showed *any* positive effects from sleep restriction in healthy adults. While it is true that one night of sleep deprivation can temporarily elevate mood in depressed patients,[20, 21] it has adverse effects on mood in healthy individuals of all ages,[22, 23] including nurses.[24] Depression increases,[25, 26] irritability increases,[27, 28] and people report feeling more stressed when sleep is restricted.[24] Extended sleep times, however, are not associated with improved mood or health and may be associated with poor health. Mortality rates were highest among subjects ages 30 to 100 years who slept 8 or more hours, and lowest among those who slept 7 hours sleep,[29] findings that were identical to those obtained a year later from a prospective study of 82,975 registered nurses (Nurses Health Study).[30]

Contrary to what one might expect, partially sleep-deprived older women (55 to 65 years) in one study suffered fewer ill effects when compared to younger women (20 to 30 years),[31] and sleep-deprived older drivers (52 to 63 years) of both genders performed better than sleep-deprived younger drivers (20 to 25 years).[32] An earlier study, however, reported that younger male drivers were more resistant to the adverse effects of sleep deprivation than older male drivers.[33]

Although some people are less impaired by insufficient sleep than others,[34] several studies have shown that failure to obtain adequate sleep is an important contributor to medical error.[25, 35–37] Although most studies have focused on measuring the effects of sleep deprivation on the performance of interns and resident physicians, sleep deprivation also has adverse effects on the performance of hospital staff nurses.[8] Using data from the first sample of nurses (n = 393) who participated in the Staff Nurse Fatigue and Patient Safety Study, Dawson and his colleagues (Dawson, personal communication, 2005) found a significant relationship between sleep in the prior 24 hours and the risk of making an error. Nurses who reported an error or near miss

obtained significantly less sleep than nurses who did not report an error or near miss (6.3 ± 1.9 hours versus 6.8 ± 1.7 hours). Using techniques described in one of their papers,[38] researchers determined that there was a 3.4 percent chance of an error when nurses obtained 6 or fewer hours of sleep in the prior 24 hours and 12 or fewer hours of sleep in the prior 48 hours (Dawson, personal communication, 2005). Although a 3.4 percent risk of an error or near miss sounds insignificant, it would translate to a probability of 34 events per day in an average teaching hospital with 1,000 nursing shifts per day.

In addition to jeopardizing patient safety, nurses who fail to obtain adequate amounts of sleep are also risking their own health and safety. According to the National Center for Sleep Disorders Research and the National Highway Transportation Safety Administration Expert Panel on Driver Fatigue and Sleepiness,[39] sleep loss is the leading cause of drowsy driving and sleep-related vehicle crashes. Drowsy drivers have slower reaction times,[40] reduced vigilance,[41, 42] and information processing deficits,[40] which make it difficult to detect hazards and respond quickly and appropriately.[39] Laboratory studies have shown that moderate levels of prolonged wakefulness can produce performance impairments equivalent to or greater than levels of intoxication deemed unacceptable for driving, working, and/or operating dangerous equipment.[43, 44] Dawson and his colleagues[43, 44] were the first to report that prolonged periods of wakefulness (i.e., 20 to 25 hours without sleep) can produce performance decrements equivalent to a blood alcohol concentration of 0.01 percent, and numerous other studies have confirmed that prolonged wakefulness significantly impairs speed and accuracy, hand-eye coordination, decisionmaking, and memory.[45–49] Although numerous studies have shown that night shift workers report very high rates of drowsy driving and motor vehicle accidents when driving home after work,[50–52] the majority of research on drowsy driving among health care providers has focused on the dangers of resident physicians driving home after a night of being on-call.

There is also a growing body of evidence that sleep duration is (1) linked to metabolism and the regulation of appetite, and (2) decreased sleep times may be a contributing factor to the growing epidemic of obesity in this country. Several large-scale studies have shown dose-dependent relationships between sleep duration and obesity, with greater sleep deprivation associated with a higher risk of obesity.[53, 54] Glucose tolerance is altered by short-term sleep restriction,[55] and habitually short sleep durations have been shown to significantly increase the risk of developing diabetes in women.[56] Tightly controlled laboratory studies have also shown that short sleep durations, e.g., 4 hours per night, can result in alterations of hormones involved in the regulation of appetite (e.g., leptin, cortisol, and thyrotropin).[57]

Sleep is also believed to play a role in regulating immune function. Both human and animal studies have shown that immunological challenges such as vaccinations and both experimentally induced and spontaneous infections tend to increase sleep duration, often increasing the duration and intensity of slow-wave sleep (deep sleep) and decreasing REM sleep (rapid eye movement sleep or dream sleep).[58, 59] Even though studies evaluating the effects of sleep deprivation on immunity have shown a variety of effects,[60–65] no study has been able to link these changes in immune function with increased rates of infection or other adverse effects on health.

Extended Work Hours

Although the hazards associated with the prolonged hours worked by resident physicians and interns have been documented in numerous studies,[25, 65–68] limited attention has been paid to the hours worked by nurses or the effects of these hours on patient safety. Early studies tended to focus on nurse satisfaction with the new 12-hour shift schedule, only minimally addressing the

increased risk of errors.[35] More recent studies, however, have shown that the 12-hour shifts favored by many nurses and frequent overtime are associated with difficulties staying awake on duty, reduced sleep times, and nearly triple the risk of making an error.[14, 69, 70]

Although the majority of hospital staff nurses (75 percent) now work 12-hour shifts, some nurses report being scheduled to work for periods as long as 20 consecutive hours.[14, 69] Data collected on 11,387 shifts revealed that nurses left work at the end of their scheduled shift less than once every six shifts (15.7 percent), and worked on average 49 to 55 minutes extra each shift they worked.[14, 69] Working overtime, whether at the end of a regularly scheduled shift (even an 8-hour shift) or working more than 40 hours in a week, was associated with a statistically significant increase in the risk of making an error.[14, 69] The most significant elevations in the risk of making an error occurred when nurses worked 12.5 hours or longer; the risk was unaffected by whether the nurse was scheduled to work 12.5 hours or more, volunteered to work longer than scheduled, or was mandated to work overtime.[14, 69]

A little over two-thirds of the nurses participating in the Staff Nurse Fatigue and Patient Safety Study reported struggling to stay awake on duty, and 20 percent reported actually falling asleep on duty.[14, 71] In fact, critical care nurses reported struggling to stay awake almost once every five shifts they worked. Not all of the difficulties remaining alert occurred at night (24:00–06:00); 479 episodes of drowsiness (40 percent) occurred between 6 a.m. and midnight, and 40 episodes (23 percent) of actually falling asleep on duty were reported between 6 a.m. and midnight.[14] Nurses working 12.5 hours or longer were significantly more likely to report difficulties remaining alert than nurses working fewer hours per day,[14] and they obtained on average 30 minutes less sleep.

Although the participants (n = 35) in Urgrovics and Wright's 1990 study[72] reported fewer difficulties driving home after switching to 12 hour shifts, at least two recent studies contradict their findings. All but two of the nurses (n = 45) who worked 12-hour night shifts in an intensive care unit of a large tertiary care center reported having at least one motor vehicle accident or near accident during the previous 12 months driving to or from work.[73] More recently, over half of the participants in the Staff Nurse Fatigue and Patient Safety Study (54 percent) reported struggling to stay awake driving home from work during the 28-day data-gathering period.[74] While difficulties remaining alert driving home were common (drowsy driving was reported approximately once every five shifts), critical care nurses reported difficulties remaining awake driving home after working 12.5 consecutive hours or more approximately once out every three shifts they worked. In fact, critical care nurses who worked 12-hour shifts had a 1.87 percent greater risk of fighting sleep on their drive home from work than nurses working traditional 8-hour shifts (95 percent confidence interval [CI] = 1.43–2.45, $P < 0.0001$).[74]

According to a recent report of the National Institute of Occupational Safety and Health (NIOSH),[75] working more than 40 hours per week (overtime), working extended shifts (more than 8 hours), and working both extended shifts and overtime can have adverse effects on worker health. Extended shifts have been associated with increased musculoskeletal injuries,[76] more cardiovascular symptoms,[77–79] the development of hypertension,[80] and higher risks for injury.[81–83] Working overtime has also been associated with poorer perceived health,[84, 85] increased neck and musculoskeletal discomfort,[76, 86, 87] increased risk for preterm birth,[88] diabetes,[89, 90] and cardiovascular disease,[91–93] as well as increased morbidity and mortality[94] and higher rates of accidents.[95, 96] Not all studies, however, suggest that overtime is associated with poorer perceived health,[97] increased risk of developing diabetes mellitus, or cardiovascular disease.[98]

Studies have shown that accident rates increase during extended periods of work,[96] with accident rates rising after 9 hours, doubling after 12 consecutive hours,[81, 83] and tripling by 16 consecutive hours of work.[82] Data from the National Transportation Safety Board aircraft accident investigations also show higher rates of error after 12 hours.[99] Other studies show no change in accident frequency or severity of accidents,[100, 101] while one study showed that workers on a 12-hour shift schedule had lower rates of injuries at work, but higher rates of more significant injuries away from work.[82] The combination of extended shifts and overtime, while rarely studied, has been associated with high rates of motor vehicle accidents or near misses in the prior year,[73] more musculoskeletal pain, and cardiovascular symptoms.[77]

Consecutive Shifts

Fatigue can be exacerbated with increased numbers of shifts worked without a day off,[102, 103] and working more than four consecutive 12-hour shifts is associated with excessive fatigue and longer recovery times.[104] Folkard and Tucker[83] also suggested that the accumulation of fatigue over successive work shifts might explain the rise in accident rates observed in their meta-analysis. On average, risk of an accident was approximately 2 percent higher on the second morning/day shift; 7 percent higher on the third morning/day shift, and 17 percent higher on the fourth morning/day shift than on the first shift. Accident risks also increased over successive night shifts (e.g., on average risk was 6 percent higher on the second night, 17 percent higher on the third night, and 36 percent higher on the fourth night) and were significantly higher than on day/morning shifts, a finding similar to that reported by Hanecke and colleagues several years earlier.[81]

Fatigue Countermeasures and Other Recommended Safety Practices

Fatigue-related problems are believed to cost the United States an estimated $18 billion dollars per year in lost productivity and accidents.[105] More than 1,500 fatalities, 100,000 crashes, and 76,000 injuries annually are attributed to fatigue-related drowsiness on the highway.[105] On-the-job performance also deteriorates: railroad signal and meter reading errors increase at night, minor errors occur more often in hospitals, and switchboard operators take longer to respond to phone calls.[106] Two significant nuclear power plant accidents (Three Mile Island and Chernobyl) and the environmentally disastrous grounding of an oil tanker (Exxon Valdez) occurred at night, during early morning hours when vigilance is at its lowest. In the case of the Exxon Valdez grounding, sleep deprivation was identified as one of the major causal factors of the grounding (the third mate had been awake 18 hours and the ship's master had not slept in the 36 hours prior to the accident).[107] According to a supplemental report,[108] sleep deprivation was a contributory, if not causal, factor in the poor decisions made the night before the launch of the Space Shuttle Challenger.

A variety of industries and professions have developed programs to reduce sleepiness-based errors under the aegis of "fatigue management."[109–111] These programs usually include an educational component [112–116] and sometimes include schedule alterations.[114, 117] Employees are usually given information about circadian rhythms, sleep hygiene measures, shift work and its adverse effects, and a variety of strategies that can be used to reduce fatigue (e.g., judicious use of caffeine and napping during night shifts).[118, 119] Managers may be urged to consider altering

the starting times of shifts whenever possible to make schedules more compatible with circadian rhythms; to avoid scheduling employees to work more than two or three consecutive night shifts; and to provide adequate recovery time between shifts, especially when an employee is rotating off night shift. Hours of service regulations, where applicable, are also considered in the development of a fatigue management program.[119]

Only limited information about the efficacy of these programs is available to the public. Although several specialized fatigue countermeasures programs have been developed and tested by the U.S Coast Guard, the Crew Endurance Management System,[113] and the Commercial Mariner Endurance Management System,[112] information about the efficacy of these programs has not been disseminated. Private companies implementing Fatigue Countermeasures Programs consider their use to be proprietary information. In fact, the only paper describing the efficacy of a fatigue countermeasures program reported only equivocal results.[116]

Other Recommended Safety Practices

Rest breaks, napping, exercise, bright lights, and pharmacologic measures may be used to provide temporary relief from the symptoms of fatigue during the work shift. Although frequent short rests breaks are usually recommended for the prevention of fatigue, anecdotal information, collective bargaining agreements, and even research studies suggest that nurses are regularly sacrificing their breaks and meal periods to provide patient care.[120–126] In fact, a recent study revealed that hospital staff nurses were completely free of patient care responsibilities during a break or meal period less than half the shifts they worked (2,429 out of 5,221 shifts). There were 334 shifts (10 percent) in which nurses reported having no opportunity to sit down for a break or meal period. The rest of the time (2,249 out of 5,211 shifts) nurses reported having the time for a break or meal, but that they were not relieved of patient responsibilities during that time.[126] On average nurses reported having only 25.7 minutes break during their entire shift. Nurses working the longest hours were least likely to receive appropriate breaks (e.g., 10 minutes every 2 hours and a 30-minute meal period free of patient care responsibilities).

Studies have shown that short breaks not only improve performance and reduce subjective fatigue,[127–130] they are effective in controlling the accumulation of risk associated with prolonged task performance (e.g., 2 hours sustained work)[131, 132] and sleepiness.[129] Other studies however, have shown that rest breaks and tea breaks can decrease fatigue but not necessarily accident risk or errors.[126, 133]

Napping. Even though napping during breaks or meal periods is often prohibited, both laboratory and field studies suggest that naps (15 minutes to 3 hours) are quite effective in increasing alertness during extended work periods or at night.[134–139] Since few operational settings allow for long naps (e.g., 3 hours), most naps studied in operational settings are short. For example, 20-minute single naps during the first night shift improved the speed of responses on a vigilance task at the end of the shift,[134] and 26-minute in-seat naps have been shown to increase physiological alertness and psychomotor performance of airline pilots.[140] When pilots were allowed a nap during night flights, their performance improved by 34 percent, and physiologic alertness improved 54 percent compared to the no-nap condition.[140]

The alerting effects of naps are varied, with most studies suggesting that improvements in subjective alertness and performance are sustained for up to an hour or more postnap.[138, 139, 141] Longer naps tend to produce longer periods of alertness and improved performance.[142] Although some studies report sleep inertia, or a period of decreased alertness and performance immediately following a nap,[138, 139, 141] this effect was not seen in Driskell's meta-analysis.[142]

Stimulants. Caffeine is probably the most commonly used fatigue countermeasure.[143] Its effects have been studied alone,[144] as well as in combination with rest breaks, naps, and other stimulant medications.[145–147] Generally, caffeine's onset of action occurs approximately 15–30 minutes after ingestion and its effects last 3–4 hours. Although tolerance can develop, significant increases in alertness and performance can be obtained with 200 mg of caffeine (approximately the amount of caffeine in one to two cups of coffee), with positive effects occurring with doses ranging from 100 mg to 600 mg.[143, 145] Although caffeine alone improved alertness and performance during a laboratory study, the combination of napping and caffeine was more efficacious than just napping or just caffeine alone in a field study of evening and night shift workers.[146] Six hundred milligrams of caffeine was also as effective as 20 mg d-amphetamine and 400 mg modafinil in producing short-term performance and alertness during prolonged sleep loss.[148] Modafinil has also been shown to be effective in increasing alertness on laboratory measures of performance among workers diagnosed with shift work sleep disorder (see Table 1 for a description of the disorder),[149–151] but produced mixed results when evaluated during a randomized, double-blind cross-over study of sleep-deprived emergency room physicians. Even though modafinil improved some aspects of cognitive functioning and perceived alertness, participants had difficulties falling asleep when given an opportunity.[152] Although other compounds have been recommended (e.g., melatonin), their efficacy has not been established.[153, 154]

Bright light. Although a number of studies have shown that bright lighting in control rooms, work areas, and laboratory environments can increase alertness at night and facilitate entrainment to night shift work,[154–157] this strategy may not help nurses as much as other types of workers. Protocols typically involve exposure to bright lights (approximately 2,500 lux) or normal lighting (approximately 150 lux) while working at a desk for periods of 2 to 6 hours. No one has evaluated the efficacy of intermittent exposure to bright lights or the effects of alternating exposure to bright lights with the dim lighting typically found in patient rooms at night.

Exercise. Exercise typically produces increased subjective alertness and improved cognitive performance in both sleep-deprived and nonsleep-deprived subjects.[158, 159] Exercising for 10 minutes, however, produces only transient (30–50 minutes) increases in subjective alertness. In one study there were no effects on performance after exercise, but within 50 minutes there were signs of increased drowsiness on electroencephalogram (EEG) recordings.[160] As a result of this finding, the authors of the study caution that people who use exercise as an intervention for maintaining alertness during a period of sleep loss may end up sleepier than if they had not exercised.

Research Evidence

There is a very large, strong body of evidence showing that insufficient sleep has adverse effects on cognition, performance, and mood. These effects have been documented by at least two meta-analyses[22, 150] and several clinical trials,[32, 161, 162] as well as by studies using somewhat less robust designs including time series, cross-sectional, before-and-after designs, and noncomparative descriptive studies.[11, 30, 37, 163–167] The adverse effects of insufficient sleep have also been documented in a variety of settings ranging from tightly controlled laboratories[11, 32, 162, 163, 166] to field studies,[30, 37, 164–167] and in a variety of occupational groups.

The studies demonstrating a relationship between adverse effects on health and obtaining less than 7 hours sleep per night tend to use less robust designs (e.g., cross-sectional designs, time series designs, comparative and noncomparative descriptive designs), but they often include large numbers of participants. Although survey and cross-sectional designs may not be as rigorous as controlled clinical trials, the number of recent studies suggesting similar relationships between insufficient sleep, altered glucose metabolism,[56, 168] and increased risks of developing diabetes mellitus[54, 169] and obesity[53, 54] is powerful and convincing evidence that a relationship exists between these variables. Longer sleep durations (e.g., more than 8 to 9 hours per night) were also associated with greater risks of dying or developing a chronic illness such as DM or cardiovascular disease,[29, 56, 168] leading researchers to speculate that individuals who routinely obtain higher than normal amounts of sleep may have preexisting health problems.[29]

The evidence regarding shift duration, however, is less clear-cut. Although some studies suggest that reductions in the work hours of resident physicians and interns is associated with fewer errors,[35] other studies suggest that the implementation of work hour limitations has not decreased the number of adverse events.[169,170] Although there are numerous literature reviews,[171–173] descriptive and other comparative studies,[14, 25, 26, 69, 174–176] there are no meta-analyses and only one systematic review[177] focusing on the impact of work hours on medical errors or work performance. The strongest study, involving 20 critical care residents and interns and direct observation of errors, found that traditional schedules were associated with 35 percent more serious errors, and shortened workdays (16 hours) were associated with both fewer order-writing errors and diagnostic errors.[35] Unfortunately, this study has not been replicated outside of the critical care setting or at any other institution.

The evidence demonstrating a relationship between working long hours and adverse effects on health is stronger. Not only are there several large-scale studies documenting higher injury rates when people worked overtime or extended shifts,[82, 178, 179] there are several literature reviews[83, 170] and three meta-analyses examining the effects on worker health.[78, 79, 83]

Clinical trials that would provide more definitive answers to questions regarding shift duration and adverse health effects have not been done, nor are they likely to be done because of ethical issues.

Although more than 170,000 employees from a variety of industries (including aviation, rail, trucking, maritime, health care, petrochemical, nuclear energy, and law enforcement) have been exposed to fatigue countermeasures programs,[115] there is very limited information about their efficacy. Typical reports indicate that some aspects of a particular program were successful (e.g., employees slept longer at night,[180] napping improved alertness on duty,[129] and that participants used most of the suggested strategies),[116] but the reports rarely assess the efficacy of the program as a whole for improving alertness on the job and reducing errors. The only published study describing the outcomes of a fatigue countermeasures program for resident physicians involved a very small sample (n = 6) and produced mixed results.[116] Although participants reported increased subjective alertness after using the suggested strategies for a month, there were no improvements in their performance, mood, or the amount of sleep obtained when working the night shift.

There is strong evidence that short naps can improve alertness during night shifts and prolonged periods of wakefulness. Data obtained from several small clinical trials,[134, 138, 140, 146] and a meta-analysis[142] all support the use of this strategy for improving alertness at night. In addition, there are several small clinical trials that suggest a short daytime nap can improve alertness during the afternoon.[181–184]

The effects of rest breaks were more variable. Study designs evaluating the efficacy of rest breaks on performance and alertness also tended to be weaker, involving quasi-experimental designs[128, 130, 131, 133, 185] rather than randomized clinical trials[129] or meta-analyses. Given that almost all of the aforementioned studies were field studies conducted at actual worksites during regular workhours, the choice of somewhat less rigorous designs is understandable.

There is strong evidence that use of caffeine, either alone or in combination with a nap, can increase alertness. Although there are no meta-analyses evaluating the efficacy of caffeine, the utility of caffeine for increasing alertness has been demonstrated through numerous clinical trials,[144, 145, 147] and its widespread use by adults. (Mean caffeine consumption in the United States is estimated at 238 mg or slightly more than two cups of coffee per day per person.)[186] Other measures to increase alertness, such as bright lighting and exercise, either lack sufficient evidence or may not be practical for nurses.

Evidence-Based Practice Implications

Although studies have not always been able to document that the cognitive deficits associated with insufficient sleep lead to medical mishaps, there is enough evidence to suggest that insufficient sleep can have adverse effects on patient safety and the health of nurses. The effects, summarized in Table 1, provide the basis for the two recommendations in Table 2.

Table 1. Adverse Effects of Restricted Sleep on Patient Safety and the Health of Nurses

Sleep Duration in 24 Hour Period	Adverse Effects on Patient Safety	Adverse Effects on Health
< 7 hours	More likely to report struggling to stay awake during work shift[14]	Increased risk of developing cardiovascular disease and DM among nurses[187] Increased risk of becoming obese over a 10-year period[53]
≤ 6 hours	Risk of making an error is 3.4% during a work shift among nurses who slept ≤ 6 hours in 24 hours prior to shift (Dawson, personal communication)	Increased prevalence of DM and altered glucose metabolism[56, 168] Risk of obesity is 23% greater than subjects sleeping 7–9 hours[53]
< 5 hours	Increased subjective and objective sleepiness, and reduced performance on cognitive tasks[22, 161]	Increased risk of developing DM demonstrated in nurses[187] Risk of obesity is 50% greater than among subjects sleeping 7–9 hours[53]
≤ 4 hours		Altered levels of appetite-regulating hormones (leptin, cortisol, and thyrotropin)[57] Risk of obesity is 73% greater than among subjects sleeping 7–9 hours[53]

Table 2. Evidenced-Based Recommendations for Practice Related to Sleep Duration[32]

Recommendation	Practice Implication
Nurses need to obtain 7–8 hours sleep per night to protect both the health of their patients and their own health	Get 7 to 8 hours of sleep each day (24-hour period) before you go to work.
Younger nurses (e.g., those 20–30 years old) need to be particularly careful about obtaining sufficient sleep, since their mood and performance may be more adversely affected by insufficient sleep.	If you are younger than 30 years of age, adequate sleep is especially important for providing safe and high-quality patient care.

To implement these recommendations, many nurses will have to be willing to make substantial changes in their behavior. Despite their more sophisticated knowledge about health and illness, the sleep habits of nurses mirror those of other Americans. Only a little more than one-fourth of the participants in the Staff Nurse Fatigue and Patient Safety Study (27.2 percent) obtained at least 6 hours sleep prior to every shift they worked during the 28-day study period; more than one-quarter of the 11,387 shifts studied (29.1 percent) were worked by nurses who obtained less than 6 hours sleep, an amount that has been associated with higher risks of errors (Dawson, personal communication, 2005). Although few nurses would consider coming to work if they were legally drunk, the data suggest that many nurses are unaware of or disregard the equally serious risks associated with insufficient sleep.

Although it might be argued that family responsibilities prevented hospitals staff nurses from obtaining sufficient sleep, regression analysis has shown that this is not the case. Neither childcare nor elder care responsibilities were associated with reduced sleep times on workdays. Instead, longer work shifts, longer commutes, higher caffeine intakes, complaints of poor sleep, and older age (of the nurse) were associated with shorter sleep durations.[188] Childcare responsibilities, however, were associated with shorter sleep times on nonworkdays.

Several authorities have recommended that work shifts be limited to 12 hours in a 24-hour period and employees limited to working no more than 48 to 60 hours per week.[171, 173, 189, 190] Although 12-hour shifts are quite popular among nurses, most authorities do not recommend the use of 12-hour shifts unless there are sufficient rest breaks, there are adequate arrangements for coverage of absentees, overtime will not be added, and shift systems are designed to minimize the accumulation of fatigue.[173, 190, 191] Rosa[173] also recommends that 12-hour shifts not be adopted if there are staffing shortages, citing the dangers associated with an already fatigued worker covering part or all of a vacant shift.

In fact, legislation pending in the Massachusetts State legislature would (1) prohibit resident physicians from working more than 10 consecutive hours in all high-intensity settings, (e.g., emergency departments, intensive care units, etc.); (2) limit resident physician workhours to 18 consecutive hours in all other areas; (3) mandate 16 consecutive hours off after an 18-hour shift and require 10 consecutive hours off between all other work shifts; and (4) require all physicians, not just trainees, to notify patients before providing care if the physician has been awake 22 hours out of the prior 24 hours.[192] Although the workhours of most nurses will not be altered by this legislation, limiting the duration of nursing shifts and mandating sufficient rest periods between shifts would also be of benefit for nurses and the patients they care for.

Table 3. Evidenced-Based Practice Recommendations Related to Shift Duration and Number of Workhours During a Week

Recommendation	Practice Implication
Schedules that involve working 48 or 60 hours per week,[193] or working 7 consecutive 12-hour shifts in one week in order to have 7 consecutive days off the next week[194] are unacceptably risky,[83] and should be prohibited.	Do not work any more than 48 hours in a 7-day period.
The continued use of 12-hour shifts cannot be recommended given the current working conditions, including the almost daily need for nurses to stay beyond the end of their scheduled shift, the frequent absence of breaks during the workday, and the higher risk of errors associated with 12-hour shifts.[14, 69, 126]	Nurse managers should not schedule nurses for 12-hour shifts and nurses should not request 12-hours shifts.
If nurses insist on continuing to work 12-hour shifts, several measures should be taken to reduce the risks to patients and nurses. These steps include reducing the number of consecutive shifts to no more than three,[83, 104] providing adequate meal and rest breaks,[120, 195] revising schedules to ensure that nurses have at least 10–12 hours off between work shifts so that they have adequate time for sleep, commuting, and completing their domestic responsibilities, and requiring that nurses use their off-duty time to get sufficient sleep.	If you are scheduled to work a 12-hour shift, (1) do not work more than three shifts without a day off; (2) insist that provisions are made for sufficient staffing to ensure that you are able to be free of patient care responsibilities for 10 minutes every 2 hours and for 30 minutes to eat a meal; and (3) insist that you have at least 10–12 hours off between shifts so that you can obtain sufficient sleep.

The emphasis on maximizing opportunities for sleep is intentional. Because long workhours are often associated with insufficient sleep,[25, 36, 196] some authorities believe that fatigue on the job is more likely to be associated with a lack of sleep than the number of hours spent working.[191, 197] Workers who report high workloads, stressful workweeks, or who score higher on burnout indexes have shorter sleep times,[198, 199] as well as more arousals, greater sleep fragmentation, more wake time after sleep onset, lighter sleep, and less deep sleep.[200, 201] Fatigue and daytime sleepiness associated with stressful working conditions and burnout is believed to be a result of insufficient sleep, rather than a direct result of stressful working conditions or burnout.

Although employer support will be required to implement schedule changes, there are several strategies that nurses can adopt to improve their ability to remain alert throughout their entire shift. Even though the following three fatigue countermeasures were developed mainly for night shift workers, the first two recommendations are also appropriate for nurses working other shifts.

Practice Recommendations for Use of Caffeine

1. Caffeine should be used therapeutically. Caffeine should not be consumed on a regular basis or when alert. Instead, caffeine consumption should occur only at the beginning of a shift or about an hour before an anticipated decrease in alertness (e.g., between 3 a.m. and 5 a.m.). To reduce the possibility of insomnia, caffeine consumption should stop at least 3 hours before a planned bedtime.[202]

2. Nurses should be allowed to nap during their break and meal periods. Naps should be short, e.g., less than 45 minutes, to reduce the likelihood of awakening from deep sleep and

experiencing sleep inertia.[143] Some nurses may prefer to take a shorter nap, and have a 15-minute wake up period before they resume patient care.

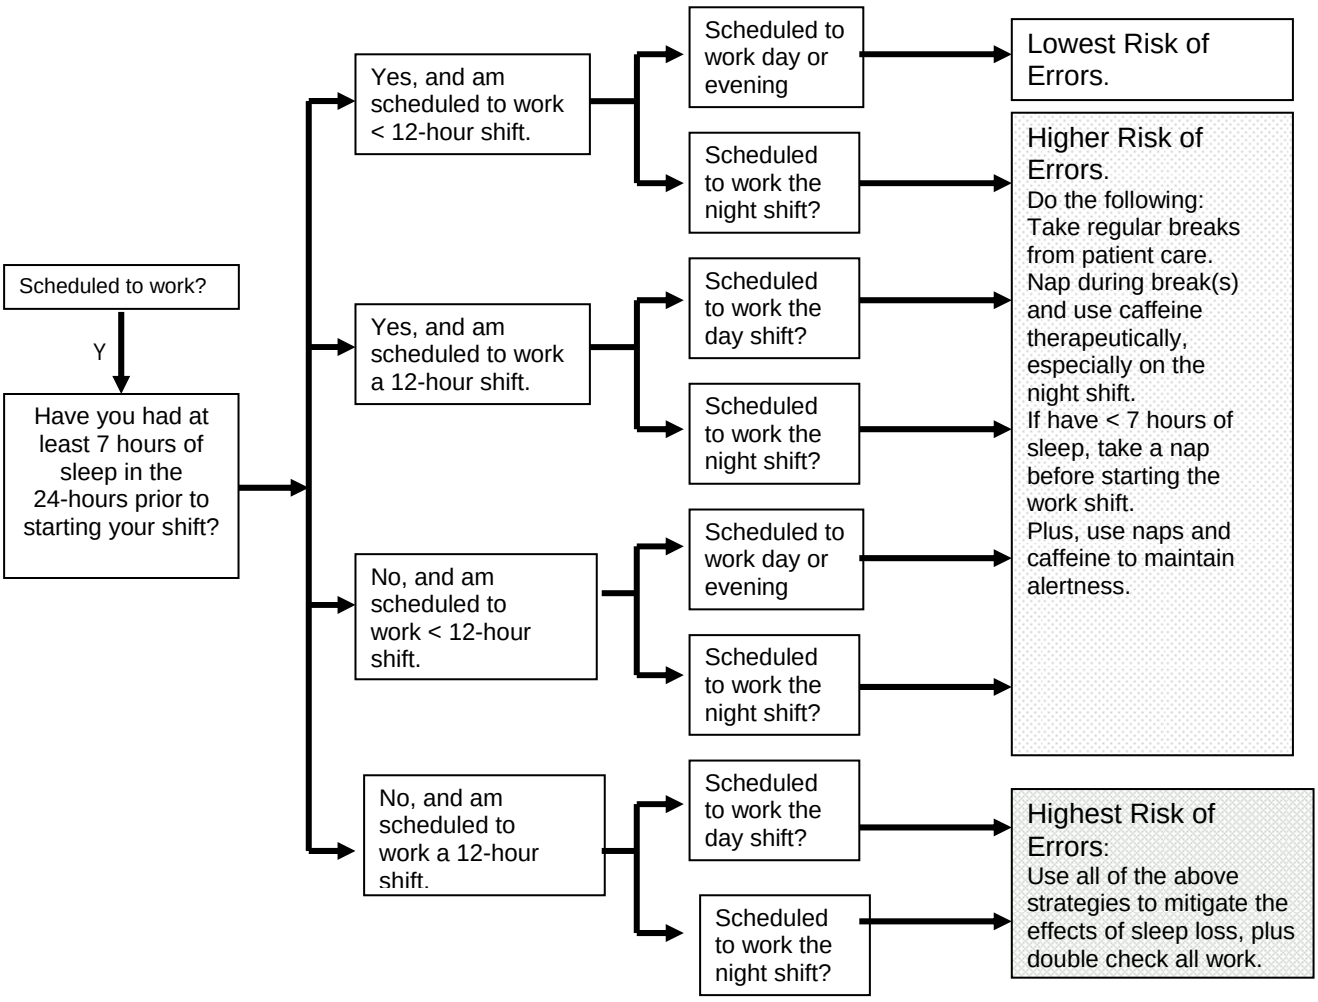
3. Nurses, particularly those who start their shift at 11 p.m. or midnight, should consider napping prior to starting their shift. Not only are nurses who work at night required to be awake and vigilant when their body temperature is lowest and their sleep tendency is greatest, they are typically awake longer before the beginning of their shift than workers on other shifts.[203]

Table 4. Evidenced-Based Recommendations for Practice Related to Improving Alertness on the Job

Recommendation	Practice Implication
Caffeine should be used therapeutically. Caffeine should not be consumed on a regular basis or when alert. Instead, caffeine consumption should occur only at the beginning of a shift or about an hour before an anticipated decrease in alertness e.g., between 3 a.m. and 5 a.m. To reduce the possibility of insomnia, caffeine consumption should stop at least 3 hours before a planned bedtime	Do not consume caffeine outside of workhours. Consume caffeinated beverages only at the beginning of the shift or about an hour before an anticipated decrease in alertness, e.g., between 3 a.m. and 5 a.m. Avoid consuming caffeinated beverages at least 3 hours before bedtime.
Nurses should be allowed to nap during their break and meal periods. Naps should be short, e.g., less than 45 minutes, to reduce the likelihood of awakening from deep sleep and experiencing sleep inertia. Some nurses may prefer to take a shorter nap and have a 15-minute wake up period before they resume patient care	Use breaks and meal periods for a short nap, particularly during the night shift. Naps should be less than 45 minutes in duration. If you are somewhat sluggish when you first awaken, take a shorter nap so that you have at least a 15-minute wake up period before resuming patient care.
Nurses, particularly those who start their shift at 11 p.m. or midnight, should consider napping prior to starting their shift. Not only are nurses who work at night required to be awake and vigilant when their body temperature is lowest and their sleep tendency is greatest, they are typically awake longer before the beginning of their shift than workers on other shifts	If you work nights, especially if you start working at 11 p.m. or midnight, take a nap prior to starting your shift to help you remain alert during the early morning hours. Although it may be more difficult to schedule, taking a short nap before working a 12-hr night shift, would also help improve your alertness during the early morning hours.

Finally, nurses should realize that most people are not accurate judges of how impaired they are by fatigue or sleep loss.[204, 205] Few adults can perform at high levels for more than 12 consecutive hours or function adequately with less than 6 hours sleep. Figure 1 illustrates the risks associated with combining insufficient sleep with extended shifts and outlines strategies to reduce fatigue-related errors.

Figure 1. Risks Associated With Various Combinations of Sleep Duration, Shift Duration, and Shift Time, and Strategies To Mitigate the Effects of Insufficient Sleep and Extended Work Shifts



Research Implications

More research is needed to understand the effects of fatigue on patient safety. Controlled trials are needed to determine optimal work schedules in hospital settings and test fatigue countermeasures. Since night shifts cannot be eliminated, the efficacy of fatigue countermeasures, naps during break periods, therapeutic use of caffeine, and other measures should be tested in hospital environments. Since the use of naps and caffeine have been shown to increased alertness during prolonged sleep deprivation and during night shift work, these measures should also be evaluated to determine if they would be effective for increasing alertness on day and evening shifts.

Finally, there is no information about the sleep of nurses working outside of hospital environments, and only limited information about the workhours of nurses in nursing homes and extended-care facilities. Nor is there any information about the sleep and performance of nurses who work 24-hour shifts (e.g., nurse-midwives and some advanced practice nurses) or who are

required to take call. These issues and others need to be examined to improve both the safety of patients and the nurses who care for them.

Although many questions remain unanswered, "We do know enough," according to L. G. Olson and A. Ambrogetti, "to end the worse abuses of the human sleep-wake cycle, and we need to see a shift by both hospital employers and the medical [nursing][*] profession towards addressing this issue"[206] (p. 416). The service regulations written during the first two decades of the 20th century recognized that people cannot work for long periods of time each day without adequate time to sleep. Eighty years later, at the beginning of the 21st century, it is perhaps time to acknowledge that nurses cannot provide safe care when they are fatigued, have worked for more than 12 consecutive hours, and/or have not had at least 12 to 16 hours off between shifts.

Table 5. Critical Research Questions

Research Question	Research Goal	Possible Study Methods
What is the optimal schedule for minimizing fatigue among hospital staff nurses? For nurses working in long-term care facilities?	To evaluate different types of schedules to determine which is the most effective for minimizing fatigue among hospital staff nurses and nurses working in long-term care facilities.	Controlled clinical trials of schedules involving different shift durations, number of consecutive days off, and types of shifts, e.g., night versus day shift.
Will the risk of making an error decrease if shifts are shortened to ≤ 10 hours and/or nurses get at least 7 hours sleep?	To determine if shorter work durations and obtaining adequate amounts of sleep reduce the risk of making an error.	Clinical trial, with one group assigned to shorter shifts, the second group assigned to obtain at least 7 hours sleep, and the third group assigned to work shorter shifts and obtain at least 7 hours sleep.
Since most nurses and managers favor 12-hour shifts despite their well-recognized hazards, how can the culture of individual nursing units be changed to discourage their use?	To determine what factors favor the continued use of 12-hour shifts and how to alter those factors to make shorter shifts more acceptable to staff nurses and nurse managers.	Qualitative approaches, in combination with rating scales to assess unit culture and institutional commitment to improving patient safety.
What differentiates those nurses who always obtain at least 6 hours sleep prior to working from those who fail to get at least 6 hours sleep prior to working?	To identify the characteristics of nurses who are most likely to obtain the minimum amount of sleep necessary to provide care safely.	Correlation studies and regression models.
Will fatigue countermeasures, e.g., naps during break periods and therapeutic use of caffeine, increase the alertness of nurses working at night? Decrease the risk of making an error?	To evaluate the efficacy of fatigue countermeasures for increasing the alertness and decreasing the risk of errors when nurses work at night.	Clinical trial comparing the alertness and risk of errors in night shift nurses assigned to fatigue countermeasures group to those who are not assigned to the intervention group.
Will fatigue countermeasures, e.g., naps during break periods and therapeutic use of caffeine, increase the alertness of nurses working 12-hour shifts? Decrease the risk of making an error?	To evaluate the efficacy of fatigue countermeasures for increasing the alertness and decreasing the risk of errors when nurses work 12-hour shifts	Clinical trial comparing the alertness and risk of errors of nurses working 12-hours shifts assigned to fatigue countermeasures group to those who are not assigned to the intervention group.
Should nurse midwives and other advanced practice nurses be allowed to work 24-hour shifts?	To determine if 24-hour shifts worked by nurse midwives and other advanced practice nurses are safe.	Observational study using methodology similar to that used to evaluate the safety of 24-hr shifts worked by critical care residents.

Conclusion

The evidence is overwhelming that nurses who work longer than 12 consecutive hours or work when they have not obtained sufficient sleep are putting their patients' health at risk; risk damaging their own health; and if they drive home when they are drowsy, also put the health of the general public at risk. Nurses, nurse managers, nursing administrators, and policymakers need to work together to change the culture that not only allows, but often encourages nurses to work long hours without obtaining sufficient sleep.

Key Terms and Definitions

Table 6. Key Definitions

Term	Definition
Insufficient sleep	A condition that results from sleeping less than needed. Healthy adults who obtain enough sleep do not require an alarm clock to awaken them in the morning, do not have difficulties with remaining alert after lunch or during a boring lecture, and do not sleep in on weekends.
Wrist actigraphy	Wristwatch-sized instrument used to record frequency and amplitude of wrist movements. Used to distinguish sleep from waking states.
Sleep debt	The difference between the amount of sleep you need and the amount you obtained. The larger the sleep debt, the more likely you are to fall asleep during the daytime.
Polysomnographic recorders	Recording equipment used to record sleep. Equipment records electroencephalograms (EEG), electro-oculograms (EOG), and electro-myograms (EMG) needed for staging sleep.
Shift work sleep disorder	A sleep disorder effecting individuals who work at night. Individuals with this disorder have difficulty remaining awake during their work shift and have trouble sleeping after working at night, yet have no trouble sleeping at night or staying awake during the day on their days off.

Search Strategy

Relevant papers for this review were identified from three databases (MEDLINE,® CINHAL,® and PsychLit) using the period 1990–2006. Several older, classical works were also cited. Hand searches were also performed examining journals such as the *Journal of Sleep Research and Sleep.* Only those papers that focused on the effects of chronic partial or total sleep deprivation for a single night, extended work shifts, and strategies to reduce fatigue-related errors and accidents were included in this review. Search terms included "caffeine," "chronic partial sleep deprivation," "fatigue," "fatigue countermeasures," "extended work shifts," "napping," "overtime," "performance," "resident physicians," "registered nurses," "rest breaks," "sleep loss," "sleep restriction," "staff nurses," "total sleep deprivation," and "vigilance."

Evidence Table 1. Effects of Insufficient Sleep on Patient Safety and Health of Individuals

Source	Safety Issued Related to Clinical Practice	Design Type	Study Design, Study Outcome Measures	Study Setting & Study Population	Study Intervention	Key Finding
Belenky 2003[161]	Chronic sleep restriction	Randomized controlled trial (2)	Randomized controlled trial (2) Vigilance, objective and subjective sleepiness (3)	69 healthy volunteers (16 women, 50 men) ages 24–62	Subjects' sleep restricted to 3 hr, 5 hr, 7 hr, or 9 hr/night for 7 nights	With mild to moderate sleep restriction (5–7 hr), performance initially declined then stabilized at levels below their baseline levels. With severe sleep restriction, performance continued to decline throughout the study period. There were no improvements in performance associated with increased sleep time (9 hr).
Harrison 1997[162]	One night's sleep loss	Randomized controlled trial (2)	Cross-over design (2), Verbal communication (3)	9 healthy college students		There was a significant reduction in word fluency, and subjects tended to become fixated within a particular semantic category. Speech was also more monotonic or flattened without appropriate intonation
Pilcher 1996[22]	Sleep loss	Meta-analysis (1)	Meta-analysis (1) Effects of sleep loss on cognition, motor performance, and mood (3)	19 studies and 1,932 participants		Sleep deprivation had more profound negative effects on mood than it did on cognition or motor performance. The effect sizes for partial sleep deprivation (≤ 5 hours sleep/night) on mood and cognitive function were larger than for long-term sleep deprivation 45 hours/week).

Source	Safety Issued Related to Clinical Practice	Design Type	Study Design, Study Outcome Measures	Study Setting & Study Population	Study Intervention	Key Finding
Philibert 2005[150]	Sleep loss and cognitive function, memory and vigilance	Meta-analysis (1)	Meta-analysis (1) Effects of sleep loss among physicians on cognitive function, memory and vigilance (3)	60 studies published between 1971 and 2004 involving 959 physicians and 1,028 nonphysicians		Cognitive performance in physicians is affected by sleep deprivation. Smaller effect sizes in studies of physicians likely related to difficulty in controlling the exact number of hours sleep in field studies or the chronic sleep deprivation experienced by the "rested cohorts."
Phillip 2004[32]	One night's sleep loss	Randomized trial (2)	Cross-over design (2) Reaction time, subjective sleepiness and performance ratings (3)	10 younger (20–25 years) and 10 older (52–63 years) drivers		Reaction times were slower in older subjects without sleep deprivation; however, after sleep deprivation, the reaction times of older subjects remained unaffected, while the reaction times of younger subjects were significantly increased. Sleepiness and perception of performance were equally affected in both groups of subjects.
Ayas 2003 (a)[56]	Insufficient sleep	Time series (7)	Longitudinal study (3), self-reported sleep duration and risk of DM (1)	70,260 women ages 45–65 years who were enrolled in the Nurses Health Study		There was an elevated risk of developing DM among nurses who obtained less than 5 hours sleep/day or more than 9 hours sleep/day.

Source	Safety Issued Related to Clinical Practice	Design Type	Study Design, Study Outcome Measures	Study Setting & Study Population	Study Intervention	Key Finding
Gangwisch 2005[53]	Sleep restriction	Time series study (7)	Cross-sectional and longitudinal examination (4) of sleep duration and weight gain over a 10-year period (2)	Participants in the NHANES I study, 9,588 participants in the cross-sectional study and 6,981 participants in the longitudinal study		Subjects with sleep durations less than 7 hours at baseline (1982) were more likely to be obese 10 years later than subjects who obtained at least 7 hours sleep. Sleep durations greater than 7 hours were not consistently associated with either an increased or decreased risk of obesity.
Gottlieb 2005[168]	Chronic sleep restriction	Cross-sectional study (4)	Cross-sectional study (5) Usual sleep time, fasting glucose levels, blood glucose levels 2 hours glucose challenge (3)	Participants in the Sleep Heart Health Study (722 men and 764 women)		Sleep durations of ≤ 6 hours or > 9 hours were associated with increased prevalence of DM and impaired glucose tolerance
Kripke 2002[29]	Chronic sleep restriction	Cross-sectional study (4)	Survey (5) Participants were 30–100 years of age, sleep durations and morbidity and mortality rates over a 6-year period (1)	1.1 million participants from the American Cancer Society's Cancer Prevention II Study.		Mortality rates were highest among subjects who obtained ≥ 8-hr sleep or less than 3.5–4.5 hr. The lowest risks were found among those who obtained 7 hours sleep.
Singh 2005[54]	Sleep restriction	Cross-sectional study (4)	Survey (5), total sleep time in the 2 weeks prior to survey, and body mass index (BMI) (3)	3,158 randomly selected adults in the metropolitan area of Detroit, MI		Overall prevalence of obesity was 24.8% and significantly higher in those with lower amount s of sleep. After controlling for age, sex, loud snoring, hypertension, DM, arthritis, and alcohol intake, sleeping less than 6 hours greatly increased the risk of being obese.

Evidence Table 2. Extended Work Hours

Source	Safety Issued Related to Clinical Practice	Design Type	Study Design, Study Outcome Measures	Study Setting & Study Population	Study Intervention	Key Finding
Arnedt 2005[174]	On-call schedules and performance	Nonrandomized trial (3)	Nonrandomized controlled trial (l3) 60-minute test battery consisting of sustained attention, vigilance, simulated driving performance, and self-reports of performance (3).	34 pediatric residents at a university hospital in the northeastern region of the U.S.	Residents tested in four conditions: (1) after a night of heavy call (on call every 4th to 5th night), (2) a night on a light call schedule (call is less frequent than heavy call), (3) after a night of light call and enough alcohol to obtain a blood alcohol level of 0.04–0.05, and (4) after a night of heavy call plus alcohol	Performance following a night of heavy call was quite similar to performance after drinking alcohol. Reaction times were slowed, errors of commission increased 40%, and lane variability and speed were significantly increased after a night of heavy call.
Fletcher 2004[169]	Number of hours worked	Systematic Review (11)	Literature review (6) Reviewed 7 studies between 1966 and 2004 related to reducing resident work hours. Outcomes included mortality, adverse events, and medication errors (1).			Research was not robust enough to reveal whether workhour limitations directly improve patient safety. None of studies involved clinical trials, and few used large databases or controlled for potential confounders.

Source	Safety Issued Related to Clinical Practice	Design Type	Study Design, Study Outcome Measures	Study Setting & Study Population	Study Intervention	Key Finding
Landrigan 2004[35]	Number of hours work	Nonrandomized trial (3)	Nonrandomized trial (3) Number of serious medical errors observed by trained observers in ICU (2), raters blinded to work schedules	20 critical care interns at large university teaching hospital	Traditional call scheduled with extended hours and every third night call, and a restricted schedule that reduced work shifts to 16 hours	Interns made 35.9% more serious medical errors during the traditional schedule than during the intervention schedule. Both the rate of serious medication errors and diagnostic errors were significantly increased during the traditional schedule compared to the intervention schedule.
Akerstedt 2002[178]	Number of hours worked, and overtime	Longitudinal, descriptive study (7)	Observational study with controls (4) Phone interviews, fatal occupational accidents (3)	47,860 Swedes interviewed over a 20-year period about issues related to work and health		There were 169 fatal occupational accidents. Predictors included male gender, difficulties sleeping in the past 2 weeks, and nonday work. Age, socio-economic status, overtime (>50 hr/week) or physically strenuous work did not increase the risk of a fatal occupational accident.
Dembe 2005[207]	Number of hours worked, overtime	Time series (7)	Survey (5), occurrence of injury (3)	10,793 Americans with a variety of occupations who participated in the National Longitudinal Survey of Youth between 1987 and 2000		Working a job with overtime was associated with a 61% higher injury rate compared to jobs without overtime. Working ≥12 hours per day was associated with a 37% increase in hazard rate, and 60 hr/week 23% increase in hazard rate. Injury rates increased in a dose-response fashion according to the number of hours per day (or week) that were worked. Injury rates were not affected by type of job or other factors such as gender.

Source	Safety Issued Related to Clinical Practice	Design Type	Study Design, Study Outcome Measures	Study Setting & Study Population	Study Intervention	Key Finding
Folkard 2003[83]	Work hours, shift work and safety	Meta-analysis (1)	Meta-analysis (1). Risks across different shifts, risks over successive shifts, risks over hours of duty, risk as a function of breaks (3)	26 studies		Risk of injury increases in a linear fashion across the shifts, with the lowest risk during the day shift and the highest risk at night. There was a slight increase in risk between 2 and 3 a.m., but effect was relatively small compared to substantial decrease in risk over most of night. Risks increased across successive shifts, e.g., risk was 6% higher on second night, 17% higher on 3rd night, and 36% higher on 4th night. Risks increased in exponential fashion after 8th hour of work, and during the 12th hour was double that during the first 8 hours. Risks of injury rose substantially between successive breaks, and that risk had doubled by the last 30-minute period before the next break. (This phenomenon occurred on all three shifts and during each 2-hour period between breaks.)
Sparks 2003[208]	Weekly workhours, ill health	Meta-analysis (1)	Meta-analysis (1) Weekly workhours, health problems (3)	21 studies		There was a mean correlation of 0.13 between weekly workhours and ill health.
Van der Hulst 2003[79]	Long work hours and health	Systematic literature review (1)	Systematic literature review (1) workhours, adverse health effects (3)	27 empirical studies		Long workhours were associated with adverse health effects (cardiovascular disease, DM, disability retirement, physiological changes, and health-related behavior).
Yang 2006[80]	Long workhours and hypertension	Cross-sectional study (4)	Survey (4), workhours/week and hypertension	24,205 working adults living in California		After controlling for age and other health and lifestyle factors, individuals working more than 50 hours/week had a 1.29 times the risk of developing hypertension than those working 15–39 hours.

Evidence Table 3. Fatigue Countermeasures

Source	Safety Issued Related to Clinical Practice	Design Type	Study Design, Study Outcome Measures	Study Setting & Study Population	Study Intervention	Key Finding
Smith-Coggins 1997[116]	Maintenance of vigilance, fatigue countermeasures program	Nonrandomized controlled trial (3)	Nonrandomized controlled trial (3) Ambulatory polysomnography recordings during main sleep period, daily performance testing, and daily subjective ratings of sleep, mood, and intervention use (3) Tested on both day and night shifts.	6 emergency room physicians	Measures obtained at baseline, after a placebo intervention, and after the implementation of a fatigue countermeasures program	Increased subjective alertness reported after 1 month, but there were no improvements in performance, mood, or the amount of sleep obtained when working night shift.
Lilley 2002[133]	Fatigue, accidents and rest breaks	Noncomparative study (8)	Survey (5) Payment method, ethnicity, injury, fatigue, sleep duration, work duration, breaks and their duration (3)	367 logging and silviculture workers in New Zeeland		Presence or absence of breaks did not affect fatigue, but was associated with few injuries.
Neri 2002[129]	Maintenance of Vigilance, rest breaks	Randomized controlled trial (2)	Randomized controlled trial (2) Continuous recordings of EEG, subjective ratings of sleepiness, psychomotor vigilance testing (reaction time) (3)	28 pilots, flight simulator	Treatment group received 5 short breaks spaced hourly during flight, control group received 1 break in middle of simulated night flight	The short breaks reduced both objective and subjective sleepiness for at least 15 minutes postbreak and perhaps up to 25 minutes.
Rogers 2004[126]	Errors and rest breaks	Noncomparative study (8)	Survey (5) Daily reports of break duration, patient care responsibilities during break and meal periods, errors and near errors (3)	393 randomly selected full-time hospital staff nurses		No significant difference in number of errors reported by nurses who were relieved of patient care responsibilities during shift and those who were not. Mean duration of break and meal period during shift was 23.8 minutes. Shift duration did not effect duration of breaks and meal periods during the shift.

Source	Safety Issued Related to Clinical Practice	Design Type	Study Design, Study Outcome Measures	Study Setting & Study Population	Study Intervention	Key Finding
Tucker 2003[131]	Injuries and rest breaks	Noncomparative study (8)	Retospective analysis of accident data over a 3-year period (4), number of injuries in each 30-minute interval that preceded a break (every 2 hours) (3)	1,954 employees at an auto assembly plant in the UK		Risk of injury rose in each 30-minute period (n = 4) preceding each scheduled break, then decreased to baseline during the first 30-minute period after the break.
Driskell & Mullen, 2005[209]	Use of napping to improve performance and reduce fatigue	Meta-analysis (1)	Meta-analysis (1) Evaluated the effect of naps on performance, the effect of the nap duration, the effect of the postnap interval (3)	12 studies		Naps improved performance and reduced fatigue. There were no circadian effects on performance and fatigue.
Gillberg 1996[184]	Maintenance of vigilance, napping during work period	Randomized controlled trial (2)	Randomized controlled trial (2) Performance measures, reaction-time tests, and EEG/EOG recordings before, during, and after drive (3)	9 sleep-deprived truck drivers, driving simulator	Subjects assigned to one of three conditions: (1) day drive of 90 min, (2) night driving with 30-min rest period, and (3) night drive with 30-min nap	Effects on driving were small but significant, with a higher variability of sleep and lane positioning. Subjective and objective sleepiness were higher in the night driving conditions. Neither the nap nor the rest period affected performance or sleepiness.
Gillberg 1996[210]	Maintenance of vigilance, napping during daytime	Randomized controlled trial (2)	Randomized controlled trial (2) Cross-over repeated measures design. Karolinska Sleepiness Scale, visual performance task, and continuous EEG/EOG recordings (3)	8 healthy young males, laboratory setting	Sleep restricted to 4 hours at night, randomly assigned to either nap (20 min during mid-day) or no nap condition	Nap decreased subjective sleepiness, improved performance during test period 30 minutes after the nap.
Harma 1989[203]	Maintenance of vigilance, napping prior to shift	Noncomparative study (8)	Survey (5) Individual characteristics, short-term memory, alertness (3)	146 nurses and nursing assistants		Participants who took a nap prior to starting their night shift were less likely to report on-the-job fatigue.

Source	Safety Issued Related to Clinical Practice	Design Type	Study Design, Study Outcome Measures	Study Setting & Study Population	Study Intervention	Key Finding
Purnell 2002[134]	Maintenance of Vigilance, napping during night shift	Randomized controlled trial (2)	Randomized controlled trial (2), counterbalanced cross-over design, performance on neurobehavioral test battery, subjective fatigue, drowsiness driving home after a 12-hour night shift (3)	Worksite in New Zealand, 24 male aircraft maintenance engineers	During experimental week, subjects were given an opportunity to take a 20-minute nap at work between 1 and 3 a.m.; were not allowed opportunity to nap during control week.	20-minute nap significantly improved speed of response on vigilance test on first night shift, but not second night shift. Subjective fatigue ratings, level of sleepiness reported during drive home from work, or subsequent sleep duration and quality.
Rosekind 1994[140]	Maintenance of vigilance, napping during work shift	Randomized controlled trial (2)	Randomized controlled trial (2) vigilance performance testing, ambulatory physiological monitoring of sleepiness (3)	Regularly scheduled trans-Pacific airline flights	Intervention group allowed to take a 40-minute planned nap during cruise over water; control group not allowed a nap	Mean nap duration was 27 minutes. Fewer lapses in vigilance performance in nap group compared to no-nap group, fewer micro-sleep events (34 compared to 120 in the no-nap group), no micro-sleep events during last 30 minutes of flight or when landing compared to 27 micro-sleep events during the last 30 minutes of flight and landing from the no-nap group. Longer naps produced longer periods of alertness. Sleep inertia was not observed in the 1-hour period after the nap.

Source	Safety Issued Related to Clinical Practice	Design Type	Study Design, Study Outcome Measures	Study Setting & Study Population	Study Intervention	Key Finding
Sallinen 1998[138]	Maintenance of Vigilance, napping during night shift	Randomized controlled trial (2)	Randomized controlled trial (2), efficacy of naps during night shift evaluated using visual reaction times, subjective ratings of sleepiness, and physiological sleepiness (3)	14 experienced male shift workers, simulated work shift in laboratory	Subjects randomly assigned to take either a 30-minute or 50-minute nap at 1 a.m. or 4 a.m. Control condition was a shift without a nap.	Naps improved ability to respond to visual signals early in second half of night shift. Physiological sleepiness was improved by the nap at 1 a.m., but not the nap at 4 a.m. Subjective sleepiness somewhat decreased by the naps. Sleep inertia lasted approximately 10–15 minutes.
Bonnet 2005[211]	Maintenance of vigilance, sleep restriction, and use of stimulants	Systematic literature review (11)	High-quality systematic literature review (1) related to the safety and efficacy of five different stimulants	239 papers, most were double-blind clinical trials		Recommend caffeine as initial stimulant of choice due to its availability in multiple forms, widespread use, limited abuse potential, and little impact on sleep several hours later.
De Valck 2001[144]	Maintenance of vigilance, slow-release caffeine	Randomized controlled trial (2)	Randomized controlled trial (2) Cross-over design with sleep restricted subjects (4.5 hours of 7.5 hours time in bed) completed a 45-minute driving task, POMS, and Stanford Sleepiness Scale (3)	12 subjects ages 20–25 years, driving simulator	Subjects randomly assigned to take 300 mg sustained-release caffeine tablet or placebo after 4 hours sleep	Caffeine intake reduced lane drifting, speed deviations, and accident liability. Sleep loss produced significant impairments in driving ability.
De Valck 2003[147]	Maintenance of vigilance, slow-release caffeine, and a nap	Randomized controlled trial (2)	Randomized controlled trial (2) Cross-over design with sleep restricted subjects (4.5 hours of 7.5 hours time in bed) completed a 45-minute driving task, POMS, and Stanford Sleepiness Scale (3)	12 subjects ages 20–25 years, driving simulator	Subjects randomly assigned to take a 30-minute nap, 300 mg slow-release caffeine tablet, or placebo after 4 hours sleep	Both the 30-minute nap and caffeine were successful in counteracting driver sleepiness. Effect of slow-release caffeine lasted longer than the effects of the 30-min nap.

Source	Safety Issued Related to Clinical Practice	Design Type	Study Design, Study Outcome Measures	Study Setting & Study Population	Study Intervention	Key Finding
Gill 2006[152]	Maintenance of vigilance, modafinil	Randomized controlled trial (2)	Randomized controlled trial (2) Cognitive performance, subjective alertness on night shift (3)	25 emergency room physicians	Cross-over design used, all subjects randomly assigned to either modafinil or placebo group. After a 2-week washout period, received either placebo or modafinil.	Although modafinil improved subjective alertness and certain aspects of cognitive function, it made it more difficult fall asleep when arrived home.
Schweitzer 2006[146]	Maintenance of vigilance, napping, and caffeine	Randomized controlled trial (2)	Randomized controlled trial (2) tests the efficacy of napping, caffeine, and the combination of napping and caffeine in laboratory study. Cross-over design (2) for field portion of study. Outcomes included maintenance of wakefulness testing and psychomotor vigilance task (3)	Laboratory study 68 healthy individuals, field study, 53 shift workers (nights and evening shift)	Laboratory study included the following treatments: (1) an evening nap before the first 2 of 4 night shifts, plus placebo; (2) caffeine taken nightly; and (3) the combination of evening naps and caffeine. Field study tested subjects in both of the following conditions: (1) an evening nap prior to the first two of 4 night shifts, plus caffeine taken nightly; and (2) no placebo and no nap group.	Laboratory study—all interventions alone and in combination improved alertness and performance. The combination of napping and caffeine was more effective than individual interventions. Field study—napping plus caffeine improved alertness and performance.

Source	Safety Issued Related to Clinical Practice	Design Type	Study Design, Study Outcome Measures	Study Setting & Study Population	Study Intervention	Key Finding
Wesensten 2005[148]	Maintenance of vigilance, caffeine, dextroamphetamine and modafinil during prolonged sleep deprivation	Randomized trial (2)	Randomized trial (2) Performance testing, Stanford Sleepiness Scale, modified Maintenance of Wakefulness Test, and test of executive functioning	48 healthy young adults, laboratory	Subjects sleep deprived for 85 hour then given 600 mg caffeine, dextro-amphetamine 20 mg, modafinil 400 mg or placebo	Caffeine, dextroamphetamine, and modafinil were equally efficacious for restoring and maintaining cognitive function and alertness during 85 hours of sleep deprivation.
LeDuc 2000[160]	Maintenance of vigilance, exercise	Randomized trial (2)	Randomized trial (2), cognitive testing, subjective alertness, mood, performance testing, and maintenance of vigilance testing (3)	12 aviators	Subjects sleep deprived then assigned to the rest condition (10 minutes) or exercise condition	No beneficial effects from 10-minute rest. Exercise produced transient improvements in alertness (30–50 minutes), but after 50 minutes evidence of increased drowsiness on EEG.

Chapter 41. Preventing Health Care–Associated Infections

Amy S. Collins

Background

The occurrence and undesirable complications from health care–associated infections (HAIs) have been well recognized in the literature for the last several decades. The occurrence of HAIs continues to escalate at an alarming rate. HAIs originally referred to those infections associated with admission in an acute-care hospital (formerly called a nosocomial infection), but the term now applies to infections acquired in the continuum of settings where persons receive health care (e.g., long-term care, home care, ambulatory care). These unanticipated infections develop during the course of health care treatment and result in significant patient illnesses and deaths (morbidity and mortality); prolong the duration of hospital stays; and necessitate additional diagnostic and therapeutic interventions, which generate added costs to those already incurred by the patient's underlying disease. HAIs are considered an undesirable outcome, and as some are preventable, they are considered an indicator of the quality of patient care, an adverse event, and a patient safety issue.

Patient safety studies published in 1991 reveal the most frequent types of adverse events affecting hospitalized patients are adverse drug events, nosocomial infections, and surgical complications.[1, 2] From these and other studies, the Institute of Medicine reported that adverse events affect approximately 2 million patients each year in the United States, resulting in 90,000 deaths and an estimated $4.5–5.7 billion per year in additional costs for patient care.[3] Recent changes in medical management settings have shifted more medical treatment and services to outpatient settings; fewer patients are admitted to hospitals. The disturbing fact is that the average duration of inpatient admissions has decreased while the frequency of HAIs has increased.[4, 5] The true incidence of HAIs is likely to be underestimated as hospital stays may be shorter than the incubation period of the infecting microorganism (a developing infection), and symptoms may not manifest until days after patient discharge. For example, between 12 percent and 84 percent of surgical site infections are detected after patients are discharged from the hospital, and most become evident within 21 days after the surgical operation.[6, 7] Patients receiving followup care or routine care after a hospitalization may seek care in a nonacute care facility. The reporting systems are not as well networked as those in acute care facilities, and reporting mechanisms are not directly linked back to the acute care setting to document the suspected origin of some infections.

Since the early 1980s HAI surveillance has monitored ongoing trends of infection in health care facilities.[8] With the application of published evidence-based infection control strategies, a decreasing trend in certain intensive care unit (ICU) health care-associated infections has been reported through national infection control surveillance[9] over the last 10 years, although there has also been an alarming increase of microorganism isolates with antimicrobial resistance. These changing trends can be influenced by factors such as increasing inpatient acuity of illness, inadequate nurse-patient staffing ratios, unavailability of system resources, and other demands that have challenged health care providers to consistently apply evidence-based recommendations to maximize prevention efforts. Despite these demands on health care workers

and resources, reducing preventable HAIs remains an imperative mission and is a continuous opportunity to improve and maximize patient safety.

Another factor emerging to motivate health care facilities to maximize HAI prevention efforts is the growing public pressure on State legislators to enact laws requiring hospitals to disclose hospital-specific morbidity and mortality rates. A recent Institute of Medicine report identified HAIs as a patient safety concern and recommended immediate and strong mandatory reporting of other adverse health events, suggesting that public monitoring may hold health care facilities more accountable to improve the quality of medical care and to reduce the incidence of infections.[3] Since 2002, four States (Florida, Illinois, Missouri, and Pennsylvania) set legislation mandating health care organizations to publicly disclose HAIs.[10, 11] In 2006, the Association for Professionals in Infection Control and Epidemiology (APIC) reported that 14 States have mandatory public reporting, and 27 States have other related legislation under consideration.[12] Participation in public reporting has not been regulated by the Federal sector at this time. Some hospital reporting is intended for use solely by the State health department for generating confidential reports that are returned to each facility for their internal quality improvement efforts. Other intentions to utilize public reporting may be aimed at comparing rates of HAI and subsequent morbidity and mortality outcomes between different hospitals. This approach is problematic as there is currently a lack of scientifically validated methods for risk adjusting multiple variations (e.g., differences in severity of illnesses in each population being treated) in patients' intrinsic and extrinsic risks for HAIs.[13–15] Moreover, data on whether public reporting systems have an effective role in reducing HAIs are lacking.

To assist with generating meaningful data, process and outcome measures for patient safety practices have been proposed.[13, 14, 16] Monitoring both process and outcome measures and assessing their correlation is a model approach to establish that good processes lead to good health care outcomes. Process measures should reflect common practices, apply to a variety of health care settings, and have appropriate inclusion and exclusion criteria. Examples include insertion practices for central intravenous catheters, appropriate timing of antibiotic prophylaxis in surgical patients, and rates of influenza vaccination for health care workers and patients. Outcome measures should be chosen based on the frequency, severity, and preventability of the outcome events. Examples include intravascular catheter-related blood stream infection rates and surgical-site infections in selected operations. Although these occur at relatively low frequency, the severity is high—these infections are associated with substantial morbidity, mortality, and excess health care costs—and there are evidence-based prevention strategies available.[17, 18]

Definitions of Health Care-Associated Infections

The Centers for Disease Control and Prevention (CDC) developed baseline definitions for HAIs that were republished in 2004.[19] HAIs were defined as those that develop during hospitalization but are neither present nor incubating upon the patient's admission to the hospital; generally for those infections that occur more than 48 to 72 hours after admission and within 10 days after hospital discharge. Some hospitals use these definitions exactly as written; other hospitals may use some but not all of the CDC definitions; and other health care facilities may need to modify or develop their own definitions. Whatever definition is used, it should be consistent within the institution and be the same or similar to those developed by CDC or those used by other investigators. Having standard definitions is useful if the health care facility wants

to compare surveillance results or performance measures within its various medical/surgical specialties, against those of other health care institutions, or with national published data.

Patient Risk Factors for Health Care–Associated Infections

Transmission of infection within a health care setting requires three elements: a source of infecting microorganisms, a susceptible host, and a means of transmission for the microorganism to the host.

Source of Microorganisms

During the delivery of health care, patients can be exposed to a variety of exogenous microorganisms (bacteria, viruses, fungi, and protozoa) from other patients, health care personnel, or visitors. Other reservoirs include the patient's endogenous flora (e.g., residual bacteria residing on the patient's skin, mucous membranes, gastrointestinal tract, or respiratory tract) which may be difficult to suppress and inanimate environmental surfaces or objects that have become contaminated (e.g., patient room touch surfaces, equipment, medications). The most common sources of infectious agents causing HAI, described in a scientific review of 1,022 outbreak investigations,[20] are (listed in decreasing frequency) the individual patient, medical equipment or devices, the hospital environment, the health care personnel, contaminated drugs, contaminated food, and contaminated patient care equipment.

Host Susceptibility

Patients have varying susceptibility to develop an infection after exposure to a pathogenic organism. Some people have innate protective mechanisms and will never develop symptomatic disease because they can resist increasing microbial growth or have immunity to specific microbial virulence properties. Others exposed to the same microorganism may establish a commensal relationship and retain the organisms as an asymptomatic carrier (colonization) or develop an active disease process.

Intrinsic risk factors predispose patients to HAIs. The higher likelihood of infection is reflected in vulnerable patients who are immunocompromised because of age (neonate, elderly), underlying diseases, severity of illness, immunosuppressive medications, or medical/surgical treatments. Patients with alterations in cellular immune function, cellular phagocytosis, or humoral immune response are at increased risk of infection and the ability to combat infection. A person with a primary immunodeficiency (e.g., anemia or autoimmune disease) is likely to have frequently recurring infections or more severe infections, such as recurrent pneumonia.[21] Secondary immunodeficiencies (e.g., chemotherapy, corticosteroids, diabetes, leukemia) increase patient susceptibility to infection from common, less virulent pathogenic bacteria, opportunistic fungi, and viruses. Considering the severity of a patient's illness in combination with multiple risk factors, it is not unexpected that the highest infection rates are in ICU patients. HAI rates in adult and pediatric ICUs are approximately three times higher than elsewhere in hospitals.[22]

Extrinsic risk factors include surgical or other invasive procedures, diagnostic or therapeutic interventions (e.g., invasive devices, implanted foreign bodies, organ transplantations, immunosuppressive medications), and personnel exposures. According to one review article, at least 90 percent of infections were associated with invasive devices.[23] Invasive medical devices bypass the normal defense mechanism of the skin or mucous membranes and provide foci where

pathogens can flourish, internally shielded from the patient's immune defenses. In addition to providing a portal of entry for microbial colonization or infection, these devices also facilitate transfer of pathogens from one part of the patient's body to another, from health care worker to patient, or from patient to health care worker to patient. Infection risk associated with these extrinsic factors can be decreased with the knowledge and application of evidence-based infection control practices. These will be discussed in further detail in Chapter 42, "Targeting Health Care–Associated Infections: Evidence-Based Strategies."

Prolonged hospitalization, due to a higher acuity of illness, contributes to host susceptibility as there is more opportunity to utilize invasive devices and more time for exposure to exogenous microorganisms. These patients are also more susceptible to rapid microbial colonization as a consequence of the severity of the underlying disease, depending on the function of host defenses and the presence of risk factors (e.g., age, extrinsic devices, extended length of stay). Exposure to these colonizing microorganisms is from such sources as (1) endemic pathogens from an endogenous source, (2) hospital flora in the health care environment, and (3) hands of health care workers. A study related to length of hospitalization examining adverse events in medical care indicated that the likelihood of experiencing an adverse event increased approximately 6 percent for each day of hospital stay. The highest proportion of adverse events (29.3 percent) was not related to surgical procedures but linked instead to the subsequent monitoring and daily care lacking proper antisepsis steps.[24]

Means of Transmission

Among patients and health care personnel, microorganisms are spread to others through four common routes of transmission: contact (direct and indirect), respiratory droplets, airborne spread, and common vehicle. Vectorborne transmissions (from mosquitoes, fleas, and other vermin) are atypical routes in U.S. hospitals and will not be covered in this text.

Contact transmission. This is the most important and frequent mode of transmission in the health care setting. Organisms are transferred through direct contact between an infected or colonized patient and a susceptible health care worker or another person. Patient organisms can be transiently transferred to the intact skin of a health care worker (not causing infection) and then transferred to a susceptible patient who develops an infection from that organism—this demonstrates an indirect contact route of transmission from one patient to another. An infected patient touching and contaminating a doorknob, which is subsequently touched by a health care worker and carried to another patient, is another example of indirect contact. Microorganisms that can be spread by contact include those associated with impetigo, abscess, diarrheal diseases, scabies, and antibiotic-resistant organisms (e.g., methicillin-resistant *Staphylococcus aureus* [MRSA] and vancomycin-resistant enterococci [VRE]).

Respiratory droplets. Droplet-size body fluids containing microorganisms can be generated during coughing, sneezing, talking, suctioning, and bronchoscopy. They are propelled a short distance before settling quickly onto a surface. They can cause infection by being deposited directly onto a susceptible person's mucosal surface (e.g., conjunctivae, mouth, or nose) or onto nearby environmental surfaces, which can then be touched by a susceptible person who autoinoculates their own mucosal surface. Examples of diseases where microorganisms can be spread by droplet transmission are pharyngitis, meningitis, and pneumonia.

Airborne spread. When small-particle-size microorganisms (e.g., tubercle bacilli, varicella, and rubeola virus) remain suspended in the air for long periods of time, they can spread to other people. The CDC has described an approach to reduce transmission of microorganisms through

airborne spread in its *Guideline for Isolation Precautions in Hospitals.*[25] Proper use of personal protective equipment (e.g., gloves, masks, gowns), aseptic technique, hand hygiene, and environmental infection control measures are primary methods to protect the patient from transmission of microorganisms from another patient and from the health care worker. Personal protective equipment also protects the health care worker from exposure to microorganisms in the health care setting.

Common Vehicle. Common vehicle (common source) transmission applies when multiple people are exposed to and become ill from a common inanimate vehicle of contaminated food, water, medications, solutions, devices, or equipment. Bacteria can multiply in a common vehicle but viral replication can not occur. Examples include improperly processed food items that become contaminated with bacteria, waterborne shigellosis, bacteremia resulting from use of intravenous fluids contaminated with a gram-negative organism, contaminated multi-dose medication vials, or contaminated bronchoscopes. Common vehicle transmission is likely associated with a unique outbreak setting and will not be discussed further in this document.

Responsibility for Risk Reduction

Infection Control Department's Program Responsibilities

In 1985, the Study of the Efficacy of Nosocomial Infection Control (SENIC) project was published, validating the cost-benefit savings of infection control programs.[8] Infection control programs were proven to be effective as hospitals with certain practices reduced their infection rates by 32 percent, compared with an *increase* of 18 percent in hospitals without these components over a 5-year period.[8, 26] Essential components of effective infection control programs included conducting organized surveillance and control activities, a trained infection control physician, an infection control nurse for every 250 beds, and a process for feedback of infection rates to clinical care staff. These programmatic components have remained consistent over time and are adopted in the infection control standards of the Joint Commission (formerly the Joint Commission on Accreditation of Healthcare Organizations, JCAHO). The evolving responsibility for operating and maintaining a facility-wide effective infection control program lies within many domains. Both hospital administrators and health care workers are tasked to demonstrate effectiveness of infection control programs, assure adequate staff training in infection control, assure that surveillance results are linked to performance measurement improvements, evaluate changing priorities based on ongoing risk assessments, ensure adequate numbers of competent infection control practitioners, and perform program evaluations using quality improvement tools as indicated.

Infection Control Personnel

It has been demonstrated that infection control personnel play an important role in preventing patient and health care worker infections and preventing medical errors. An infection control practitioner[27] (ICP) is typically assigned to perform ongoing surveillance of infections for specific wards, calculate infection rates and report these data to essential personnel, perform staff education and training, respond to and implement outbreak control measures, and consult on employee health issues. This specialty practitioner gains expertise through education involving infection surveillance, infection control, and epidemiology from current scientific publications

and basic training courses offered by professional organizations or health care institutions.[28, 29] The Certification Board of Infection Control offers certification that an ICP has the standard core set of knowledge in infection control.[30, 31, 32]

Over time, the workload responsibilities of the ICP have significantly increased to encompass additional administrative functions and regulatory compliance reporting, sometimes covering prevention of infection activities in other facilities that belong to the health care system (e.g., long-term care, home care, and outpatient settings). The expanding scope of ICP responsibilities being performed with limited time and shrinking resources has created an imbalance in meeting all tasks, leading to regular completion of only essential functions and completing less essential functions when time permits. In a 2002 ICP survey examining resource allocations, the activity consuming the greatest amount of mean estimated time was surveillance, followed by education, prevention strategies to control transmission, infection control program communication, and outbreak control. In examining the tasks and the time allocations necessary to complete essential infection control responsibilities, a recent expert review panel recommended new and safer staffing allocations: 1 full-time ICP for every 100 occupied beds. Further staffing levels and recommendations are included for different types of health care facilities by bed size.[33] To maximize successful completion of current reporting requirements and strategies for the prevention of infection and other adverse events associated with the delivery of health care in the entire spectrum of health care settings, infection control personnel and departments must be expanded.[34]

Nursing Responsibilities

Clinical care staff and other health care workers are the frontline defense for applying daily infection control practices to prevent infections and transmission of organisms to other patients. Although training in preventing bloodborne pathogen exposures is required annually by the Occupational Safety and Health Administration, clinical nurses (registered nurses, licensed practical nurses, and certified nursing assistants) and other health care staff should receive additional infection control training and periodic evaluations of aseptic care as a planned patient safety activity. Nurses have the unique opportunity to directly reduce health care–associated infections through recognizing and applying evidence-based procedures to prevent HAIs among patients and protecting the health of the staff. Clinical care nurses directly prevent infections by performing, monitoring, and assuring compliance with aseptic work practices; providing knowledgeable collaborative oversight on environmental decontamination to prevent transmission of microorganisms from patient to patient; and serve as the primary resource to identify and refer ill visitors or staff.

Prevention Strategies

Multiple factors influence the development of HAIs, including patient variables (e.g., acuity of illness and overall health status), patient care variables (e.g., antibiotic use, invasive medical device use), administrative variables (e.g., ratio of nurses to patients, level of nurse education, permanent or temporary/float nurse), and variable use of aseptic techniques by health care staff. Although HAIs are commonly attributed to patient variables and provider care, researchers have also demonstrated that other institutional influences may contribute to adverse outcomes.[35, 36] To encompass overall prevention efforts, a list of strategies are reviewed that apply to the clinical

practice of an individual health care worker as well as institutional supportive measures. Adherence to these principles will demonstrate that you H.E.L.P. C.A.R.E. This acronym is used to introduce the following key concepts to reduce the incidence of health care–associated infections. It emphasizes the compassion and dedication of nurses where their efforts contribute to reduce morbidity and mortality from health care–associated infections.

Hand Hygiene

…so they shall wash their hands and their feet, that they die not:
and it shall be a statute for ever to them…
Exodus 30:21 Revised Standard Version

Overview. For the last 160 years, we have had the scientific knowledge of how to reduce hand contamination and thereby decrease patient infections from the seminal work on hand washing by the Hungarian obstetrician, Ignaz Semmelweis. Epidemiologic studies continue to demonstrate the favorable cost-benefit ratio and positive effects of simple hand washing for preventing transmission of pathogens in health care facilities.[37, 38] The use of antiseptic hand soaps (i.e., ones containing chlorhexidine) and alcohol-based hand rubs also effectively reduce bacterial counts on hands when used properly. Even though the clear benefits of hand washing have been proven in multiple settings, the lack of consistent hand-washing practices remains a worldwide issue. In a resource-poor area of Pakistan, a recent household hand-washing campaign demonstrated a 50 percent lower incidence of pneumonia in children younger than 5 years compared to households that did not practice hand washing. Children under 15 years in hand-washing households had a 53 percent lower incidence of diarrhea and a 34 percent lower incidence of impetigo. Hand washing with plain soap prevented the majority of illnesses causing the largest number of childhood deaths globally.[39] The World Alliance for Patient Safety, formed by the World Health Organization, has adopted infection reduction programs—in both developed and developing countries—as its first goal.[40, 41] The World Alliance for Patient Safety advocates a "clean care is safer care" program, in which health care leaders sign a pledge to take specific steps to reduce HAIs in their facilities. Hand hygiene is the first focus in this worldwide initiative.

Understaffing and hand hygiene. Hospitals with low nurse staffing levels and patient overcrowding leading to poor adherence to hand hygiene have been associated with higher adverse outcome rates and hospital outbreak investigations.[34, 42, 43] In an ICU setting,[44] it was demonstrated that understaffing of nurses can facilitate the spread of MRSA through relaxed attention to basic infection control measures (e.g., hand hygiene). In a neonatal ICU outbreak,[45] the daily census was above the maximum capacity (25 neonates in a unit designed for 15), and the number of assigned staff members was fewer than the number necessitated by the workload, which resulted in relaxed attention to basic infection-control measures (use of multidose vials and hand hygiene). During the highest workload demands, staff washed their hands before contacting devices only 25 percent of the time, but hand washing increased to 70 percent after the end of the understaffing and overcrowding period. Ongoing surveillance determined that being hospitalized during this period was associated with a fourfold increased risk of acquiring an HAI. These studies illustrate an association between staffing workload, infections, and microbial transmission from poor adherence to hand hygiene policies.

Time demands. A perceived obstacle is that time to complete patient care duties competes with time needed for hand washing, particularly in technically intense settings such as an ICU. Hospital observational studies demonstrate that the frequency of hand washing varies between

hospital wards and occurs an average of 5 to 30 times per shift, with more hand washing opportunities in an ICU.[46] With time limitations due to patient acuity demands or nurse-patient ratios and limited availability of sinks, the use of waterless, alcohol-based hand rubs has been shown to improve health care workers' compliance with hand hygiene practices in the ICU.[47]

Hand washing behaviors. Observational studies have found that on average, health care workers adhere to recommended hand hygiene procedures 40 percent of the time (with a range of 5 to 80 percent).[44] These studies implemented various interventions to improve hand washing, but summarized effects by measuring responses over a short time frame, without demonstrating long-lasting behavioral improvements. Two studies demonstrated the use of multidisciplinary interventions to change the organizational culture on frequency of hand washing that resulted in sustained improvements during a longer followup time period.[48, 49]

Behavioral theories that examine the relationship of multiple factors affecting behavioral choices have been applied to the complex issue of hand washing compliance. These theories illustrate the influence of the individual *intention* to perform hand washing and organizational influences that affect the outcome behavior. The Theory of Planned Behavior has been studied in this context, acknowledging that the intention to wash hands involves a person's (1) attitude whether or not the behavior is beneficial to themselves, (2) perception of pressure from peers, and (3) perceived control on the ease or difficulty in performing the behavior.[50–53] These perceptions are also influenced by the strength of the person's beliefs about the significance of the outcomes of the behavior; the normative beliefs, which involve the individual evaluation of peer expectations; and control beliefs, which are based on a person's perception of their ability to overcome obstacles that obstruct their completion of the behavior.

Monitoring compliance. Although standards for hand hygiene practices have been published with an evidence-based guideline[44] and professional collaborations have produced the *How-to-Guide: Improving Hand Hygiene,*[54] there is no standardized method or tool for measuring adherence to institutional policy. Varying quality improvement methodologies and a lack of consensus on how to measure hand hygiene compliance have made it difficult to determine the effectiveness of hand hygiene expectations within and across health care settings. The Joint Commission has instituted a partnership with major infection control leadership organizations in the United States and abroad to identify best approaches for measuring compliance with hand hygiene guidelines in health care organizations though its Consensus Measurement in Hand Hygiene (CMHH) project. The participating organizations include APIC, CDC, the Society for Healthcare Epidemiology of America, the World Health Organization World Alliance for Patient Safety, the Institute for Healthcare Improvement, and the National Foundation for Infectious Diseases. The final product of this project, due to be completed in early 2008, will be an educational monograph that recommends best practices for measuring hand hygiene compliance.[55]

Summary. Hand hygiene adherence and promotion involve multiple factors at the individual and system level to provide an institutional safety climate for patients and health care staff. Methods used to promote improved hand hygiene require multidisciplinary participation to identify individual beliefs, adherence factors, and perceived barriers. Program successes have been summarized and should be reviewed to establish improved hand hygiene as a priority program at your facility.[44, 56, 57]

Hand Hygiene: Key Points

- The practice of appropriate hand hygiene and glove usage is a major contributor to patient safety and reduction in HAIs. It is more cost effective than the treatment costs involved in a health care–associated infection.
- Joint Commission infection control standards include hand washing and HAI sentinel event review, which are applicable to ambulatory care, behavioral health care, home care, hospitals, laboratories, and long-term care organizations accredited by the Joint Commission.
- Hand hygiene is the responsibility of the individual practitioner and the institution. Developing a patient safety culture backed by administrative support to provide resources and incentives for hand washing is crucial to a successful outcome.
- Hand hygiene promotion should be an institutional priority.
- Select methods to promote and monitor improved hand hygiene. Monitor outcomes of adherence to hand hygiene in association with reduced incidence of HAI.
- Establish an evaluation model to recognize missed opportunities for appropriate hand hygiene.

Environmental Cleanliness

The health care environment surrounding a patient contains a diverse population of pathogenic microorganisms that arise from a patient's normal, intact skin or from infected wounds. Approximately 10^6 flat, keratinized, dead squamous epithelium cells containing microorganisms are shed daily from normal skin,[58] and patient gowns, bed linens, and bedside furniture can easily become contaminated with patient flora. Surfaces in the patient care setting can also be contaminated with pathogenic organisms (e.g., from a patient colonized or infected with MRSA, VRE, or *Clostridium difficile*) and can harbor viable organisms for several days. Contaminated surfaces, such as blood pressure cuffs, nursing uniforms, faucets, and computer keyboards,[59, 60] can serve as reservoirs of health care pathogens and vectors for cross-contamination to patients. Studies have demonstrated that health care workers acquire microorganisms on gloved hands without performing direct patient contact and when touching surfaces near a colonized patient.[59, 61] Another study determined that a health care worker's hand became contaminated after entering a regular patient's room (one who was not on contact precautions) and only touching common surfaces close to the patient (bed rails, bedside table), without direct patient contact. The same hand contact was done by other personnel in unoccupied rooms that had been terminally cleaned after patient discharge. Ungloved hands became contaminated with low levels of pathogenic microorganisms more than 50 percent of the time, even from surfaces in rooms that had been terminally cleaned after patient discharge.[62] It is important to consider this likelihood of hand contamination could occur (contamination would also apply to the external surface of gloves, if worn) and to perform routine hand hygiene to bare hands or ungloved hands to reduce hand contamination before touching clean**,** general-use surfaces (e.g., computer keyboard, telephone, med cart, medical record, cleaning supplies, etc.). Proper disinfection of common surfaces and proper hand hygiene procedures (after direct contact to surfaces or contact with glove usage) is also critically important to reduce direct or indirect routes of transmission.[63] Persistence of environmental contamination after room disinfection can occur and has been recently demonstrated to increase the risk of transmission to the next susceptible room occupants.[64–66]

Thus, patients with known colonization or diseases with multi-drug-resistant organisms or *Clostridium difficile* require Contact Precautions in addition to the Standard Precautions to reduce the risk of transmission from the patient and the contaminated environment to others.

Nurses can ensure clean medical equipment is used between patients and can work with environmental services personnel to maximize clean conditions in and around patient rooms. It is necessary to consistently perform hand hygiene after routine patient care or contact with environmental surfaces in the immediate vicinity of the patient. Infection control procedures are recommended to reduce cross-contamination under the following situations:[67]

1. Use EPA-registered chemical germicides for standard cleaning and disinfection of medical equipment that comes into contact with more than one patient.
2. If *Clostridium difficile* infection has been documented, use hypochlorite-based products for surface disinfection as no EPA-registered products are specific for inactivating the spore form of the organism.
3. Ensure compliance by housekeeping staff with cleaning and disinfection procedures, particularly high-touch surfaces in patient care areas (e.g., bed rails, carts, charts, bedside commodes, doorknobs, or faucet handles).
4. When contact precautions are indicated for patient care (e.g., MRSA, VRE, *C. difficile*, abscess, diarrheal disease), use disposable patient care items (e.g., blood pressure cuffs) wherever possible to minimize cross-contamination with multiple drug-resistant microorganisms.
5. Advise families, visitors, and patients regarding the importance of hand hygiene to minimize the spread of body substance contamination (e.g., respiratory secretions or fecal matter) to surfaces.

A patient safety goal could be to adopt a personal or an institutional pledge, similar to the following: I (or name of health care facility) am committed to ensuring that proper infection control and environmental disinfection procedures are performed to reduce cross-contamination and transmission so that a person admitted or visiting to this facility shall not become newly colonized or infected with a bacterium derived from another patient or health care worker's microbial flora.

Leadership

Health care workers dedicate enormous effort to providing care for complex medical needs of patients, to heal, to continuously follow science to improve the quality of care—all the while consciously performing to the best of their ability to *Primum non nocere* (First, do no harm). Though medical errors and adverse events do occur, many can be attributed to system problems that have impacted processes used by the health care worker, leading to an undesired outcome. Health care workers evaluate their professional impact based on outcomes that demonstrate that medical and nursing orders are completed properly, that a sentinel event did not occur, clinical judgment was properly utilized to improve patient care, and that most patients leave in stable or better health than when they arrived. With all the complicated patient care administered, if the patient did not acquire an infection during a hospitalization, is that an indication that all patient care interactions were practiced aseptically? Or could the lack of infection be attributed to some process interactions where the patient received a microbial exposure that was less than the threshold needed to acquire an infection or, fortuitously, the patient had enough natural immunity to ward off a potential infection? Although success is measured by an outcome with or without infection, we should consistently practice in such a manner to reduce patient exposure to exogenous microorganisms, which would consequently reduce the risk of infection.

Responsibility for risk reduction involves the institution administrators, directors, and individual practitioners. It is clear that leaders drive values, values drive behaviors, and

behaviors drive performance of an organization. The collective behaviors of an organization define its culture. The engagement of nursing leaders to collaborate with coworkers and hospital administrators in safety, teamwork, and communication strategies are critical requirements to improve safe and reliable care. Developed and applied concurrently, they weave a supporting framework for the effective implementation of new technologies and evidence-based practices.[68] If patients are not receiving all the evidence-based care that is indicated (regardless of a noninfectious outcome measure), then we have a professional obligation to demonstrate leadership to develop the methods to improve that care. The challenge is how to develop and sustain the change necessary to translate infection prevention knowledge into everyday clinical practice. As each person accepts his or her role in that responsibility, that leadership and role model example will influence a standard culture and expectation for all health care workers and support personnel to implement best practices.

Each institution must communicate the evidence-based practices to health care staff, have access to expertise about infection control practices, employ the necessary resources and incentives to implement change, and receive real-time feedback of national and comparative hospital-specific data.

> Health care institutions simply must expect more reliable performance of essential infection-control practices, such as hand hygiene and proper use of gloves. It is no longer acceptable for hospitals with substandard adherence to these basic interventions to excuse their performance as being no worse than the dismal results in published reports. Most institutions still tolerate defect or failure rates in hand hygiene of 40 percent or more—levels that would be considered shocking in any other industry[69] (p. 274).

Institution improvements should focus on process improvements that sustain best practices, using multifactorial approaches, and a commitment from the top administration through all levels of staff and employees to implement best practices.[70]

Proper Use of Personal Protective Equipment

Infection control practices to reduce HAI include the use of protective barriers (e.g., gloves, gowns, face mask, protective eyewear, face shield) to reduce occupational transmission of organisms from the patient to the health care worker and from the health care worker to the patient. Personal protective equipment (PPE) is used by health care workers to protect their skin and mucous membranes of the eyes, nose, and mouth from exposure to blood or other potentially infectious body fluids or materials and to avoid parenteral contact. The Occupational Safety and Health Administration's Bloodborne Pathogens Standard states that health care workers should receive education on the use of protective barriers to prevent occupational exposures, be able to identify work-related infection risks, and have access to PPE and vaccinations.[71]

Proper usage, wear, and removal of PPE are important to provide maximum protection to the health care worker. However, PPE may not be 100 percent protective, individual work practices may lead to exposure (e.g., needlestick injury), breaches in PPE might occur, and some breaches may go unrecognized. All PPE should be removed when leaving the patient care area.[25] Gloves prevent gross contamination of the hands when touching body fluids, reduce the likelihood that microorganisms present on the hands of personnel will be transmitted to patients during invasive or other patient care procedures, and reduce the likelihood that hands of personnel contaminated with microorganisms from a patient or a fomite can transmit these microorganisms to another

patient. Gloves may have small, unapparent defects or may be torn during use, and hands can become contaminated during removal of gloves,[72–75] thus hand hygiene is essential before donning another pair of gloves.

Various types of masks, goggles, and face shields are worn alone or in combination to provide barrier protection. A surgical mask protects a patient against microorganisms from the wearer and protects the health care worker from large-particle droplet spatter that may be created from a splash-generating procedure. When a mask becomes wet from exhaled moist air, the resistance to airflow through the mask increases. This causes more airflow to pass around edges of the mask. The mask should be changed between patients, and if at anytime the mask becomes wet, it should be changed as soon as possible. Gowns are worn to prevent contamination of clothing and to protect the skin of health care personnel from blood and body fluid exposures. Gowns specially treated to make them impermeable to liquids, leg coverings, boots, or shoe covers provide greater protection to the skin when splashes or large quantities of potentially infective material are present or anticipated. Gowns are also worn during the care of patients infected with epidemiologically important microorganisms to reduce the opportunity for transmission of pathogens from patients or items in their environment to other patients or environments. When gowns are worn, they must be removed before leaving the patient care area and hand hygiene must be performed.

Improper use and removal of PPE can have adverse health consequences to the health care worker. During the 2003 severe acute respiratory syndrome (SARS) outbreak in Canada, 44 percent of the probable SARS cases were in health care workers. After institutional implementation of SARS-specific infection control precautions, 17 workers developed disease. Fifteen were interviewed to determine their knowledge and work practices that could have contributed to their infection. Only 9 (60 percent) reported they had received formal infection control training; 13 (87 percent) were unsure of the proper order in which to don and remove PPE; 6 (40 percent) reused items (e.g., stethoscopes, goggles, and cleaning equipment) elsewhere on the ward after initial use in the room of a SARS patient; and 8 (54 percent) were personally aware of a breach in infection control precautions. Fatigue and multiple consecutive shifts may have contributed to the transmission.[76]

From the experiences observed during the SARS outbreak, CDC developed training materials to increase the safety of the health care worker environment through improved use of PPE by health care personnel. Posters (bilingual), slides, and video information are available on the CDC Web site: http://www.cdc.gov/ncidod/dhqp/ppe.html.

Consistent Evidence-Based Practices

Professional organizations for infection control and health care epidemiology publish evidence-based guidelines regarding the practice of health care infection control, strategies for surveillance and prevention, and control of HAIs in U.S. health care facilities. These consensus-based scientific publications provide priority recommendations on the basis of the existing scientific data; theoretical rationale; and applicability of well-designed experimental, clinical, or epidemiologic studies to prevent HAIs in different patient care settings. Additionally, the Joint Commission's initiative, Shared Visions—New Pathways 2004 accreditation process, focuses on continuous compliance with its standards, which contributes to health care organizations' maintenance of safe, quality care and improved organizational performance.[77]

Despite the high educational level of health care workers and knowledge of aseptic practices, adherence to published infection control precautions is not consistently applied.[78] In one study, a

self-reported questionnaire demonstrated that although all health care providers knew the appropriate protective barrier equipment required for a particular patient care interaction, their reasons for nonadherence included perceived time constraints (64 percent), inconvenience (52 percent), and presumption that the patient was not infected (34 percent).[79] The observed rate of compliance was inversely related to the years of health care experience.

Translation of evidence-based guidelines into clinical practice may require more than reliance on an individual practitioner's knowledge and intentions. Organizational interventions may be necessary to better understand the barriers that impede the process of effectively reviewing and implementing evidenced-based practices into daily clinical practice.[80–83] Standard policies and standards of practice should be time specific, measurable, and should also define the specific population of patients that will be affected. When the institution implements an evidence-based guideline that updates the current policy, a multidisciplinary intervention should be planned to ensure staff concurrence with the change; agreement that the new approach is crucial; an assurance that there will be adequate staff, knowledge, and resources to implement the change; and a method to evaluate the impact of the change.[84]

Antimicrobial-Resistance Campaign

"In theory, there is no difference between theory and practice. But in practice, there is."
Jan L. A. van de Snepshceut, computer scientist and educator

Background. After the first use of penicillin in the 1950s, antibiotic resistance developed rapidly in some bacteria such as *Staphylococcus aureus.* Over the last several decades, a shift in the etiology of more easily treated pathogens has increased toward more antimicrobial-resistant pathogens with fewer options for therapy. Infections from antimicrobial-resistant bacteria increase the cost of health care, cause higher morbidity and mortality, and lengthen hospital stays compared to infections from organisms susceptible to common, inexpensive antimicrobials. Antimicrobial resistance has continued to emerge as a significant hospital problem affecting patient outcomes by enhancing microbial virulence, causing a delay in the administration of effective antibiotic therapy, and limiting options for available therapeutic agents. In a 2003 Institute of Medicine report, antimicrobial resistance was noted as a paramount microbial threat of the 21st century.[85]

Burden of organisms. Rates of antimicrobial resistance among hospital and community pathogens have increased considerably during the past decade. More than 70 percent of the bacteria that cause hospital-associated infections are resistant to at least one of the drugs most commonly used to treat these infections.[86] According to 2003 National Nosocomial Infections Surveillance System data from ICU patients, 60 percent of *Staphylococcus aureus* isolates were resistant to methicillin, oxacillin, or nafcillin (MRSA)—an 11 percent increase from data reported the year before.[87] There was a nearly 50-percent increase in nonsusceptible *Klebsiella pneumoniae* isolates to 3rd generation cephalosporins between 2002 and 2003. Although the rate of vancomycin-resistant enterococcus (VRE) has shown a less drastic increase than previous years, it still increased 12 percent in 2003 (for a total of 28.5 percent of all enterococci isolates).

Another recent national survey of antimicrobial resistance trends and outbreak frequency was performed among U.S. hospitals (those hospitals having at least 50 beds, both general medical and surgical services, and accreditation by the Joint Commission) using the American Hospital Association annual survey data set.[88] A total of 494 of the 670 hospital laboratories (74 percent) responded. Antimicrobial resistance rates were highest for oxacillin-resistant *Staphylococcus*

aureus (ORSA, also referred to as MRSA) (36 percent); two-thirds of the hospitals reported increasing MRSA rates, 4 percent reported decreasing rates, and 24 percent reported MRSA outbreaks.

Mechanism of antibiotic resistance. The treatment of bacterial infections is not a straightforward process. Bacterial microorganisms are initially susceptible to a new antibiotic, but over time, as use of the antibiotic increases, new generations of the organism will selectively adapt by developing antibiotic resistance. These organisms have the ability to undergo protective spontaneous mutation within themselves or acquire an exogenous antibiotic-resistant gene through genetic transfer from another organism, which enables it to inactivate an antibiotic or nullify its killing activity. The human microbial population includes a combination of susceptible bacteria and antibiotic-resistant bacteria. Antimicrobial usage changes the competitive balance of the microbial population by decreasing the amount of susceptible bacteria, providing an opportunity for resistant bacteria to flourish. Areas within hospitals such as ICUs that have high rates of antimicrobial usage also have the highest rates of antimicrobial resistance.

Patients can acquire an antibiotic-resistant organism through other mechanisms. Increased antibiotic treatments received in community settings can lead to the presence or colonization of antimicrobial-resistant organisms in the community population, which can be introduced into the hospital by patients on admission. These colonized organisms may not be detected if the patient is admitted for noninfectious reasons. This underscores the need for routine hand hygiene after all patient care, not just after care to patients on Contact Precautions. Often, it becomes apparent that silent transmission has occurred when the newly discovered presence of a resistant organism can be traced back to another patient who is later found to have been infected or colonized with the resistant organism. More frequently, however, the exact source of resistant organisms or the source of transmission within the institution remains undetermined.

Prevention of antibiotic-resistant organisms. Authors of evidence-based guidelines on the increasing occurrence of multidrug-resistant organisms propose these interventions: stewardship of antimicrobial use, an active system of surveillance for patients with antimicrobial-resistant organisms, and an efficient infection control program to minimize secondary spread of resistance.[89–91] Antimicrobial stewardship includes not only limiting the use of inappropriate agents, but also selecting the appropriate antibiotic, dosage, and duration of therapy to achieve optimal efficacy in managing infections. A prospective study on hospital mortality due to inadequate antimicrobial treatment demonstrated that the infection-related mortality rate for patients receiving inadequate antimicrobial treatment (42 percent) was significantly greater than the infection-related mortality rate of patients receiving adequate antimicrobial treatment (17.7 percent) in a medical or surgical ICU setting.[92]

Earlier guideline recommendations by professional organizations were published between 1995 and 1997 for the prevention of antimicrobial resistance in hospitals.[93–95] To evaluate the application of the recommendations, a cross-sectional survey was performed to determine what types of antimicrobial-use programs were being used among 47 U.S. hospitals participating in the ICU component of the CDC's National Nosocomial Infections Surveillance System.[96] All 47 hospitals had some established programs, although their practices did not meet all of the published recommendations. For example, one programmatic practice was to consult with an infectious disease physician or pharmacist (used 60–70 percent of the time) to discuss initial antimicrobial options; however, only 40 percent reported a system to measure compliance with administering the recommended antimicrobial agent. The Cochrane Collaboration reviewed 66 published papers to develop "interventions to improve antibiotic prescribing practices for

hospital inpatients."[97] Interventions were aimed at varying outcomes (e.g., increase/decrease treatment, regimen, timing of dosing, restrictive or persuasive methods to reduce unnecessary antibiotic use). Studies showed that about half of the time, hospital physicians were not prescribing antibiotics properly. Nonetheless, most interventions demonstrated some improvement in antibiotic prescribing to reduce antimicrobial resistance or hospital-acquired infections. Hospital campaigns to prevent antimicrobial resistance include steps to (1) employ programs to prevent infections, (2) use strategies to diagnose and treat infections effectively, (3) operate and evaluate antimicrobial use guidelines (stop orders, restrictions, and criteria-based clinical practice guidelines), and (4) ensure infection control practices to reduce the likelihood of transmission.[98] Nurse practitioners have a role as part of the health care team diagnosing and treating infections appropriately and should be familiar with strategies to improve antimicrobial use. All health care workers play a critical role in reducing the risk of transmission.

Based on the factors contributing to antibiotic resistance in health care settings that were identified through data collection, guidelines, professional recommendations, and scientific research, the CDC compiled several tools in 2002 to increase awareness in health care settings. The Campaign to Prevent Antimicrobial Resistance in health care settings utilizes four strategies to increase awareness and encourage the best practices for antibiotic use and interventional programs to prevent resistance: prevent infection, diagnose and treat infection effectively, use antimicrobials wisely, and prevent transmission. Laminated cards, posters, slide sets, and fact sheets that can be used in a health care setting to promote recognition and utilization are listed at http://www.cdc.gov/drugresistance/healthcare/default.htm. A summary of the CDC's 12-step program and specific nursing interventions is provided in Appendix 2.

Summary of key concepts. A program that only scrutinizes and monitors antimicrobial use will not be effective to reduce antimicrobial resistance; it must also implement proper infection control measures and have laboratory, surveillance, and administrative support. The optimal strategy for control of antibiotic-resistant organisms is not the same for every health care facility as this individually depends on the levels of endemic colonization, presence of one or more resistant organisms, and levels of infection (low or outbreak levels). The ICP and hospital epidemiologist at each facility are valuable resources to provide programmatic education and recommend targeted infection control measures (e.g., use of personal protective barriers, hand hygiene resources, patient placement/segregation, and admission surveillance cultures). Similar to the example of antibiotic consultation practices and outcome measures, this plan will have little effect or opportunity to reduce the morbidity and mortality of infectious complications unless there is committed organizational support, including expert recommendations that are adopted into daily practice routines. Nursing personnel have the most patient contact and the most opportunity to interrupt the chain of transmission through adherence to consistent aseptic practices.

Respiratory Hygiene and Cough Etiquette

Respiratory viruses are easily disseminated in a closed setting such as a health care facility and can cause outbreaks that contribute to the morbidity of patients and health care staff. Personnel and patients with a respiratory illness commonly transmit viruses through droplet spread. Droplets are spread into the air during sneezing, talking, and coughing and can settle on surfaces. Transmission occurs by direct contact with mucous membranes or by touching a contaminated surface and self-inoculating mucous membranes. Respiratory viruses can sometimes have aerosol dissemination.

Precautions to prevent the transmission of all respiratory illnesses, including influenza, have been developed.[99] The following infection control measures should be implemented at the first point of contact with a symptomatic or potentially infected person. Occupational health policies should be in place to guide management of symptomatic health care workers.

1. Post visual alerts (in appropriate languages) at the entrance to outpatient facilities instructing patients and escorts (e.g., family, friends) to notify health care personnel of symptoms of a respiratory infection when they first register for care.
2. Patients and health care staff should consistently practice the following:
   a. Cover the nose/mouth when coughing or sneezing.
   b. Use tissues to contain respiratory secretions and dispose of them in the nearest waste receptacle after use.
   c. Perform hand hygiene after having contact with respiratory secretions and contaminated objects or materials.
3. During periods of increased respiratory infection activity in the community or year-round, offer masks to persons who are coughing. Either procedure masks (i.e., with ear loops) or surgical masks (i.e., with ties) may be used to contain respiratory secretions. Encourage coughing persons to sit at least 3 feet away from others in common waiting areas.
4. Health care personnel should wear a surgical or procedure mask for close contact (and gloves as needed) when examining a patient with symptoms of a respiratory infection. Maintain precautions unless it is determined that the cause of symptoms is not an infectious agent (e.g., allergies).

Evaluation

The ICP or a nurse on a specific patient care unit should design a periodic evaluation program of infection control practices, including aseptic technique practices. Evaluation methods include a self-assessment survey of intended practices, direct observational assessments by another health care worker or a patient, and self-completion of checklists that review work practices and identify opportunities for improvement within the health care operations. If deficiencies or problems in the implementation of standardized infection control procedures are identified, further evaluation activities (e.g., root-cause analysis) may be indicated to identify and rectify the contributing factors to the problem.[100]

Most evaluation reviews are generated after a major, life-threatening error occurs, which usually happens infrequently. Historically, when an evaluation determined that a process completed by personnel was deficient, problem-solving efforts focused on the identification of the specific individual(s) who "caused" the problem. Later, quality improvement efforts focused on developing a culture of safety and recognized that additional contributions to errors were due to complex, poorly designed systems. The advantage of an evaluation that reviews system problems is that it encourages health care professionals to report adverse events and near misses that might be preventable in the future, while balancing the identification of system problems with holding individual providers responsible for their everyday practices. Improvement is impossible without evaluation reports to provide data on the factors that contribute to mistakes and lead to subsequent individual and system changes that support safer practices.[101]

An evaluation strategy examining process measures include the following examples:

- Document staff use of maximum sterile barriers (cap, mask, sterile gown, sterile gloves, large sterile sheet) and aseptic technique for the insertion of central intravenous catheters or guidewire exchange.
- Document timing of antibiotic prophylaxis when used in surgical patients (e.g., within 1 hour of incision).
- Document if hand hygiene is performed and clean or sterile gloves are worn before assessing a catheter insertion site or changing a dressing on intravascular catheters.
- Document time elapsed from when patient culture (microbiology and susceptibility) results are reported and when the appropriate isolation precautions are instituted (patient room placement, signs, PPE used, disposable equipment used, medical record documentation, etc.).
- Ensure that staff (nurses, doctors, and housekeeping) enter a contact isolation room using the specified personal protective barriers (e.g., gloves, gown) on each entry.
- Ensure that staff properly remove PPE after leaving a patient's room.
- Assess the annual rates of influenza vaccination for health care workers and other personnel eligible to receive vaccination; assess the rates of influenza vaccination for patients.
- Ensure that needle disposal containers are no more than three-quarters full at time of disposal.
- Periodically monitor and record adherence with the hand hygiene guidelines: the number of times personnel washed their hands divided by the number of hand-hygiene opportunities, computed by ward or by service. Provide feedback to personnel regarding their performance.
- Monitor the volume of alcohol-based hand rub (or detergent used for handwashing or hand antisepsis) used per 1,000 patient days.
- When outbreaks of infection occur, assess the adequacy of health care worker hand hygiene.
- When a patient with a known colonization or infection with a multidrug-resistant organism (e.g., MRSA, VRE) is transferred to your facility, evaluate effectiveness of system notification to health care personnel in the receiving facility.
- Record compliance with hospital policy for catheter-site dressing changes.

Research Implications[*]

1. Research and apply behavioral and management sciences to achieve implementation of evidence-based clinical guidelines and compliance with infection prevention policies.
2. Develop methods to improve the appropriateness of antimicrobial use based on identified antimicrobial control measures and institution microbial susceptibility patterns.
3. Collect data for the economic impact of HAIs and other adverse effects and resulting return of investment for prevention methods.
4. Identify specific components of infection prevention and control programs and staffing in health care institutions that are effective (and cost effective) in reducing rates of infection.

[*] Adapted from Lynch et al. 2001[104] and Aboelela et al. 2006.[105]

5. Improve health care institution information systems for seamless review of appropriateness of infection control-related care based on patient diagnosis.
6. Determine standard indices for measurement of effectiveness and cost of infection control measures.
7. Measure effect of staffing changes (reduced personnel, prolonged work hours, varying levels of formal education) on patient outcomes related to infectious outcomes of morbidity and mortality (e.g., colonization of microorganisms, postoperative wound infections, and catheter-related infections).
8. Design studies so that independent effects of specific interventions can be identified.
9. Monitor the implementation of interventions in a multicenter study to examine a cause-and-effect response and differentiate between efficacy and effectiveness.
10. Develop interdisciplinary research teams to improve the rigor and sophistication of studies conducted.

Conclusions

It is the responsibility of all health care providers to enact principles of care to prevent health care–associated infections, though not all infections can be prevented. Certain patient risk factors such as advanced age, underlying disease and severity of illness, and sometimes the immune status are not modifiable and directly contribute to a patient's risk of infection. Depending on the patient's susceptibility, a patient can develop an infection due to the emergence of their own endogenous organisms or by cross-contamination in the health care setting. Benefits of antimicrobial therapy will alter the microbial flora by reducing one microbial presence but may allow the emergence of another, causing a new infection (e.g., antibiotic-associated diarrhea).

Nurses can reduce the risk for infection and colonization using evidence-based aseptic work practices that diminish the entry of endogenous or exogenous organisms via invasive medical devices. Proper use of personal protective barriers and proper hand hygiene is paramount to reducing the risk of exogenous transmission to a susceptible patient. For example, microorganisms have been found in the environment surrounding a patient and on portable medical equipment used in the room. Environmental surfaces around a patient infected or colonized with a multidrug-resistant organism can also become contaminated. Health care workers should be aware that they can pick up environmental contamination of microorganisms on hands or gloves, even without performing direct patient care. Proper use and removal of PPE followed by hand hygiene will reduce the transient microbial load that can be transmitted to self or to others. Identified aseptic and infection control practices have been proven to reduce the dissemination of organisms to a single patient, to prevent repeated transmissions that contribute to an outbreak situation among multiple patients, or to become established in the health care environment as endemic hospital flora.

Nursing has many complicated scopes of practice, which challenge time management, priority setting, and efficiency of practice. Although system and administrative support is beneficial to supporting aspects of nursing care, direct care is performed by individuals. Every individual nurse focuses on making a difference throughout the daily workloads and enormous responsibilities but changes in a patient's medical condition can become overwhelming. One nurse comes to mind who found the resolve to make significant strides within the patient ward dealing with chronically overwhelming situations. She was administratively responsible for

directing and addressing the challenges of all patients' chronic wound infections, ongoing cross-contamination, lack of needed medical supplies and equipment, severe understaffing, working extra shifts, and still finding time to provide care and comfort to patients. By her personal efforts to improve wound care, aseptic practices, and hand hygiene among all nursing and medical staff, mortality dropped in a dramatic decline from 33 percent to 2 percent within a 9-month period.[102] These sustained and dedicated efforts to reduce patient infections and improve patient care in light of overwhelming adversity set a standard of practice for all nurses to follow. That nurse was Florence Nightingale, defining the art of nursing in the 1850s. Although medical care is more advanced and technically more complex since that time, it was the dedication of a nurse (like you) to ensure aseptic practices despite the significant nursing demands of patient care that makes the difference for the patients—then and now.

National surveys of the public have repeatedly found nursing to be one of the most trusted professions. The public trusts us to provide safe care and employ best practices by following certain principles: (1) to not work while having an infectious illness, (2) to be knowledgeable about the methods to protect our patients from transmission of disease, (3) to perform aseptic practice and monitor patient infections, (4) to participate in quality improvement initiatives to reduce infections, and (5) to provide care even if it means self-risk from infection. As nurses we have an ethical obligation to meet that trust and uphold the highest standards for our patients and the public, whether we are providing direct care, teaching about proper health care, or overseeing nursing practice.[103]

It has been demonstrated that nursing and medical practices can pick up transient microorganisms from intact patient skin and from environmental surfaces. Although the amount of contamination is not quantified and the exact incidence is not apparent, it does occur. Hand hygiene and aseptic practices before caring for a susceptible patient can reduce the transient carriage and transfer of microorganisms. The protective benefits of infection control using evidence-based practices are cost effective and numerous: they not only contribute to the best individual patient care outcome, but also protect health care workers, increase public awareness in all health care settings about infection control issues, and maintain the highest standards in nursing, which positively contributes to our goal for the best possible patient and public health outcomes.

Appendix 2. Campaign To Prevent Antimicrobial Resistance in Health Care Settings

Centers for Disease Control and Prevention

Adapted from information on http://www.cdc.gov/drugresistance/healthcare/default.htm

Strategy	Steps	Related Fact	Nursing Actions
Prevent Infection	1. Influenza and Pneumococcal vaccinations	Predischarge immunizations of at-risk hospital patients and health care personnel will prevent infections.	♦ Give influenza and *pneumococcal* vaccine to at-risk patients before discharge. ♦ Receive annual influenza vaccinations.
	2. Get the catheter out	Catheters and other invasive devices are the # 1 exogenous cause of hospital-onset infections.	Use catheters— ♦ Only when essential. ♦ With proper insertion and care protocols. ♦ Only as long as needed.
Diagnose and Treat Infection Appropriately	3. Target the pathogen	Appropriate therapy (correct regimen, timing, dosage, route, and duration) saves lives.	♦ Culture the patient. ♦ Verify empiric therapy is to a likely pathogen and definitive therapy is treating a known pathogen.
	4. Access the experts	Infectious disease expert collaboration improves the outcome of serious infections.	Incorporate guidance from infectious disease experts into daily care plan. All full-time, part-time, and contract staff should know and utilize recommendations.
Use Antimicrobials Wisely	5. Practice antimicrobial control	Programs to improve antibiotic use are effective.	Know your pharmacy policies on ordering, restrictions, switching, and stopping. Utilize or develop online ordering with computerized decision support/rationale.
	6. Use local data	The prevalence of resistance can vary by time, locale, patient population, hospital unit, and length of stay.	Know the common organisms in your clinical area and the effective antibiotics used to treat each infection.
	7. Treat infection, not contamination	A major cause of antimicrobial overuse is “treatment” based on results of patient cultures that become contaminated.	Utilize proper protocols to collect patient blood and other specimens for culture. Submit to laboratory in proper medium/collection containers and within the recommended time.
	8. Treat infection, not colonization	A major cause of antimicrobial overuse is “treatment” based on colonization.	Be familiar with practice guidelines for clinical assessments of new symptoms (i.e., fever) in critically ill patients and when cultures are warranted.
	9. Know when to say “no” to vanco	Vancomycin overuse promotes emergence, selection, and spread of resistant pathogens.	Be familiar with hospital policy on proper vancomycin utilization and when it should be discouraged (e.g., routine surgical prophylaxis and the exceptions, etc.).

Strategy	Steps	Related Fact	Nursing Actions
	10. Stop antimicrobial treatment	Failure to stop unnecessary antimicrobial treatment contributes to overuse and resistance.	Be aware of the patient's infection status and need for an antibiotic. Stop or don't use antibiotics when ♦ The infection is cured; ♦ Cultures are negative and infection is unlikely; and ♦ Infection is not diagnosed.
Prevent Transmission	11. Isolate the pathogen	Patient-to-patient spread of microorganisms can be prevented.	Practice strict aseptic technique to prevent transmission of organisms. Strict oversight of proper contact precautions when used and proper room disinfection.
	12. Break the chain of contagion	Health care personnel can spread antimicrobial-resistant pathogens from patient to patient.	Clean hands can pick up and transfer microorganisms. Hand hygiene is essential—set an example for others.

Chapter 42. Targeting Health Care–Associated Infections: Evidence-Based Strategies

Ruth M. Kleinpell, Cindy L. Munro, Karen K. Giuliano

Background

Hospitalization for an acute illness, trauma, chronic care, or other health care conditions is a common occurrence. There were 39.2 million hospital discharges in 2005, with an average length of stay of 4.6 days.[1] Hospitalization brings associated risks, including risk of infection. Nosocomial infections, or hospital-associated infections, are estimated to occur in 5 percent of all acute care hospitalizations, or 2 million cases per year.[2] Hospital-associated infections have been identified as one of the most serious patient safety issues in health care.[3]

Infections that become clinically evident after 48 hours of hospitalization are considered hospital-associated.[2] Risks factors for hospital-associated infections are generally categorized into three areas: iatrogenic, organizational, or patient-related. Iatrogenic risk factors include invasive procedures (e.g., intubation, indwelling vascular lines, urine catheterization) and antibiotic use and prophylaxis. Organizational risk factors include such things as contaminated air-conditioning systems, contaminated water systems, staffing (e.g., nurse-to-patient ratio), and physical layout of the facility (e.g., open beds close together). Examples of patient-related risk factors include severity of illness, immunosuppression, and length of stay.[2]

Nosocomial infections more than double the mortality and morbidity risk for hospitalized patients, resulting in an estimated 20,000 deaths a year.[2] Nosocomial infections increase the costs of hospitalization in addition to increasing morbidity and mortality risk. A meta-analysis of 55 studies examining nosocomial infections and infection control interventions determined that attributable costs are significant; costs associated with bloodstream infections (mean = $38,703) and methicillin-resistant *Staphylococcus aureus* infections (mean = $35,367) are the largest.[3]

Most infections in hospitalized patients are endogenous, meaning they are caused by bacteria that have already colonized the patient's digestive tract prior to infection.[4] The majority (60 percent) of infections in patients hospitalized in an intensive care unit (ICU) setting are caused by bacteria already colonizing the patient on admission (primary endogenous). A lesser amount (23 percent) of infections result from bacteria acquired during the ICU stay, leading to colonization before infection (secondary endogenous). A total of seventeen percent of infections are caused by bacteria introduced from the ICU environment that lead to infection without prior colonization (exogenous). Targeting hospital-associated infections is, therefore, a very important aspect of providing quality health care.

This chapter reviews the evidence-based knowledge on health care–associated infections, highlighting important information for nurses caring for hospitalized patients. The review focuses on hospital-associated pneumonia, urinary tract infection, catheter-related bloodstream infection, sepsis, and antibiotic-resistant infection. An evaluation of the literature, including recent research, and evidence-based practices are presented.

Hospital-Associated Pneumonia

Pneumonia is the second most common hospital-associated infection (after urinary tract infection).[5] In critically ill patients, ventilator-associated pneumonia (VAP) is the most common nosocomial infection. VAP doubles the risk of death, significantly increases ICU length of stay, and adds more than $10,000 to each affected patient's hospital costs.[6]

The current evidence-based recommendations by the Centers for Disease Control and Prevention (CDC) for prevention of nosocomial pneumonia were published in 2004.[5] Although some of the interventions to reduce nosocomial pneumonia are the responsibility of physicians or other health care workers, many of the interventions are the direct responsibility of nurses or can be influenced by nurses. Nursing care can directly contribute to prevention of hospital-associated pneumonia, particularly in patients who are most at risk due to advanced age, postoperative status, or mechanical ventilation. The evidence shows that the most important contributions of nursing care to prevention of hospital-associated pneumonia are in four areas: hand hygiene, respiratory care, patient positioning, and education of staff.

Hand Hygiene

Hand hygiene is an essential component of hospital-associated pneumonia reduction. Evidence-based guidelines have been published for general hand hygiene[7, 8] as well as specific hand hygiene measures related to respiratory care.[6]

Excellent evidence exists that alcohol hand rubs effectively reduce the transmission of potential pathogens from health care workers' hands to patients. For hands that are not visibly soiled, alcohol hand rubs are more effective than hand washing with plain or antimicrobial soap.[8, 9] In the health care setting, the preferred method for cleaning visibly soiled hands is washing with water and antimicrobial soap. Gloves should be worn for handling respiratory secretions or any objects contaminated with respiratory secretions.[5] If soiling from respiratory secretions is anticipated, a gown should also be worn. Hand decontamination and glove changes are required between contacts with different patients, as well as in an encounter with a single patient between contacts with a contaminated body site and the respiratory tract or respiratory equipment.

Respiratory Care

Encouraging patients to do deep-breathing exercises is a common component of nursing care to reduce respiratory complications, particularly in postoperative patients. Most research supports this practice, although some controversy remains regarding the effectiveness of deep-breathing exercises versus incentive spirometry in particular patient populations. Thomas and McIntosh[10] conducted a meta-analysis of literature from 1966 through 1992 that focused on the effects of deep-breathing exercises, incentive spirometry, and intermittent positive pressure breathing on pulmonary complications after upper abdominal surgery. They concluded that both deep-breathing and incentive spirometry were more effective than no treatment, but there was no significant difference between any of the three treatments. More recently, a systematic review of postoperative incentive spirometry studies from 1966 through 2000 concluded that there was not enough evidence to support the use of incentive spirometry to reduce postoperative respiratory complications.[11]

Chumillas and colleagues[12] randomized subjects who had upper abdominal surgery to a breathing exercise program or to no breathing exercise. Postoperative pulmonary complications were reduced in the deep-breathing group (7.5 percent versus 19.5 percent in the control group), and the deep-breathing group had fewer postoperative chest radiograph abnormalities ($P = 0.01$). In a study of 456 abdominal surgery patients, Hall and colleagues[13] found that deep-breathing exercises for low-risk patients, and incentive spirometry plus physiotherapy for high-risk patients, was as effective for prevention of postoperative pulmonary complications as incentive spirometry.

Deep breathing also appears to be effective after coronary artery bypass graft (CABG) surgery. Westerdahl and colleagues[14] randomly assigned subjects for the first 4 postoperative days to hourly deep-breathing exercises during the daytime (n = 48) or to no breathing exercises (n = 42). Compared to the control group, the deep-breathing group had smaller atelectasis on spiral CT scan ($P = 0.045$ at the basal level and $P = 0.01$ at the apical level) and significantly smaller postoperative reduction in lung function (forced vital capacity [FVC], $P = 0.01$; forced expiratory volume [FEV1], $P = 0.01$). In contrast, a randomized study of 56 abdominal surgery patients at high risk for postoperative pulmonary complications demonstrated beneficial results of early postoperative mobilization; however, the study produced no statistically significant difference in outcomes when deep breathing and coughing interventions were added to the early mobilization.[15] Based on current evidence, CDC guidelines encourage deep breathing for all postoperative patients and use of incentive spirometry on postoperative patients who are at high risk for pneumonia.[5]

The earliest CDC guidelines addressing nosocomial pneumonia, published in 1981, placed great emphasis on standardization of practices related to care of respiratory equipment, and this area has been a continued focus in subsequent reports. Recommendations related to procedures for cleaning, sterilizing or disinfecting, and maintaining respiratory equipment now have a strong evidence base, and those recommended procedures are presented in detail in the current CDC report.[5] Compliance with those procedures is primarily the responsibility of respiratory therapy, but it requires the cooperation and support of nurses. Many unresolved issues remain regarding optimal procedures for respiratory tract secretion suctioning, including whether sterile or clean gloves should be used when performing endotracheal suctioning, and whether multiuse closed-system suction catheters or single-use open-system suction catheters are more effective in prevention of pneumonia.

Patient Positioning

Elevation of the head of the bed is believed to reduce the risk of gastroesophageal reflux and aspiration of gastric secretions, and thus to reduce risk of hospital-associated pneumonia. Supine position is an independent risk factor for mortality in mechanically ventilated patients[16, 17] and in all ICU patients.[18] Torres and coworkers[19] conducted a randomized crossover study of the effect of semirecumbent versus supine position in 19 critically ill mechanically ventilated adults. After radiolabeling gastric contents, the researchers found higher radioactive counts in endobronchial aspirates when subjects were in a supine position than when in a semirecumbent position ($P = 0.036$). In a similar design, Orozco-Levi and coworkers[20] introduced radio label through nasogastric tubes in 15 mechanically ventilated subjects and obtained radioactive counts in pharyngeal and endobronchial secretions over a 5-hour period in supine and semirecumbent positions. Bronchial radioactive counts were higher at 5 hours in a supine position compared with baseline ($P < 0.05$) and semirecumbency ($P < 0.01$); importantly, significant reflux

occurred by 5 hours even with semirecumbent positioning. These studies support a relationship between head-of-bed position and aspiration of gastric secretions.

Two clinical trials have examined the effect of head-of-bed position on VAP. Prior to the publication of the 2004 CDC guidelines, Drakulovic and coworkers[21] conducted a randomized clinical trial assigning 86 mechanically ventilated ICU subjects to semirecumbent (45 degree) or supine (0 degrees) positions, with position documented once daily. The trial was stopped early because significant findings at an interim analysis showed that the semirecumbent group had lower frequency of clinically suspected pneumonia ($P = 0.003$) and microbiologically confirmed pneumonia ($P = 0.018$) than the supine group. Both supine body position ($P = 0.006$) and enteral nutrition ($P = 0.013$) were identified as independent risk factors for nosocomial pneumonia. A second, larger multicenter trial by van Nieuwenhoven and colleagues[22] was published in 2006. Mechanically ventilated ICU patients were prospectively randomly assigned to a semirecumbent position (45 degrees, n = 109) or standard care (10 degrees, n = 112). Because backrest elevation was continuously electronically monitored during the first week of mechanical ventilation, the researchers were able to document that subjects assigned to 45-degree elevation achieved the target position only 15 percent of the study time, despite intensive efforts to ensure provider compliance. Average elevations (28 degrees in the group assigned to 45-degree elevation, and 10 degrees in the standard-care group) were significantly different between groups ($P < 0.001$), but differences in VAP were not demonstrated.

These two clinical trials of the effect of head-of-bed elevation on VAP differed in several ways that may have affected study outcomes. Important differences existed in the comparison groups, with Draculovic and colleagues assigning subjects to 0 degree elevation, while the subjects assigned to usual care in the van Nieuwenhoven study had an average elevation of 10 degrees. The nosocomial pneumonia rate in the van Nieuwenhoven standard-care group was 6.5 percent, much lower than the 23 percent reported for the Draculovic control group (23 percent). While current evidence and practice guidelines support the elevation of the head of bed to reduce pneumonia risk, additional research is needed to further determine the optimal level for head-of-bed elevation.

Grap and colleagues[23] examined the relationship of backrest elevation to VAP in a descriptive study of 66 subjects over a total of 276 patient days. Backrest elevation was continuously monitored. Mean backrest elevation for the entire study period was 21.7 degrees, but backrest elevations were less than 30 degrees 72 percent of the time, and less than 10 degrees 39 percent of the time. In a statistical model predicting pneumonia risk on study day 4, 81 percent of the variability ($F = 7.31$, $P = 0.003$) was accounted for by the pneumonia score on study day 1, severity of illness, and percentage of time spent at less than 30 degrees in the first 24 hours. Thus, early initiation of elevated backrest may influence outcomes in patients who are at highest risk.

Elevation of the head of the bed for patients at risk is a simple and inexpensive intervention that has the potential to decrease nosocomial pneumonia. Adverse effects of elevating the head of the bed have not been demonstrated in patients who do not have a medical contraindication. However, most evidence suggests that this intervention is not widely used. The effectiveness of turning or lateral rotation remains an unresolved issue. Additional research is needed to identify optimal or sufficient head-of-bed elevation to prevent nosocomial pneumonia, to determine the effects of turning, and to address barriers to implementation of optimal patient positioning.

The Institute for Healthcare Improvement (IHI) outlines a ventilator bundle, or care strategies, to target VAP. A “bundle” is a group of interventions that when implemented

together, produce better outcomes than when implemented individually.[24] The ventilator bundle incorporates evidence-based interventions aimed at reducing VAP incidence, including head-of-bed elevation greater than 20 degrees, assessment of the need for continued mechanical ventilation, and prophylaxis for stress ulcer disease and deep vein thrombosis.[25]

Additional VAP Prevention Measures

Additional measures for VAP prevention include preventing orophyarngeal colonization through oral care and effective endotracheal tube maintenance. Guidelines for VAP prevention recommend maintaining endotracheal tube cuff pressures above 20 cm H20 to ensure minimal leakage.[26] Continuous aspiration of subglottic secretions has also been advocated for preventing microaspiration. A meta-analysis assessing the impact of continuous aspiration of subglottic secretions in five randomized clinical trials found a 50-percent reduction in VAP and a delayed onset in the development of VAP by 6.8 days,[27] yet further research on the use and cost-effectiveness is needed.

Implementation of oral care protocols can be an effective mechanism to target removal of dental plaque and minimize colonization and aspiration of biofilm. Several studies have demonstrated benefits of tooth brushing and oral suctioning.[28–31] Research assessing the impact of chlorhexidine gluconate (CHG) for oral care hygiene has demonstrated beneficial impact with tooth brushing,[31, 32] however additional research is indicated.[33]

Staff Education and Compliance

The CDC urges education of staff and involvement of health care workers at all levels in implementing interventions to prevent hospital-associated pneumonia, and nurses are an essential component of these preventive efforts. The potential for compliance programs to positively affect nosocomial infections was demonstrated by Won and colleagues[34] in their study of hand hygiene. Following an intensive hand hygiene compliance program in a neonatal ICU, which increased hand hygiene compliance from 43 percent to 80 percent, a significant decrease in all nosocomial infections ($P = 0.003$) was documented. The effect was even more apparent for nosocomial respiratory infection ($P = 0.002$), with a significant correlation between hand washing compliance and nosocomial respiratory infections ($r = –0.385$; $P = 0.014$).

Education aimed at reducing the occurrence of VAP using a self-study module on risk factors and practice modifications demonstrated beneficial results in another study.[35] The education program, directed toward respiratory care practitioners and ICU nurses, was developed by a multidisciplinary task force. Fact sheets and posters reinforcing the study module information were distributed in an urban teaching hospital. Following implementation of the education intervention, the rate of VAP decreased from 12.6 per 1,000 ventilator days to 5.7 per 1,000 ventilator days, a decrease of 57.6 percent ($P < 0.001$).

In addition to promoting best practices for the care of ventilator patients, nurses should advocate for physician practices that reduce the risk of hospital-associated pneumonia. The use of noninvasive modalities whenever possible (for example, positive pressure ventilation by face mask to reduce endotracheal intubation) and removal of invasive devises when they are no longer necessary are important considerations. The IHI bundle focuses on daily assessment of the need for mechanical ventilation as one mechanism for removing invasive devices when indicated. Nurses can also help to educate all hospital personnel about procedures to prevent

pneumonia that are appropriate to the worker's level of responsibility. Table 1 outlines evidence-based guidelines for hospital-associated pneumonia prevention and management, including nursing-based care.

Urinary Tract Infections

The use of indwelling urinary catheters is common in the hospital setting. Urinary tract infection (UTI) is the most common hospital-associated infection, and a major associated cause is indwelling urinary catheters.[36] UTIs account for about 40 percent of hospital-associated infections, and an estimated 80 percent are associated with urinary catheters.[37] Almost 1 million episodes of nosocomial UTI occur each year in the United States,[38] and the most important risk factor is the presence of an indwelling urinary catheter.[39] Biofilm formation by uropathogens on the urinary catheter have been implicated as the underlying cause of catheter-associated UTI.[40] Adverse consequences of a catheter-associated UTI include local and systemic morbidity, secondary bloodstream infection, increased costs, and mortality.[41] In the hospital setting, the ICU has the highest prevalence of nosocomial UTIs with an estimated rate of 8–21 percent.[39] Guidelines for the prevention of catheter-associated UTIs issued by the CDC outline several recommendations, including appropriate use of indwelling catheters, education of personnel on proper catheter insertion using aseptic technique and sterile equipment, and maintenance to ensure closed sterile drainage (see Table 2).[42]

Due to increased risk of infection associated with urinary catheters, a number of practices have been evaluated in an attempt to reduce the incidence of urinary catheter-related infections.[38] These include alternative approaches to use of urinary catheters and antimicrobial urinary catheters.

Alternative Approaches to Urinary Catheterization

A Cochrane systematic review has investigated the advantages and disadvantages of alternative approaches to indwelling catheters for short-term bladder drainage in adults.[37] Of 17 randomized clinical trials, 14 compared indwelling urethral catheterization with suprapubic catheterization, and 3 trials compared indwelling urethral catheterization with intermittent catheterization. Patients managed with an indwelling urinary catheter had higher incidences of bacteriuria (relative risk [RR] = 2.60, 95% confidence interval [CI] = 2.12–3.18), more frequent recatheterizations (RR = 4.12, 95% CI = 2.94–7.56), and more reports of patient discomfort (RR = 2.98, 95% CI = 2.31–3.85). Of the trials assessing indwelling urethral catheters with intermittent catheterization, fewer cases of bacteriuria were found in patients receiving intermittent catheterization (RR = 2.90, 95% CI = 1.44–5.84). The results of the systematic review indicate that suprapubic catheters have advantages over indwelling urinary catheters in terms of incidence of bacteriuria, recatheterization, and patient reports of discomfort. Intermittent catheterization was also associated with a lower risk of bacteriuria compared to indwelling urinary catheters, but supported with limited evidence. However, suprapubic catheterization typically involves percutaneous placement of a urinary catheter directly into the bladder, a technique that is considered minor surgery;[38] therefore, the practical application of this alternative measure is questionable. A previous review of studies assessing the efficacy of suprapubic catheters with standard noncoated catheters also substantiated lower rates of bacteriuria for suprapubic catheters, but highlighted that mechanical complications—including

catheter dislodgement, obstruction, and failed introduction—can occur. The review could not substantiate the overall benefit of routine suprapubic catheterization.[38]

Antimicrobial Catheters

A variety of specialized urethral catheters have been designed to reduce the risk of catheter-associated UTI. These include antiseptic-impregnated catheters and catheters coated with silver alloy or nitrofurazone.[36, 41] A Cochrane systematic review has examined 18 clinical trials to assess the different types of urethral catheters for the management of short-term catheter use in hospitalized patients.[36] Silver oxide catheters were not associated with a statistically significant reduction in bacteriuria, but the confidence intervals were wide (RR = 0.89, 95 percent CI = 0.68–1.15). Silver alloy catheters were found to significantly reduce the incidence of bacteriuria (RR = 0.36, 95 percent CI = 0.24–0.52). The results of the review indicated advantages from silver alloy catheters, including an economic benefit compared to standard catheter use. A previous review of four clinical trials studies assessing silver alloy catheters also substantiated a significant reduction in the development of catheter-associated bacteriuria.[38]

Another systematic review of antimicrobial urinary catheters in the prevention of catheter-associated UTI in hospitalized patients analyzed 12 clinical trials of nitrofurazone-coated or silver alloy-coated urinary catheters. Both nitrofurazone-coated and silver alloy-coated catheters reduced the development of bacteriuria in comparison with latex or silicone control catheters.[41] However data on comparative efficacy is lacking as no trial directly compared nitrofurazone-coated and silver alloy-coated catheters. While evidence exists to support the use of antimicrobial urinary catheters in preventing bacteriuria in hospitalized patients during short-term catheterization, estimates on cost-effectiveness have not been established.[41] Additional strategies for preventing catheter-associated UTI—including hand-held bladder scanners, computerized order/entry system prompts, and education on appropriate use of indwelling urinary catheter—have also proved beneficial.[43]

Table 2 outlines evidence-based strategies for UTI prevention. Nursing-related care aspects include thorough assessment to determine need for indwelling catheter use, aseptic insertion technique, indwelling catheter care to minimize infection risk, and astute monitoring of patients with urinary catheters for signs of UTI. All of these are important measures to decrease the risk of catheter-associated UTI.

Catheter-Related Bloodstream Infection

Central venous catheters (CVCs) are frequently used in hospitalized patients and they carry associated risks, the most common being bloodstream infection (BSI). According to the CDC, up to 250,000 hospital-associated catheter-related bloodstream infections (CR-BSIs) occur annually in U.S. hospitals, with approximately 80,000 of these occurring in ICUs.[44] CVCs of all types are the most frequent cause of nosocomial BSIs.[45]

A CR-BSI is defined as the presence of bacteremia in a patient with an intravascular catheter with at least one positive blood culture and clinical signs of infections (i.e., fever, chills, and/or hypotension), with no apparent source for the BSI except the catheter. Specific criteria for CR-BSI include either a positive culture with the same organism isolated from the catheter and peripheral blood, simultaneous blood cultures with a $\geq$ 5:1 ratio of catheter versus peripheral culture, or a differential period of catheter culture versus peripheral blood culture positivity of >

2 hours.[46] A BSI is considered to be associated with a central line if the line was in place during the 48-hour period before development of the BSI.[46] Although CVSs account for only a small percentage of all intravenous lines, they cause most CR-BSIs.[47] The most common mechanism of CVC-BSI is migration of the organism from the insertion site along the surface of the catheter and colonization of its distal part.[48] CR-BSIs can also occur from contamination of the catheter hub or infusate administered through the device.[45]

Several practices have been evaluated in an attempt to reduce the incidence of CVC-BSI. These include the use of antimicrobial catheters, antimicrobial-impregnated dressings, and interventions related to catheter insertion and maintenance.

Antimicrobial Catheters and Dressings

Catheters impregnated or coated with antimicrobials or antiseptics have been shown to decrease the risk of CVC-BSI. Multiple randomized controlled trials and several meta-analyses have demonstrated that catheters coated on the external surface with chlorhexidine/silver sulfadiazine or minocycline/rifampin reduce the risk for CVC-BSI compared with standard noncoated catheters.[49–52] Chlorhexidine-impregnated dressings have also been found to reduce the rate of CVC colonization.[48] While evidence for the efficacy of CVC catheters coated with antibacterial or antiseptic agents exists, limited information exists related to their cost-effectiveness. Current CDC recommendations include use of CVC catheters coated with antibacterial or antiseptic agents for high-risk patients or situations in which CR-BSI rates are high despite careful attention to guidelines.[52]

Catheter Insertion and Maintenance Interventions To Reduce CVC-BSI

CVC-BSIs often result from contamination of the catheter during insertion.[52] Maximum sterile barrier precautions during insertion are indicated to reduce the incidence of CVC-BSI. Effective barrier precautions include the use of sterile gloves, long-sleeved gowns, full-size drape, masks, and head covers by all personnel involved in the central line insertion procedure.[52]

In addition to maximal barrier precautions during insertions, the 2002 CDC guidelines for the prevention of CVC infections outline other evidence-based practices, including the following:[53]

1. Use of a 2-percent chlorhexidine preparation as the preferred skin antiseptic prior to insertion
2. Education and training of staff who insert and maintain intravenous lines
3. No routine replacement of central lines at scheduled intervals

Additional measures advocated for best practices for CVC care include hand hygiene by washing hands with conventional antiseptic-containing soap and water or with waterless alcohol-based gels or foam before and after palpating insertion sites; and before and after insertion, replacing, accessing, or dressing a CVC.[53] Avoidance of antibiotic ointment at insertion sites, which can promote fungal infections and antibiotic resistance, and restricted use of stopcocks on any tubing other than pressure tubing to minimize contamination are also recommended.[53] Either sterile gauze or transparent, semipermeable dressings can be used, as research has demonstrated similar risks of CVC-BSI.[53] Gauze dressings should be replaced every 2 days and transparent dressings every 7 days or when the dressing becomes damp, loose, or soiled.[53, 54]

The IHI has also published a central line bundle to reduce CVC-BSI.[55] The components of the central line bundle include hand hygiene to prevent contamination of central lines, maximal

barrier precautions and CHG antisepsis for central line insertion, optimal catheter site selection with the subclavian vein as the preferred site for nontunneled catheters, and daily review of line necessity with removal of unnecessary lines.[55]

Educational measures related to CVC insertion and maintenance have proven effective in several studies.[56–58] Focused aspects of education included proper insertion and maintenance, a catheter insertion cart, a checklist to ensure adherence to evidence-based guidelines, and empowering nurses to stop the catheter insertion procedure if a violation of guidelines is observed. Table 3 outlines evidence-based strategies for CVC-BSI prevention. Nursing-related care aspects include maximal barrier precaustings during CVC insertion; maintenance of central line site to minimize infection risk; prevention of contamination of CVC ports during blood sampling, infusion of intravenous fluids, or medication administration; maintenance of sterile technique for dressing changes; intravenous tubing changes based on protocol guidelines; and astute monitoring of patients with central lines for signs of infection.

Sepsis

Sepsis, or clinical manifestation of the systemic response to infection, represents a significant condition that results in increased mortality for hospitalized patients. The incidence of sepsis is increasing, with more than 750,000 cases occurring in the United States each year.[59] Severe sepsis, which occurs when sepsis progresses to involve acute organ dysfunction, results in more than 200,000 annual fatalities, and the number of cases are projected to increase.[59] Epidemiological studies indicate that between 11 percent and 27 percent of ICU admissions have severe sepsis, with mortality rates ranging from 20 percent to more than 50 percent.[59–62] As infections can progress to sepsis, heightened monitoring of hospitalized patients for signs of sepsis are indicated for any patient with a suspected or confirmed infection. Focal areas pertinent to sepsis include monitoring, treatment, and prevention.

Monitoring for Sepsis Risk

Many risk factors exist for the development and progression of sepsis, including advanced age, compromised immune system response, chronic illness, broad spectrum antibiotic use, and exposure to infection risk associated with surgical and invasive procedures.[63] The severity of sepsis varies widely. Some patients experience a controlled inflammatory response to systemic infection.[64] However, the majority of patients with sepsis develop organ dysfunction (severe sepsis) with hypotension and a resultant state of decreased tissue perfusion. In addition to inflammation, severe sepsis is associated with activation of coagulation and impairment of fibrinolysis, which further impairs perfusion. The development of organ system failure can occur in the initial stages of severe sepsis, but the duration and progression of organ failure are influential in predicting survival.[65] Septic shock is the most severe form of sepsis: hypotension is resistive to fluid resuscitation, a condition which is often associated with high mortality rates.[64] Identified risk factors for increased mortality in sepsis include the microbiological etiology of sepsis; the site of the infection, with increased mortality associated with intra-abdominal or lower respiratory tract infections; presence of underlying disease; presence of shock; need for vasopressors; multiple organ failure; and neutropenia.[66] Many factors contribute to multiple organ dysfunction syndrome in sepsis, including inadequate tissue/organ perfusion, cellular injury, ischemia, and diffuse endothelial cell injury.[63] The progression of sepsis can be deterred

by early recognition and treatment, including early goal-directed therapy focusing on establishing adequate perfusion and targeted measures for sepsis treatment.[24, 67]

Treatment of Sepsis

The Surviving Sepsis Campaign evidence-based guidelines for the treatment of sepsis were released in 2004 and have been promoted to improve outcomes for patients with severe sepsis.[24, 68] The guidelines outline recommendations for targeting treatment of patients at risk of developing severe sepsis and septic shock. The guideline recommendations are aimed at providing resuscitation for sepsis-induced hypoperfusion and enhancing perfusion, antibiotic administration to combat infection, cultures to identify the source of infection, mechanical ventilation to optimize oxygenation, and source control to contain the infection. Additional treatment practices include glycemic control, steroid administration for adrenal insufficiency, prophylaxis measures for deep vein thrombosis and stress ulcer prevention, renal replacement therapies, administration of recombinant human activated protein C (rhAPC), blood product administration, sedation and analgesia, and consideration for limitation of support in critically ill patients.[68] These evidence-based guidelines are outlined in Table 4.

Bundles are also established for recognition and treatment of severe sepsis. The severe sepsis bundles are categorized into 6- and 24-hour bundles. The 6-hour bundle outlines the following interventions, which should be implemented immediately and within the first 6 hours of identification of severe sepsis:

1. Measure serum lactate.
2. Obtain blood cultures prior to antibiotics.
3. Administer broad-spectrum antibiotics within 3 hours from time of presentation in the emergency room and 1 hour for nonemergency room ICU admissions.
4. For hypotension and/or lactate > 4 mmol/L,
    a. Administer an initial minimum of 20 ml/kg of crystalloid (or colloid equivalent).
    b. Administer vasopressor for hypotension not responding to initial fluid resuscitation to maintain mean arterial pressure $\geq$ 65 mm Hg.
5. With persistent hypotension despite fluid resuscitation and/or lactate > 4 mmol/L,
    a. Achieve a central venous pressure (CVP) $\geq$ 8 mm Hg.
    b. Achieve a central venous oxygen saturation ($S_{CV}O_2$) of $\geq$ 70 percent.

The 24-hour bundle outlines the following interventions, which should be implemented immediately and within the first 24 hours of identification of severe sepsis:

1. Administer low-dose steroids for septic shock based on a standardized ICU policy.
2. Administer drotrecogin alfa (activated) based on a standardized ICU policy.
3. Maintain glucose control $\geq$ lower limit of normal, but < 150 mg/dL.
4. Maintain inspiratory plateau pressures < 30 mm H_20 for mechanically ventilated patients.

Implementation of the Surviving Sepsis Campaign guidelines, including the sepsis bundles, can favorably influence the course of sepsis. Additional focused approaches to the management of sepsis include early rapid-resuscitation shock protocols,[69] comprehensive interdisciplinary sepsis treatment protocols,[70] and algorithm-based or goal-directed care.[71]

Prevention of Sepsis

Nursing-related implications for early detection and treatment of sepsis include assessing patients for signs of infection, obtaining cultures for suspected infection, providing medical treatments for sepsis, and infection-prevention measures.[72] Awareness of the risk factors, clinical signs and symptoms, pathophysiology, and updates in the management of sepsis can enhance the nursing care for patients with severe sepsis and promote best practices for sepsis care in the ICU. Infection-prevention measures for sepsis include general infection control practices, hand-washing principles, and measures to prevent nosocomial infections (oral care and proper positioning to prevent nosocomial pneumonia, care of invasive catheters, skin care, wound care, identifying patients at risk for infection, prioritizing cultures for patients with suspected infection, and providing astute clinical assessment for early detection of sepsis).[73] Table 5 outlines general infection-prevention measures, highlighting nursing care considerations. A Cochrane systematic review is currently underway to assess the impact of the use of preoperative bathing or showering with skin antiseptics in reducing surgical-site infections.[74] Keeping up to date with evidence-based and research practices aimed at preventing health care–associated infections is an additional essential aspect of nursing care.

Antibiotic-Resistant Infections

Both the CDC and the World Health Organization have identified antibiotic resistance as an important public health concern.[75] The emergence of antimicrobial resistance in hospitals has been attributed to antibiotic use patterns as well as the capability of bacterial strains to develop resistance mechanisms through genetic alterations.[76] It is estimated that up to 50 percent of antibiotic use in hospitals is inappropriate.[77] According to the CDC, more than 70 percent of the bacteria that cause hospital-associated infections are resistant to at least one of the drugs most commonly used to treat them.[78]

When compared to infections caused by susceptible bacteria, infections caused by multidrug-resistant bacteria are associated with higher incidences of mortality, morbidity, and increased hospital length of stay.[77] Hospitalized patients who contract an infection with an antibiotic-resistant organism also have more costly management and therapies, and encounter more medical complications, than patients who do not acquire an infection or become infected with sensitive organisms.[79–80]

Data from many sources, including the CDC, indicate that antibiotic resistance to all the commonly used drug classes is increasing.[79] For example, between 1998 and 2003, the following increases in resistant organisms have occurred in critically ill patients: 11 percent increase in methicillin-resistant *Staphylococcus aureus* (MRSA); 12 percent increase in vancomycin-resistant *enterococci* (VRE); 47 percent increase in 3rd generation cephalosporin-resistant *Kliebsiella pneumoniae*; and a 20 percent increase in 3rd generation cephalosporin-resistant *Pseudomonas aeruginosa*.[81] An additional nosocomial infection that has been linked to antibiotic use in the hospital setting is *Clostridium difficile* (*C. difficile*). Although *C. difficile* is not an antibiotic-resistant infection, increased incidences in hospitalized settings have heightened awarenes.[82]

Because of the widespread increases in resistant organisms with the concomitant difficulties associated with treatment and complications, addressing the issue of resistant organisms has become one of the CDC's major concerns. Several main areas of focus for the prevention of

antibiotic-resistant infections include control of antibiotic use, determining the right antibiotic, and control of patient-to-patient spread.

Control of Antibiotic Use

Antibiotics are effective in treating infections because they kill or inhibit the growth of susceptible bacteria; however, they are not effective against viral infections. In an ever-increasing number of instances, one of more of the bacteria causing the infection are able to survive. Those bacteria are then able to multiply and begin to proliferate a new strain of bacteria that have developed the inherent ability to survive in the presence of the antibiotics that are designed to eradicate them. The more exposure bacteria have to various antibiotics, the more likely it is that resistant organisms develop.

According to the CDC, the biggest contribution to the development and continuing increase in resistant organisms is the overuse of antibiotics. Therefore, decreasing inappropriate antibiotic administration is the best way to control resistance. In 1995, the CDC[83] launched a national campaign to reduce antimicrobial resistance. The two major goals of this campaign are (1) to reduce inappropriate antibiotic use, and (2) to reduce the spread of resistance to antibiotics. Following are the three major CDC recommendations for supporting and achieving these goals:

- Prescribe antibiotic therapy only when it is likely to be beneficial.
- Use an agent that targets the likely pathogens.
- Order the antibiotic for the appropriate dose and duration.

Determining the Right Antibiotic

To effectively reduce antimicrobial resistance, prescribing health care providers must keep themselves informed about the most common infectious organisms present in the patient populations that they treat. For example, both VAP and hospital-associated pneumonia due to MRSA are becoming more common, and treatment strategies have emerged. Data compiled by an expert panel of the American Thoracic Society[26] support the following recommendations:

1. Apply early, appropriate, broad-spectrum antibiotic therapy at adequate doses; avoid excessive antibiotics through appropriate antibiotic deescalation.
2. Empiric regimens should include agents from a different antibiotic class than the patient has recently received.
3. Combination therapy should be used judiciously.
4. Linezolid may be an appropriate alternative to vancomycin.
5. Shorten antibiotic duration to the minimum effective period, and use short-course therapy whenever possible.
6. Use local microbiologic data to adapt treatment recommendations to the clinical setting.

Research has demonstrated the benefit of focused interventions aimed at improving antibiotic prescribing practices for hospital patients. A Cochrane systematic review of 66 studies revealed that interventions to improve antibiotic prescribing, dosing, timing of first dose, and duration of treatment are successful in reducing antimicrobial resistance.[77] Specific interventions included distribution of educational materials; reminders provided verbally, on paper, or by computer; formulary restrictions; therapeutic substitutions; automatic stop orders; antibiotic policy change strategies, including cycling, rotation, and crossover studies; computerized order entry; and Web-based antimicrobial approval systems.[77, 84] Other strategies, such as selective decontamination of

the digestive tract and use of CHG for daily bathing of hospitalized patients, have demonstrated efficacy in single-site controlled trials, but require further study.[4, 85]

Control Patient-to-Patient Spread

Controlling the patient-to-patient spread of bacteria is one of the least expensive, most basic, and effective means for controlling the spread of resistant organisms. Both MRSA and VRE, two of the most troublesome resistant organisms, are spread primarily from person-to-person contact. In hospitalized patients, this includes transmission by the hands of a health care provider caring for an infected patient. Diligent hand washing is therefore of the utmost importance, and nurses can have a major influence. Both MRSA and VRE can also survive on equipment and surfaces, such as floors, sinks, and blood pressure cuffs.

Specific CDC recommendations to prevent the spread of antimicrobial-resistant infections in hospitalized patients are outlined in Table 6. Focused measures include monitoring antimicrobial resistance of both community and nosocomial isolates on a regular basis, monitoring use of antimicrobials, increasing clinical staff awareness, and use of the CDC's guidelines for isolation precautions in hospitals.[76, 78] Preventative nursing care measures are essential in minimizing infection risk for hospitalized patients. Table 5 outlines additional essentials of infection-prevention measures for reducing the risk of health care associated infection among hospitalized patients.

Evidence-Based Practice Implications

Implementation of evidence-based practices, such as those that follow, can have a significant impact on lowering the incidence of health care–associated infections:

- Preventing health care–associated infections is an important component of ensuring a safe health care environment for hospitalized patients.
- Hand hygiene is an essential aspect of hospital-associated infection-reduction strategies.
- Nursing care measures can directly contribute to prevention of central line infections, urinary tract infections, sepsis, and antibiotic-resistant infections.
- Nursing care can directly contribute to prevention of hospital-associated pneumonia, particularly in patients who are most at risk related to advanced age, postoperative status, or mechanical ventilation. The evidence shows that the most important contributions of nursing care to prevention of hospital-associated pneumonia are in four areas: hand hygiene, respiratory care, patient positioning, and education of staff.
- Nursing-related care aimed at preventing urinary tract infections includes thorough assessment to determine need for indwelling catheter use, aseptic insertion technique, indwelling catheter care to minimize infection risk, and astute monitoring of patients with urinary catheters for signs of infection.
- Nursing-related measures to reduce the incidence of central line-associated infections include ensuring maximal barrier precautions during line insertion, maintenance of the central line site to minimize infection risk, prevention of contamination of central line ports during blood sampling, and maintenance of sterile techniques for dressing changes.

- Infection-prevention measures for sepsis include general infection control practices, hand-washing principles, and measures to prevent nosocomial infections (oral care and proper positioning to prevent nosocomial pneumonia, care of invasive catheters, skin care, wound care, identifying patients at risk for infection, prioritizing cultures for patients with suspected infection, and providing astute clinical assessment for early detection of sepsis).
- The main areas of focus for the prevention of antibiotic-resistant infections include control of antibiotic use, determining the right antibiotic, and control of patient-to-patient spread.
- Controlling patient-to-patient spread of infection with hand hygiene and general infection control practices are the most effective means for controlling the spread of resistant organisms.
- Keeping up to date with evidence-based and research practices aimed at preventing health care–associated infections is an essential aspect of nursing care.

Research Implications

Given the gaps in the current evidence base, additional research is needed in the following areas:

1. Continuous aspiration of subglottic secretions for VAP prevention
2. Semirecumbent position for VAP prevention
3. Silver alloy-coated catheters to prevent hospital-associated UTI
4. Suprapubic catheters to prevent hospital-associated UTI
5. Strategies to ensure use of full barrier precautions (gowns and gloves, dedicated equipment, dedicated personnel) during central line insertion
6. Tunneling short-term CVCs to decrease central line infections
7. Antibiotic limitations on hospital-associated infections due to antibiotic-resistant organisms
8. Strategies to promote appropriate antibiotic administration in hospitals, including the use of informatics technology (e.g., computer-assisted decision support) to assist in point-of-care prescribing and patient-outcome monitoring
9. Source control measures such as chlorhexidine gluconate for bathing, oral care protocols, and selective decontamination of the digestive tract
10. Strategies to improve hand-washing compliance (education/behavior change, sink technology and placement) to reduce hospital-associated infections

Conclusion

A number of factors can lead to the development of health care–associated infections in the hospital setting, including increasing patient acuity levels, chronically ill and acutely ill patients who harbor antibiotic-resistant bacteria, and frequent use of broad-spectrum antibiotics. Health care–associated infections can significantly impact patient outcomes, including morbidity and mortality rates, length of hospital stay, and costs of care. Therefore, focusing on health care–associated infections is an important aspect of providing quality health care.

A targeted approach to infection in hospitalized settings includes prevention measures, early recognition and treatment of infection, appropriate use of antimicrobials, and measures to prevent the transmission of infection among hospitalized patients. This chapter has reviewed the evidence-based knowledge on health care–associated infections—including hospital-associated pneumonia, urinary tract infection, catheter-related bloodstream infection, sepsis, and antibiotic-resistant infections—highlighting important information for nurses caring for hospitalized patients. Nurses can play a key role in the prevention, identification, and management of infections in hospitalized patients through the use of evidence-based measures to ensure a safe health care environment for hospitalized patients.

Table 1. Evidence-Based Guidelines for Prevention and Management of Hospital-Associated Pneumonia

- Hand hygiene as an essential component of hospital-associated pneumonia reduction.
- Respiratory care with encouragement of deep-breathing exercises.
- Head-of-bed elevation to between 30 and 45 degrees.
- Daily assessment of readiness for extubation.
- Control of oral-tracheal secretions and oral care to minimize colonization and aspiration of biofilm.
- Staff education about the significance of nosocomial pneumonias in patients and how interventions can reduce VAP.
    - Consider forming a multidisciplinary team (nurses, physicians, respiratory therapist, clinical pharmacist) or a unit group of staff to address VAP practice changes.
    - Develop communication strategies to alert and remind staff of the importance of VAP interventions.

Sources: Adapted from Institute for Healthcare Improvement. *Getting Started Kit: Prevent Ventilator Associated Pneumonia,* 2006, http://www.ihi.org/NR/rdonlyres/A448DDB1-E2A4-4D13-8F02-16417EC52990/0/VAPHowtoGuideFINAL.pdf (accessed March 11, 2006); and the American Association of Critical Care Nurses practice alert: Ventilator-Associated Pneumonia, http://www.aacn.org (accessed March 5, 2006).

Table 2. Evidence-Based Strategies for Urinary Tract Infection Prevention

- Indwelling urinary catheters should be inserted using aseptic technique and sterile equipment.
- Only hospital personnel who know the correct technique of aseptic insertion and maintenance of the catheter should handle catheters.
- Hospital personnel should be provided with periodic in-service training stressing the correct techniques and potential complications of urinary catheterization.
- Indwelling urinary catheters should be inserted only when necessary and left in place only for as long as necessary.
- Other methods of urinary drainage such as condom catheter drainage, suprapubic catheterization, and intermittent urethral catheterization should be considered as alternatives to indwelling urethral catheterization.
- Hand washing should be done immediately before and after any manipulation of the indwelling urinary catheter site or apparatus.
- Indwelling catheters should be properly secured after insertion to prevent movement and urethral traction.
- A sterile, continuously closed drainage system should be maintained.
- The catheter and drainage tube should not be disconnected unless the catheter must be irrigated, and irrigation should be used only for suspected obstruction.
- If breaks in aseptic technique, disconnection, or leakage occur, the collecting system should be replaced using aseptic technique after disinfecting the catheter-tubing junction.
- Specimen collections should be obtained from the distal end of the catheter, preferably from the sampling port after cleansing with a disinfectant and then the urine specimen aspirated with a sterile needle and syringe.
- Consider the use of antimicrobial catheters for indwelling urinary catheters.

Source: Adapted from Wong ES, *Guideline for Prevention of Catheter-Associated Urinary Tract Infections.* http://www.cdc.gov/ncidod/dhqp/gl_catheter_assoc.html.

Table 3. Evidence-Based Strategies for Central Line Infection Prevention

- Education and training should be provided for staff who insert and maintain intravenous lines.
- Maximal sterile barriers should be used during catheter insertion (cap, mask, sterile gown and gloves, and a large sterile drape).
- A 2% chlorhexidine preparation is the preferred skin antiseptic, to be applied prior to insertion.
- Antiseptic- or antibiotic-impregnated catheters should be reserved for very high-risk patients or situations in which catheter-related BSI rates are high despite careful attention to these recommendations.
- Replace peripheral intravenous sites in the adult patient population at least every 96 hours but no more frequently than every 72 hours. Peripheral venous catheters in children should be left in until the intravenous therapy is completed, unless complications such as phlebitis or infiltration occur.
- Replace intravenous tubing at least every 96 hours but no more frequently than every 72 hours.
- Replace intravenous catheters as soon as possible when adherence to aseptic technique during catheter insertion cannot be ensured (i.e., prehospital, code situation).
- Central lines should not routinely be replaced at scheduled intervals.
- Consider use of a central line insertion checklist to ensure all processes related to central line insertion are executed for each line placement.
- Consider use of a central line insertion cart to avoid the difficulty of finding necessary equipment to institute maximal barrier precautions.
- Replace central line dressings whenever damp, loose, or soiled or at a frequency of every 2 days for gauze dressings and every 7 days for transparent dressings.
- Avoid use of antibiotic ointment at insertion sites because it can promote fungal infections and antibiotic resistance.
- Include daily review of line necessity.
- Assess competency of staff who insert and care for intravascular catheters.

Sources: Adapted from: O'Grady NP, et al., *Guidelines for the Prevention of Intravascular Catheter-Related Infections,* Centers for Disease Control and Prevention, MMWR Recomm Rep 2002;51(RR-10):1–29; Institute for Healthcare Improvement, *Getting Started Kit: Prevent Central Line Infections,* 2006, available at: http://www.ihi.org/NR/rdonlyres/BF4CC102-C564-4436-AC3A-0C57B1202872/0/CentralLinesHowtoGuideFINAL720.pdf (accessed March 11, 2006); and American Association of Critical Care Nurses practice alert: *Preventing Catheter-Related Bloodstream Infections,* www.aacn.org (accessed March 5, 2006).

Table 4. Evidence-Based Guidelines for Sepsis

The Surviving Sepsis Campaign guidelines outline evidence-based recommendations for targeting treatment of patients at risk of developing severe sepsis and septic shock.

The following grading system was used to classify the treatment recommendations:

A. Supported by at least two level I investigations (large, randomized trials with confident results)
B. Supported by one level I investigation
C. Supported by level II investigations only (small, randomized trials with uncertain results)
D. Supported by at least one level III investigation (nonrandomized study)
E. Supported by level IV (nonrandomized, historical controls, and expert opinion) or level V evidence (case series, uncontrolled studies, and expert opinion)

a. Initial resuscitation for sepsis-induced hypoperfusion—grade B
   - Fluid resuscitation to a central venous pressure of 8–12 mmHg
   - Early goal-directed therapy

- Transfusion of packed red blood cells to achieve a hematocrit of ≥ 30 percent
- Administration of inotropic infusion (e.g., dobutamine)

b. Diagnosis
- Obtain cultures: at least two blood cultures with one drawn percutaneously and one drawn through each vascular access device; cultures of other sites such as urine, wounds, respiratory secretions should be obtained *before* antibiotic therapy is initiated—grade D
- Diagnostic studies (e.g., ultrasound, imaging studies)—grade E

c. Antibiotic therapy
- Empirical antibiotics—grade E

d. Source control
- Removal of potentially infected device, drainage of abscess, debridement of infected necrotic tissue—grade E

e. Enhance perfusion
- Fluid therapy—grade C
- Vaspressors—grade E
- Inotropic therapy—grade E

f. Steroids
- For patients with relative adrenal insufficiency—grade C

g. Recombinant human activated protein C (rhAPC)—grade B
- For patients with sepsis-induced multiple organ failure with no absolute contraindication related to bleeding risk

h. Blood product administration
- To target hemoglobin of 7.0 to 9.0 g/dL—grade B

i. Mechanical ventilation
- Lung protective ventilation for acute lung injury/acute respiratory distress syndrome—grade B

j. Sedation, analgesia, and neuromuscular blockade
- To provide comfort yet avoid prolonged sedation—grade B

k. Glucose control
- To maintain blood glucose <150 mg/dL—grade D

l. Renal replacement
- For acute renal failure—grade B

m. Prophylaxis measures
- Deep vein thrombosis—grade A
- Stress ulcer—grade A

n. Consideration for limitation of support
- Discuss end-of-life care for critically ill patients—grade E
- Promote family communication to discuss use of life-sustaining therapies—grade E

Source: Adapted from Dellinger et al. Surviving Sepsis Campaign guidelines for management of severe sepsis and septic shock. Crit Care Med 2004;32:858-72.

Table 5. General Infection-Prevention Measures

- Standard precautions apply to the care of all patients.
- Contact precautions apply to patients with a known or suspected infection with pathogens that can be transmitted by direct or indirect contact.
- Droplet precautions apply to patients with a known or suspected infection with pathogens that can be transmitted by infectious droplets.
- Airborne precautions apply to patients known or suspected to be infected with epidemiologically important pathogens that can be transmitted by the airborne route.

Categories of Infection-Prevention Measures

- Hand washing: after touching blood, body fluids, secretions, excretions, and contaminated items, whether or not gloves are worn; after gloves are removed, between patient contacts, between tasks and procedures
- Gloves: when touching blood, body fluids, secretions, excretions, and contaminated items; before touching mucous membranes and nonintact skin; between tasks and procedures; after contact with potentially contaminated material
- Mask, eye protection, face shield: to protect mucous membranes of the eyes, nose, and mouth during procedures and patient-care activities with the potential to generate splashes or sprays of blood, body fluids, secretions, and excretions
- Gown: to protect skin and prevent soiling of clothing during procedures and patient-care activities with the potential to generate splashes or sprays of blood, body fluids, secretions, or excretions
- Patient care equipment: appropriate handling of used patient-care equipment soiled with blood, body fluids, secretions, and excretions to prevent skin and mucous membrane exposures, contamination of clothing, and transfer of microorganisms to other patients and environments; to ensure that reusable equipment is not used until it has been cleaned and reprocessed appropriately; to ensure that single-use items are discarded properly
- Environmental control: to ensure adherence with procedures for the routine care, cleaning, and disinfection of environmental surfaces, beds, bedrails, bedside equipment, and other frequently touched surfaces
- Linen: procedures for handling, transporting, and processing used linen soiled with blood, body fluids, secretions, and excretions to prevent skin and mucous membrane exposures and contamination of clothing; to avoid spread of microorganisms to other patients and environments
- Patient placement: placement of patients with the potential to contaminate the environment in a private room

Source: Adapted from CDC, *Standard Precautions.* http://www.cdc.gov/ncidod/dhqp/gl_isolation_standard.html. Accessed February 21, 2006

Table 6. Measures To Prevent Antimicrobial Resistance in Hospitalized Patients

- Establish systems for monitoring bacterial resistance and antibiotic use.
- Place limitations on antibiotic use.
- Establish systems for monitoring both process and outcome measures for infected patients, such as appropriate use of universal precautions, compliance with hand washing, length of hospital stay, or complication rates.
- Adopt the recommendations of the CDC's guidelines for isolation precautions in hospitals to prevent colonization and/or spread of resistant microorganisms.
- Place infected patients in private rooms or only with other infected patients.
- Hospital staff should wear gloves and gowns whenever they enter the room of an infected patient, even if there is no direct patient contact, because these organisms can extensively contaminate the environment.
- Patient-care items should be single-patient use whenever possible.
- Use a notification system so that staff are aware of the detection of cases where antimicrobial-resistant infections such as MRSA and VRE have been detected.
- Ensure that clinical staff are knowledgeable about hospital policies regarding antimicrobial-resistant infections such as MRSA and VRE colonizing in or infecting patients.

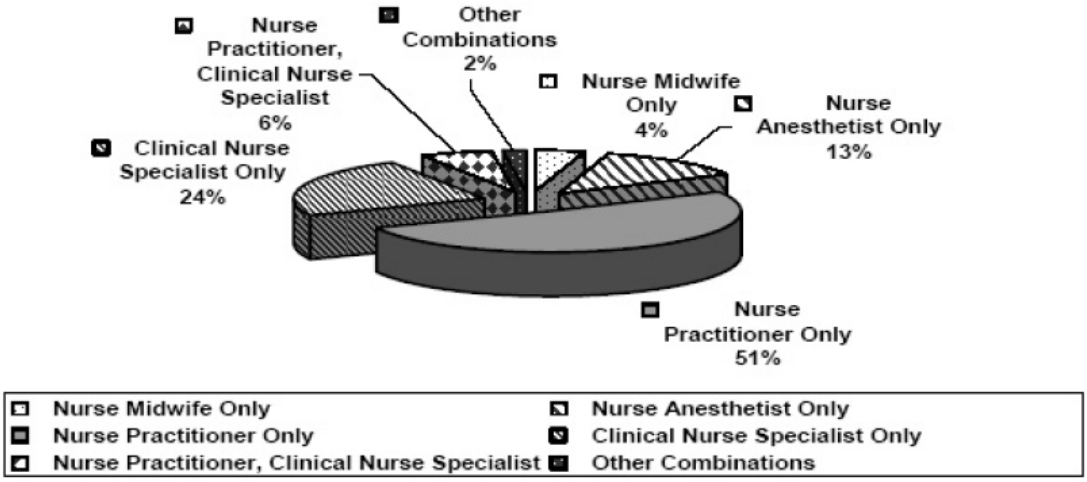
Chapter 43. Advanced Practice Registered Nurses: The Impact on Patient Safety and Quality

Eileen T. O'Grady

Background

This chapter will define the role of advanced practice nurses (APNs), review a selected sample of the literature regarding what we know about APNs and patient safety/quality, and describe the research gaps and limitations. Advanced practice registered nurse is a term used to encompass certified nurse-midwife (CNM), certified registered nurse anesthetist (CRNA), clinical nurse specialist (CNS), and nurse practitioner (NP). Advanced practice nursing is broadly defined as nursing interventions that influence health care outcomes, including the direct care of individual patients, management of care for individuals and populations, administration of nursing and health care organizations, and the development and implementation of health policy.[1] In 2004, the number of registered nurses (RNs) prepared to practice in at least one advanced practice role was estimated to be 240,461, or 8.3 percent of the total RN population. As noted in figure 1 below, the largest group among the APNs was NPs, followed by CNSs. The APN movement has been growing exponentially with APNs employed in every health care sector. According to the Bureau of Labor Statistics,[2] the demand for APNs is expected to continue to increase over the next decade and beyond, as the need and demand for effective health care increases, especially in rural, inner-city, and other underserved areas.

Figure 1. Registered Nurses Prepared for Advanced Practice, March 2004



Source: 2004 National Sample Survey of Registered Nurses, U.S. Department of Health and Human Services, Health Resources and Services Administration. http://bhpr.hrsa.gov/healthworkforce/reports/rnpopulation/preliminaryfindings.htm.

Direct clinical practice is a core competency of any APN role, although the actual skill set varies according to the needs of the patient population.[3] APNs build on the competence of the

RN skill set and demonstrate a greater depth and breadth of knowledge, a greater synthesis of data, increased complexity of skills and interventions, and significant role autonomy. The APN is prepared to assume responsibility and accountability for health promotion and the assessment, diagnosis, and management of patient problems, including the use and prescription of pharmacologic and nonpharmacologic interventions.[4]

Advanced Practice Nurses Evolve to the Doctoral Level

The American Association of Colleges of Nursing envisions all APN master's-level programs will evolve to a doctorate of nursing practice (DNP) by 2015.[5] This evolution to the doctoral level for APN education stems from the three Institute of Medicine (IOM) reports, *Too Err is Human*,[6] *Crossing the Quality Chasm*,[7] and *Health Professions Education: A Bridge to Quality*,[8] which emphasized widespread problems related to patient safety and called for dramatic restructuring of traditional health professions education. These reports recommended all health professionals should be educated to deliver patient-centered care as members of an interdisciplinary team, emphasizing evidenced-based practice, quality improvement, and informatics. It was emphasized that the best-prepared senior-level nurses should be in key leadership positions and participating in executive decisions. Complex practice and delivery system demands create a mandate to expand the clinical education and leadership capacity of APNs. Graduates of DNP programs are expected to use advanced communication skills/processes to lead quality improvement and patient safety initiatives in health care systems.

Research Evidence

Certified Nurse-Midwife

CNMs are licensed health care practitioners educated in the two disciplines of nursing and midwifery. They provide primary health care to women of childbearing age, including prenatal care, labor and delivery care, care after birth, gynecological exams, newborn care, assistance with family planning decisions, preconception care, menopausal management, and counseling in health maintenance and disease prevention. CNMs attend more than 10 percent of the births in the United States; 96 percent of these are in hospitals.[9]

What we know. MacDorman and Singh[10] used logistic regression models to examine differences between CNMs and physician-delivered births in infant perinatal mortality on all singleton vaginal births between 35 and 43 weeks gestation in the United States (n = 810,790) in 1991. After controlling for all social and health risk factors, the CNM risk of infant death was 19 percent lower, neonatal mortality was 3 percent lower, and low-birth-weight infants were 31 percent fewer than with the physician-delivered babies. The mean birth weight was 37 grams heavier for the CNM-attended births. The researchers concluded that CNMs provide a safe and viable alternative to maternity care in the United States, particularly for low- to moderate-risk women. The retrospective study design could not address the inherent selection bias of mothers who choose midwives versus mothers who choose physicians to assist with delivery.

Rosenblatt and colleagues[11] compared a random sample of records of Washington State obstetricians, family physicians, and CNMs for low-risk women over a 1-year period (n = 1,322). The researchers found that CNM patients were less likely to receive continuous fetal monitoring and had lower rates of labor induction, epidural injections, and caesarean sections

and overall used fewer resources. The researchers concluded that overall, in Washington State, low-risk patients of CNMs received fewer obstetrical interventions than similar patients cared for by family physicians or obstetricians, especially lower cesarean rates and resource use. There was no controlling for maternal risk factors such as maternal age and birth weight in this study, and the degree of selection bias in pregnant women choosing a CNM versus a physician could have influenced these results.

Oakley and colleagues[12] compared the pregnancy outcomes (n = 1,181) of low-risk pregnant women cared for by either an obstetrician or a CNM. After controlling for maternal risk and selection bias, the nurse-midwife group had statistically significant fewer infant abrasions, perineal lacerations, and complications; higher satisfaction with care; and lower hospital and professional fee charges. The researchers concluded that important significant differences were found between the CNMs and obstetricians and that CNMs are contributing significantly to lowering maternity care costs and improving maternal outcomes of low-risk women.

While most of the research on CNM quality covered low-risk women, Davidson[13] explored the effectiveness of CNM care for high-risk women. Outcomes of high-risk women cared for by CNMs in an inner-city hospital (n = 803) were compared with all women who delivered in the United States in 1994. The comparison suggests that CNMs can provide safe care to women with high-risk conditions. The single site of the study sample and lack of a controlled pair group make generalizability of these findings difficult.

Nurse Anesthetist

A CRNA is a registered nurse who is educationally prepared for and competent to engage in the practice of nurse anesthesia. CRNAs administer approximately 27 million anesthetics in the United States each year, practice in every setting where anesthesia is available, and are the sole anesthesia providers in more than two-thirds of all rural hospitals.[14] CNRAs can also administer every type of anesthetic and provide care for every type of surgery or procedure, from open heart to cataract to pain management. CRNAs are both responsible for and accountable to others for their individual professional practices. In addition, CRNAs are capable of exercising independent professional judgment within their scope of competence and licensure.[3] CRNAs provide anesthetics to patients in collaboration with surgeons, anesthesiologists, dentists, podiatrists, and other qualified health care professionals. When anesthesia is administered by a nurse anesthetist, it is recognized as the practice of nursing and is not a medically delegated act.[14]

What we know. In 1988, the Centers for Disease Control and Prevention (CDC)[15] conducted a pilot study to explore anesthesia outcomes. The study concluded that anesthesia-caused mortality and severe morbidity were too low to warrant a broader study. The CDC found that precise estimates would require studying 290 hospitals and would cost $15 million over 5 years, which was not deemed feasible. According to the IOM,[6] it is estimated that death occurs only once for every 200,000–300,000 anesthetics administered. This low incidence of error makes studying the safety of CRNAs as a distinct provider group extremely difficult as it would require an enormous number of study subjects.

To answer questions about surgical patients' safety with regard to CRNAs versus anesthesiologists, Pine and colleagues[16] studied 404,194 anesthesia cases across 22 States. Risk adjustment was conducted for case mix, risk factors, hospital characteristics, geographic location, and surgical procedure. The study found no statistically significant difference in the mortality rate for CRNAs and anesthelogists working together versus working individually. There was no statistically significant difference between hospitals staffed by CRNAs (without

anesthesiologists) versus hospitals in which anesthesiologists provided or directed the anesthesia care. The researchers concluded that, based on the surgical procedures included in the study, inpatient surgical mortality is not affected by whether the anesthesia provider is a CRNA or an anesthesiologist.

Anesthesia-related accidents are infrequent, largely due to systemic quality improvements in applied technology, anesthetic agents, multimodal pain management, and development and adoption of practice guidelines in the broad field of anesthesiology over the last 40 years. The dramatic decrease in anesthesia-related deaths since 1960 may be largely attributable to the disciplinewide sharp focus on safety issues such as increased vigilance during long operations and rapid response teams. The pulse oximeter, standardization of equipment, and changes in education, including the use of simulation, have also contributed to threshold improvement in patient safety. In fact, anesthesia as a health care discipline is an exemplar case study of how local but complex, high-risk, dynamic patient care has noticeably reduced its error rate[6] (p. 164). The administration of anesthesia is built on a foundation of sound safety principles and has been a strong leader in creating systems built around patient safety.

Clinical Nurse Specialist

The CNS is an expert clinician in a specialized area of nursing practice. The specialty may be a population (e.g., pediatrics), a setting (e.g., critical care), a disease (e.g., cardiovascular or mental health), or a type of problem (e.g., wound or pain). CNSs are engaged in direct clinical practice; function as consultants in their area of expertise; provide expert coaching and guidance; interpret, evaluate, and participate in research; provide clinical and professional leadership; collaborate; and employ ethical decisionmaking.[3]

What we know. In 2001, a randomized controlled clinical trial by Brooten, Youngblut, and colleagues[17] looked at prenatal, infant (194) and maternal (173) outcomes where half of the prenatal care was delivered in the home by CNSs. Results found that the group cared for in the home by CNSs experienced fewer fetal/infant deaths, fewer preterm infants, fewer prenatal hospitalizations, and fewer rehospitalizations compared to the control group. Researchers concluded that the CNS prenatal home care saved 750 hospital days or about $2.5 million dollars.

Topp, Tucker, and Weber[18] conducted a retrospective chart review on 491 hospitalized congestive heart failure patients over a 12-month period. Results indicated that length of stay and hospital charges were significantly less in patients who were case-managed by a CNS.

Naylor and colleagues[19] conducted a randomized clinical control trial with 276 patients and 125 caregivers to show the effects of a comprehensive discharge planning protocol. The discharge planning protocol was specifically designed for elderly medical and surgical patients and implemented by a gerontological CNS. From the initial discharge until 6 weeks after discharge, the medical intervention group had fewer readmissions, fewer total days of rehosptilization, lower readmission charges, and lower charges for all health care services after discharge compared to the control group and the surgical intervention group.

Brooten, Kumar, Brown, and colleagues[20] conducted a randomized clinical trial on the effectiveness of CNS home care on the early hospital discharge of very low-birth-weight infants (n = 79). The researchers found that hospital costs were 27 percent less than for the control group. The researchers concluded that early hospital discharge for very low-birth-weight infants was safe with CNSs conducting home followup care.

Nurse Practitioner

NPs are registered nurses who are prepared, through advanced education and clinical training, to provide a wide range of preventive and acute health care services to individuals of all ages. NPs take health histories and provide complete physical examinations; diagnose and treat many common acute and chronic problems; interpret laboratory results and x-rays; prescribe and manage medications and other therapies; provide health teaching and supportive counseling, with an emphasis on prevention of illness and health maintenance; and refer patients to other health professionals as needed.[21] Hughes and colleagues[22] have categorized the 40-year history of NP research into succinct eras, chronicling the evidence base on NPs, by far the largest of all of the four APN roles. The current era is characterized by strategies to combat rising costs and tension-building between NPs and the medical profession. The authors provide keen insight into why benchmarking NP care against physician care may have taken us to the end of that research road.

What we know. Lambing and colleagues[23] sought to build the evidence base for NP effectiveness in the acute care setting. They conducted a descriptive, comparative research design on 100 randomly selected hospitalized geriatric patients and a sample of 17 professional providers who staffed 3 hospital units over a 1-month period. The researchers found that the patients of NPs were older and sicker at the time of discharge and that readmission and mortality rates were similar amongst NPs and physicians. The researchers concluded that NPs provide effective care to hospitalized geriatric patients, particularly to those who are older and sicker.

Mundinger, Kane, and colleagues[24] conducted the most definitive research on NPs and quality by exploring the outcomes of care in patients randomly assigned either to a physician or to a nurse practitioner for primary care after an emergency or urgent care visit. The NP practice had the same degree of independence as the physicians, making this study unique. Patient interviews and health services utilization data were used on a total of 1,316 patients, and it was determined that the health status of the NP patients and the physician patients were comparable at initial visits, 6 months, and 12 months. A followup study conducted in 2004[25] showed that patients 2 years later confirmed continued comparable outcomes for the two groups of patients. No differences were identified in patient outcomes such as health status; physiologic measures; satisfaction; and use of specialists, emergency room, or inpatient services. The researchers concluded that NP care and physician care was comparable.

A study by Avorn and colleagues[26] used a sample of 501 physicians and 298 NPs who responded to a hypothetical scenario regarding a patient with epigastic pain (acute gastritis). They were able to request additional information before recommending treatment. If adequate history taking was performed, the provider would have learned that the patient ingested aspirin, coffee, and alcohol, and was under a great deal of psychosocial stress. Compared to NPs, the physician group was more likely to prescribe a medication without seeking the relevant history. NPs, in contrast, asked more questions, obtained a complete history, and were less likely to recommend prescription medication. This study suggests that NP-delivered care may be superior to that of physicians when a diagnosis is history dependent.

Summary of APN Research on Quality

A selected sample of research on APNs and quality and safety was conducted because much of the APN research lacked randomization, had sample sizes too small to be generalizable to the national health care system, or was not relevant to quality or safety. The summary of the preceding research samples suggests that APN[*]-delivered care, across settings, is at least equivalent to that of physician-delivered care as regards safety and quality. In the case of the CNSs, it appears that CNSs demonstrate competence and cost savings as case managers for patients transitioning from acute care to home care. Overall, however, the study designs and sample sizes are too limited to draw conclusions that are generalizable to the United States population. Widely accepted methodological techniques and research best practices outlined in the report of the Agency for Healthcare Research and Quality (AHRQ), *Evidence Report to Rate the Strength of Scientific Evidence*[27] (see Table 1), have not been applied to the emerging research on APN practice and quality. Methodologic quality has been defined as the extent to which all aspects of a study's design and conduct can be shown to protect against systematic bias, nonsystematic bias, and inferential error. Not met were certain design elements in the preceding APN research design, conduct, or analysis that have been shown through empirical work to protect against bias or that are long-accepted practices in epidemiology and related research fields. These research evaluation criteria include quality, quantity, and consistency that are well-established variables for characterizing how confidently one can conclude that a body of knowledge provides information on which clinicians or policymakers can act. As the research on APN and quality evolves over time, the rigor of the research and its capacity to influence policy will improve.

Table 1. Important Domains and Elements for Systems To Grade the Strength of Evidence

Quality:	The aggregate of quality ratings for individual studies, predicated on the extent to which bias was minimized.
Quantity:	Magnitude of effect, numbers of studies, and sample size or power.
Consistency:	For any given topic, the extent to which similar findings are reported using similar and different study designs.

These studies are also limited in looking specifically at patient safety as a subset of health care quality. According to *Crossing the Quality Chasm*,[7] the American health care system is in need of fundamental change because health care frequently harms and fails to deliver its potential benefits. The preceding literature compared APNs to physicians within the context of a health care system that is not necessarily patient safety focused. Comparing APN to physician outcomes was an important validation of APN practice as these professions evolved. Given the current mandate for fundamental system change, new research questions on APN practice as they relate to patient safety have emerged. Most outcome studies to date have focused on acute care

[*] No studies comparing CNSs to physicians have been conducted.

nurse staffing and nursing-sensitive outcomes such as decubitus ulcers.[28] The research to measure APN outcomes with valid tools has yet to be developed.

While the summary of research related to the safety and quality of APNs validates them as competent and comparable to physicians in many aspects, more research is needed to reduce errors and enhance patient safety. Threshold improvement cannot be accomplished without interdisciplinary practice approaches—which are going to require revolutionary change to flatten the educational and cultural silos between medicine and nursing education.[29] It is crucial that APNs are separated out as distinct provider types in all interdisciplinary research and administrative and clinical datasets. It has taken the nursing profession decades to untangle nursing's unique role and value within the hospital and decouple professional registered nursing from the "hotel costs" of a hospital stay. RNs have historically been characterized as a cost center rather than a highly valued revenue source within hospitals. If all professional nursing activity was billed for separately, such as is done with physician care, nursing's value would not have to be debated. As the evidence base on interdisciplinary teams is built, APNs must not become invisible on the health care team. Building a research portfolio on APN practice will require adherence to methodological quality that explores APN practice within an interdisciplinary context. Practice Implications—Barriers to APN Practice

Lack of Collaboration

Health professionals work together in small groups providing care, be it oncology, the operating room, end of life, or primary care. These team members, however, are educated in their health professional silo and likely have little knowledge of their team members' skill sets. The IOM report, *To Err is Human*,[6] suggested that health professionals should be educated in teams using evidenced-based methods employed in aviation such as simulation and checklists. People make fewer errors when they work in teams because it forces processes to be planned and standardized, forces team members to have a clear role and to look out for one another, noticing errors before they become an accident. In an effective interdisciplinary team, members come to trust one another's judgments and attend to one another's safety concerns.

In no uncertain terms, the IOM declares that most care delivered today is done by teams of people, yet training often remains focused on individual responsibilities, leaving practitioners inadequately prepared to enter complex settings. The silos created through training and organization of care impede safety improvements.[6]

The *Quality First* report highlighted "… the need for clinicians to develop a broader systems perspective. Specifically, the commission states that '… in health care organizations, much of the learning is aimed at improving individual physicians learning to become better physicians, nurses learning to become better nurses, rather than learning how the system as a whole can improve.'"[30] Irrespective of health care setting, there is a high premium placed on medical autonomy and perfection and a historical lack of interprofesional cooperation and effective communication.[6]

Learning and working in a true interdisciplinary context is a requirement for improved patient safety, and the silo systems in place now are viewed as wholly inadequate. It is the space between the disciplines that may create the most opportunity for patient safety improvement. The following quote expresses the opportunity created in this interdisciplinary space as John Brown, an information technology leader, discusses how his company lost the commercial market share on the world's first personal computer solely due to a lack of interdisciplinary collaboration:

> First of all, we were fundamentally noncollaborative, there was surprisingly little cross-disciplinary work. There were turf wars and physicists, for example, were not allowed to talk to computer scientists . . . To me the white space between fields is the place to explore. . . . If you get multiple disciplines together working around the root of a problem, it pulls you out of your own discipline and fuses different points of view that lead to a reframing.[31]

Exemplars in collaborative models have demonstrated quality and safety improvements in two divergent settings, acute and chronic care. The Rapid Response Team (RRT)—known by some as the Medical Emergency Team (MET)—is a team of clinicians who bring critical care expertise to the patient's bedside (or wherever it is needed) in the acute care setting. The concept is relatively simple: create a small but powerful team experienced at assessing patients' symptoms and make that team continuously and readily available to any provider who wants a second opinion about a patient, particularly a patient showing signs of potential decline, as patients often exhibit signs and symptoms of physiological instability for some period of time prior to a cardiac arrest.[32]

Another model, the Chronic Care Model, also has great potential to improve health care quality by employing a team of providers to apply a high standard of scientific evidence to groups of patients with a chronic illness.[33] Yet the role of providers, the community, and patients with chronic care needs can be unclear and at times disjointed.

Missing in the APN research is the notion of team-delivered care as it relates to quality. One study[34] explored only cost implications, and not quality per se, of multidisciplinary teams of hospitalists, nonhospitalist attending physicians, and NPs. The study model employed NPs to supplement physician care and ensure continuity of care, comparing this approach for managing 581 general medicine patients in one unit of a large academic medical center during hospitalization and for 30 days after discharge with usual care for 626 patients in another general medicine unit. The research findings indicated that reduced hospital length of stay (LOS) and increased hospital profits occurred in the collaborative model when compared with physician-only care. This approach reduced the average LOS from 6 to 5 days. By reducing the number of hospital days after the first 4 days, which are the most profitable ones, hospital profits increased by $1,591 per day for each patient without increasing hospital readmission or mortality rates.[34]

State Regulation of APN Practice

The 50 States and the District of Columbia have vastly different laws governing APN practice. The 51 nurse practice acts currently lack any clear framework or congruence amongst each other.[35] This high degree of variation suggests that the regulatory framework for APN practice is not evidence-based and that States are not promulgating APN regulations with a coherent patient safety orientation.

By way of example, some States employ a joint board of nursing-board of medicine to regulate APNs, while others require physicians and APNs to be in collaborative or even supervisory relationships with each other. Some States consider APN practice a medically delegated act and require physician, dentist, or podiatrist supervision of APNs, while other States require physicians to be in contact with the APN periodically throughout the week or to be physically within a defined radius (defined in miles) of the NP. Some States require APNs with doctorates to "hide" their doctoral degree credential from patients, and other States do not require APNs to be nationally certified to practice. These practice acts vary even within States

(urban or rural) and can specify the types of medical conditions APNs are permitted to treat. The current APN regulatory environment has numerous issues that foster poor quality or impair patient safety. Regulatory barriers that directly impact patient safety include onerous entry into APN practice; cryptic scope of practice regulations; polices that restrict APN hospital and prescriptive privileges and impede continuity of care, the capacity of NPs to serve as primary care providers (NP empanelment), to receive third-party payment, or the pharmacist from printing the prescribing APN name on the prescription bottle, making it difficult for pharmacists or patients to contact the prescribing APN. The APRN Joint Dialogue Group[36] of the National Council of State Boards of Nursing (NCSBN) recommends sole board of nursing regulation for APN practice and that APNs be independent practitioners with no regulatory requirement for supervision from another discipline across all States. Standardizing nurse practice acts will establish the groundwork necessary to move to a mutual recognition (interstate compact) for APNs.

This high degree of variation across the States for APN regulation has spotlighted the need to ensure that regulation serves the public, promotes public safety, and does not present unnecessary barriers to patients' access to care. Likewise, the regulatory bodies overseeing APN practice are slow or unable to keep pace with changes in health care. Moreover, the Internet has rendered geographic boundaries irrelevant, and as technology and national delivery systems infiltrate care delivery, these practice acts will strangle innovation. The *Crossing the Quality Chasm* report notes that State practice acts that limit nonphysician providers, e-health, and multidisciplinary teams act as a barrier to innovative health care because these innovations can help care for patients across settings and over time[7] (p. 215). *Crossing the Quality Chasm* recommends greater coordination and communication among professional boards, both within and across States, as the patchwork of NP regulations are resolved over time.

The IOM's *Crossing the Quality Chasm* recommends that regulators create an infrastructure to support evidence-based practice, facilitate the use of information technology, align payment incentives, and prepare the workforce to better serve patients in a world of expanding knowledge and rapid change[7] (p. 5). The report stresses that if innovative programs are to flourish, regulatory environments will be required to foster innovation in organizational arrangements, work relationships, and use of technology. The 21st century health care system described in *Crossing the Quality Chasm* simply cannot be achieved in the current environment of regulation and oversight. The report summarizes the current patchwork of regulatory frameworks as inconsistent, contradictory, duplicative, outdated, and counter to best practices. Moving the NCSBN's vision for APN regulation into reality across all of the States is requisite to promote APNs and patient safety.

APN Invisibility

Many polices have rendered APN practices "invisible" or established barriers that adversely impact accurate measurement of quality-related data. By way of example, Medicare has a policy that allows physician practices to bill Medicare for NP-provided services as "incident-to" the physician. This allows medical practices to bill for NP care through a physician, creating perverse incentives to make NPs invisible, as NPs are reimbursed 100 percent of the physician rate when billing Medicare "incident-to." When APNs bill Medicare directly, they bill at 85 percent of the physician rate. The cost savings of using a less expensive provider are passed onto the physician practice, not the patient or the payer.

Another startling example of APN invisibility is that the most comprehensive ambulatory care data, the National Ambulatory Medical Care Survey (NAMCS) produced by the National Center for Health Statistics, does not include APNs. This important national survey is conducted annually on the provision and use of ambulatory medical care services in the United States. Findings are based on a sample of visits to nonfederally employed office-based physicians who are primarily engaged in direct patient care. Each physician is randomly assigned to a 1-week reporting period. During this period, data for a systematic random sample of visits are recorded by the physician or office staff on an encounter form provided for that purpose. Data are obtained on patients' symptoms, physicians' diagnoses, and medications ordered or provided. The survey also provides statistics on the demographic characteristics of patients and services provided, including information on diagnostic procedures, patient management, and planned future treatment. APNs practicing in ambulatory care are not surveyed or discussed in the 906 million visits to physician offices.[37]

In that same vein, the Center for Studying Health System Change (HSC), whose mission is "to inform policy makers about how local and national changes in the financing and delivery of health care affect people … strives to provide high-quality, timely and objective research and analysis that leads to sound policy decisions, with the ultimate goal of improving the health of the American public."[38] HSC employs rigorous surveys and in-depth case studies and chronicles trends in the health care system; however, their provider surveys include only physicians. HSC unquestionably influences decisionmakers on all sides of the issues and guides those crafting health care policy in Government and private industry. More must be done to encourage thought leaders to think about health system change more broadly.

APNs are also invisible in the basic county-specific Area Resource File (ARF), a database containing more than 6,000 variables for each of the Nation's counties. ARF contains information on health facilities; health professions; and measures of resource scarcity, health status, economic activity, health training programs, and socioeconomic and environmental characteristics. In addition, the basic file contains geographic codes and descriptors that enable it to be linked to many other files and to aggregate counties in various geographic groupings. This database is used to establish Health Professional Shortage Areas (HPSAs), using criteria of population-to-clinician ratios. It is difficult to include APNs in the ratio as there is no uniform data source at the ZIP Code level on APNs. HPSA designation is important to communities because of the enormous funding priority they receive in more than 34 Federal programs that depend on the shortage designation to determine eligibility.[39] About 20 percent of the U.S. population reside in primary medical care HPSAs, and APNs are not considered full-time equivalent providers in the designation because of the lack of data. Fully counting APNs could thus impact the distribution of Federal funds to counties.

The Federal requirement that CRNAs must be in a supervisory relationship with anesthesiologists creates enormous barriers to adequate measuring of patient safety data, as the CRNA may not be identified as a distinctive provider group, rendering CRNA-delivered anesthesia invisible. This policy also has a detrimental effect on rural States that cannot staff their hospitals with anesthesiologists; therefore, many States have opted out of the Federal requirement for CRNA supervision in order to meet their patients' needs.

These policies, in each of the preceding examples, remove or marginalize the APN from all administrative and clinical data systems or survey designs. This lack of inclusion in these national research endeavors makes it impossible to understand the full dimensions and value of NP practice.

Practice Implications

The intense drive to measure quality is a deep concern for payers, regulators, and increasingly consumers. As data systems evolve and payers insist on "paying for performance," a level of accountability and transparency will be required regardless of provider type or health care setting. As these quality measures are developed, the current focus seems to be entirely on physician-delivered care. Quality data will be embedded with health information systems, so it will be imperative that APNs are involved in both the development of quality measures and the inclusion of APN practice as distinct from that of other providers. The database on nurse-sensitive indicators is being built at the inpatient level of hospitals. As many APNs practice in settings outside of the hospital, the need to create APN-sensitive measures cannot be overemphasized. The Medicare objective to align quality incentives through payment creates enormous opportunity for APNs. As Medicare gathers the evidence on effective strategies, it will phase in new payment systems intended to promote transformational quality improvement in the health care industry. This realignment will encourage innovation and efficiency and promote coordination of care across time and settings.[40] These activities are central to the APN function and have historically been undervalued and invisible in the fee-for-service model.

Pay-for-performance initiatives are occurring outside of Government as well. Bridges to Excellence (http://www.bridgestoexcellence.org/) is a multistate, multiemployer coalition developed by employers, physicians, health care services researchers, and other experts. Its mission is to reward quality across the health care system. In Bridges to Excellence's three program areas, physicians are targeted exclusively by certifying physicians in diabetes, cardiac care, and electronic office systems. The physician receives a financial bonus of up to $180 per year per patient treated. There are no other providers included in this program, despite the claimed mission to improve health care across the health care system.

Health Services Research Field Gains Strength

Over the last 20 years, the evolution of health services research (HSR), a distinct area of scholarship, has grown dramatically in both resources and influence and is currently funded publicly at $1.5 billion annually. HSR is important to APNs because it addresses questions that require observational or quasi-experimental design. This form of research includes determining the comparative effectiveness of interventions across a range of different settings, economic evaluation of different financing and organizational decisions, and qualitative designs that help us understand the how and why of social interactions.[41] The HSR field is uniquely suited to exploring APN practice because it provides a mixing bowl of interdisciplinary perspectives working on similar problems. As HSR methods become increasingly more prestigious and influential, APN research must be framed within a broader HSR and patient safety context.

Research Implications

The rapid growth and success of the APN movement has been described as a disruptive innovation—in that APNs can in many ways provide the same care or better care than physicians, at a lower cost in a more convenient setting. This disruption has contributed to professional turf battles that do not promote quality and patient safety. Strong leadership to study

innovative models on interdisciplinary team approaches that foster patient safety, including how to eliminate barriers to interdisciplinary education and practice, is required.

Turning the disruption of APNs toward improved patient safety will require a more robust evidence base and laser beam focus by these professionals. APNs must demonstrate specific clinical performance and patient outcomes. To develop this research agenda, stakeholders must convene and map out a vigorous research agenda that distinguishes APNs in the context of interdisciplinary practice. APN organizations along with the governmental and private research enterprise must come together and build a strategic plan identifying the most critical research questions. This research agenda would address strategies for APN inclusion in electronic administrative and clinical data systems, quality measurement, cost containment, as well as influential surveys such as the NAMCS and HSC. As pay-for-performance initiatives are transformed into payment policy, it is essential that researchers include APNs in the quality measurement process. This research agenda must be highly relevant to address today's health care problems and overcome APN invisibility; it must recognize APNs' unique contribution and discipline.

APN research must expand to an HSR orientation. This includes developing a research agenda that has methodological dialogue with other disciplines and fits within a framework of agreed-upon methods in the field of HSR. This research agenda must consistently and systematically translate APN research into sound health policy. Applying randomized thinking to nonrandomized problems is seldom useful to inform public policy because the researcher cannot expose a randomized group to the policy on a qualitative problem. The research must help the policymaker see the intended and unintended consequences that follow enactment of policies over time.

The Agency for Healthcare Research and Quality (AHRQ) has emerged as the premier funder for HSR, and this funding source should be explored to a far greater degree by APN researchers. While the National Institutes of Health focus on the biomedical aspect of diseases, AHRQ focuses on patient outcomes, cost, use of services, access disparities, quality of care, and patient safety. The focus of AHRQ is becoming increasingly important as the delivery system undergoes transformation, driven by transparency and quality. AHRQ's goal is to ensure that the knowledge gained through HSR is translated into measurable improvements in the health care system and better care for patients.[42] This goal could be shared by members of the APN community by sharpening and aligning the APN research focus on systems of care.

There are a number of informational or empirical issues lacking in the current APN evidence base. Future research must be independent, longitudinal, and directed to authoratitively answer the most urgent policy-relevant questions concerning APNs. Following are some of the questions that research into APN practice should address.

Cost and Quality

- Do APNs create value for payers to improve the quality in health care? Is APN practice economically efficient and effective? Are APNs a competitive advantage in the health care marketplace? Does APN practice demonstrate a threshold improvement in lowering cost, reducing misuse, overuse, and errors?
- What is the most reliable, valid, and feasible approach(es) to measuring quality of care delivered by APNs?
- Are there certain settings (acute care, palliative care) or content areas (obesity, cardiac disease) that APNs are most effective?

- How does APN practice uniquely respond to patient preferences?
- What are the outcomes of APN interventions targeted at changing patient behaviors and lifestyle? Do APNs uniquely or qualitatively employ effective strategies to promote health and human wholeness and prevent disease?
- What is the most effective health care team composition for acute care? Primary care? Palliative care? How do we build an evidence base on interdisciplinary approaches or "collaboratories" to function as incubators and disseminators of team-delivered care?
- How do State nurse practice acts enhance or create barriers to safe, effective, and innovative APN-delivered care?

Medicare

- What is the advantage to Medicare to include APNs in its pay-for-performance initiatives? Do APNs, as central members of the health care team, demonstrate threshold quality improvements? How do these findings inform Medicare's Graduate Medical Education program currently targeting primarily physicians?
- How can the cost savings on APN practice be passed onto consumers, Medicare, and other payers?

Access

- What impact do APNs have on vulnerable segments of the population? How do they impact the uninsured? Elderly? Children? Rural residents? How do APNs participate in the safety net?
- How are access and quality of care impacted once a State has adopted NCSBNs regulatory vision for APN practice, which eliminates barriers to APN practice?
- Does APN practice improve health care disparities? Do improvements benefit minority populations preferentially?

Educational Issues

- How are APNs demonstrating interdisciplinary patient safety curricula with educational simulation techniques for use early in professional schooling, continuing throughout training, and at intervals during professional practice?
- How do APNs maintain continued competence throughout their career trajectory?
- What would be included in a curriculum that demonstrated competency in patient safety?

Data and Dissemination Issues

- How can the Health Resources and Services Administration's National Sample Survey of RNs be conducted more frequently, expanded and designed to include a sample of APNs? How frequently should the survey be conducted in order to yield the most timely workforce projections?
- How do APNs get built into the Area Resource File?
- How can a database on APNs answer the following questions?
    - How many ANPs are there?
    - Where do they practice, what do they practice, and who do they care for?
    - What constitutes a full-time equivalent APN?

- When do APNs enter the workforce, and when and how to they leave/retire?
- How should APNs be included in shortage designation methodologies?
- What would a national, integrated workforce planning initiative look like?
- What is the best way to communicate APN-related research to the public, policymakers, payers, and media?

Conclusion

In addition to developing a robust APN research agenda, APN organizations must strategize to have APNs appointed to Federal and private advisory commissions that oversee or develop quality improvement measures. APN organizations must also identify key corporate boards and develop long-term strategies and political capital to get APNs appointed to those influential boards. This sector of the health policymaking process is increasingly influential as payers seek to know more about what they are getting from their health care dollar vis-à-vis pay-for-performance initiatives.

Findings from APN research must be published in journals outside of nursing to reach a broader policymaking and public audience. Key policymakers as well as the public could be made more aware of the contributions that APNs make in reducing health care costs and improving access and quality of care. Achieving broader recognition, reducing APN invisibility, and removing barriers to APN practice will be contingent on APNs communicating methodologically sound APN research that produces results that are generalizable to the larger delivery system.

Search Strategy

Both MEDLINE® and CINAHL® databases were searched to locate literature for this review. The search terms were “advanced practice nursing,” “certified nurse midwives,” “certified registered nurse anesthetists,” “clinical nurse specialists,” “nurse practitioners,” “quality,” “safety,” and “outcomes.” For both databases, the searches were limited to research articles published in the English language between 1991 and 2006 and restricted to research within the United States.

There were 97 articles identified in the CINAHL search and 54 identified by the MEDLINE search, with some duplication in the citations identified by the two databases. All abstracts were reviewed and most were eliminated from further consideration because they were not evidence based or there were methodology concerns. For example, articles about advanced practice roles, delivery models, theoretical papers, educational and curriculum issues, international issues, advanced practice nursing in defined specific populations (e.g., rural, emergency departments, gerontological) or diseases (e.g., sexually transmitted infection, heart disease), and all meta-analyses and studies with fewer than 70 subjects were omitted from this review. Once the unrelated articles were eliminated, a complete copy of each of these papers was acquired and read. Four professional associations were contacted to obtain the strongest research papers on the four APN roles (American College of Nurse Midwives, American Association of Nurse Anesthetists, the American Association of Clinical Nurse Specialists, and the American College of Nurse Practitioners). Dominant among the reasons for excluding papers were that they were not research based, they were short reports that were lacking essential details, or there were methodological concerns.

Evidence Table. Advanced Practice Nurses: Impact on Safety and Quality of Care

Source	Safety/Quality Issue Related to Clinical Practice	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Quality Evidence on CNMs					
Davidson 2002[13]	High-risk obstetrical care	Level 3. Univariate analysis on vaginal births after cesarean, forceps, and vacuum-assisted deliveries, cesarean delivery, 5 minute Apgar score, maternal fever, and meconium stained amniotic fluid outcomes.	High-risk mothers who received care from an urban, mid-Atlantic hospital-based OB clinic during a 10-year period from 1988 to 1998, N = 803.	Risk factors managed by CNMs compared to the national population.	83% of the CNM deliveries were spontaneous vaginal births, compared to the national average of 79%. Seventy four percent of the CNM births after cesarean births delivered vaginally, significantly higher than the national average of 28%. Instrument delivery rates were considerably lower for the CNM group (4%) compared to the national average (9%). Only 12% of the CNM group had cesarean sections, compared to the national average of 21%. The researcher concludes that CNMs provide high-quality care to high-risk women in an urban setting.
MacDorman 1998[10]	Birth outcomes and infant survival	Level 3. Logistic regression on infant, neonatal, post-neonatal mortality and risk of low birth weights.	All singleton vaginal births at 35–43 weeks gestation in the United States in 1991, N = 810,790.	CNM care compared to physician-delivered births.	After controlling for medical and social risk factors, the risk of experiencing an infant death was 19% lower for CNM-attended than for physician-attended births, the risk of neonatal mortality was 33% lower, and risk of delivering a low-birth-weight infant was 31% lower. National data demonstrate that CNMs have excellent birth outcomes amongst low- to moderate-risk women.
Oakley 1996[12]	Pregnancy/ perinatal outcomes	Level 3. Logistic regression analyzed outcome measures: infant and maternal outcomes, 30 clinical indicators, satisfaction with care, and monetary charges.	At intake, all women qualified for CNM care and a convenience sample identified 710 low-risk, singleton pregnant women cared for by obstetricians and 471 cared for by CNMs in private practice.	CNM care compared to obstetrician care.	After controlling for social and health risk factors, multivariate analysis found statistically significant ($P \leq 0.05$) differences between obstetricians and CNMs on 7 outcome measures. Infant abrasion (7% OB vs. 4% CNM), infant remaining with mother for the entire hospital stay (15%OB vs. 27%CNM), 3rd or 4th degree perineal lacerations (23% OB vs. 7%CNM), number of complications (0.7 OB vs. 0.4 CNM), satisfaction with care, average hospital charges ($5,427 OB vs. $4,296 CNM), average professional fee charges ($3,425 OB vs. $3,237 CNM). It was concluded that CNMs provide a safe, effective maternity care for low-risk women and that CNMs contribute to lowering maternity care costs and improving maternal outcomes of low-risk women.

Source	Safety/Quality Issue Related to Clinical Practice	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Rosenblatt 1997[11]	Patterns of obstetric care	Level 3. Provider behavior pattern was the unit of analysis; outcomes included cost of prenatal and intrapartum care.			In Washington State, CNMs were more likely to deliver babies without an operative intervention. Obstetricians were more likely to conduct amniocentesis in the prenatal period (7%) compared to family physicians (1%) or CNMs (2%). Obstetricians were far more likely to perform C-section (15 %) than family physicians (14%) or CNMs (9%). CMNs were far less likely to induce or augment (episiotomy, epidural, fetal monitoring) their patients during delivery. The authors conclude that CNMs have a different approach to intrapartum care than their physician colleagues, which uses fewer resources.
Quality Evidence on CRNAs					
Pine 2003[16]	Surgical patient safety related to type of anesthesia provider	Level 3. Surgical mortality restricted to carotid endartectomies, cholecystectomies, herniorrhaphies, mastectomies, hysterectomies, prostatectomies, and knee replacements.	Retrospective observation on Medicare patients, N = 404,194, from 22 States from 1995 to 1997.	Anesthesia-related deaths among anesthetists vs. nurse anesthetists.	There is no statistically significant difference in the mortality rate for CRNAs and anesthesiologists working together or individually. Inpatient surgical mortality is not affected by whether the anesthesia provider is a CRNA or an anesthesiologist.
Quality Evidence on CNSs					
Brooten 2001[17]	Prenatal, maternal, and infant outcomes	Level 1. Randomized clinical trial n = 173 women and 194 infants.	1-year study period in one delivery system of women at high risk for delivering low-birth-weight infants.	Half of the study sample received prenatal care in the home by CNS while they received traditional obstetrical care.	Group cared for in the home had 2 fetal infant deaths compared to the control group (9); fewer preterm infants, 78% of twin pregnancies carried to term (9), control group = 33%); 4 prenatal hospitalizations, 18 infant rehospitalizations (control group = 24). CNS home care saved 750 total hospital days or about $2.5 million.

Source	Safety/Quality Issue Related to Clinical Practice	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Brooten 1996[20]	Safety and cost effectiveness of care by CNSs.	Level 1. Randomized clinical trial, n = 79 patients in one system. Outcomes included hospital costs, physician fees, home followup care by CNSs.	Very low-birth-weight infants discharged from a hospital early.	Home care followup by CNS.	Mean hospital costs were 27% less than the control group ($47,520 vs. $64,940, $P < 0.01$); the mean physician charge was 22% ($P < 0.01$) less in the group cared for in the home by CNS. The mean cost of home care was $576, yielding a net savings of $18,560
Naylor 1994[19]	Hospital transition to home for frail elderly	Level 1. Randomized clinical trial; initial hospital discharge until 6 weeks after discharge.	Medical and surgical patient and caregiver posthospital discharge outcomes and cost of care, N = 276 patients and 125 caregivers	Comprehensive CNS-delivered discharge planning protocol.	The medical patient group had fewer hospital readmissions, fewer total days of hospital readmission, lower readmission charges. The surgical intervention group showed no significant differences with the control group during the discharge period.
Topp 1998[18]	Effect of CNS case management	Level 4. Quasi-experimental comparative, correlational. Outcomes included nursing interventions, length of stay, complication rate.	Chart review of 164 post-op total knee replacements in one delivery system.	CNS case management	Patients in the units with CNSs received more nursing interventions, had shorter lengths of stay.
Quality Evidence on NPs					
Avorn 1991[26]	Treatment comparisons between NPs and MDs	Level 4. Randomized selection of MDs and NPs given a case vignette.	501 MDs and 298 NPs were presented a case vignette.	Hypothetical scenario involving epigastic pain	More than one-third of the physicians chose to initiate therapy without seeking a relevant history. Nearly half of all physicians indicated that a prescription would be the single most effective therapy; 65% recommended a histamine antagonist. By contrast, only 19% of NPs opted to treat without taking further history; the nurse sample asked an average of 2.6 questions vs. 1.6 for physicians. These findings suggest that NPs ask more questions and were less likely to recommend prescription medication when not indicated by clinical circumstances.

Source	Safety/Quality Issue Related to Clinical Practice	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Lambing 2004[23]	Acute care outcomes of frail elderly	Level 4. Descriptive comparative, research using a convenience sample of providers and self report. Outcomes measures obtained from claims data include charges for length of stay, hospital readmission, and mortality rates.	Random selection of 100 inpatient geriatric patients and a convenience sample of 17 professional providers who cared for them in one hospital in the Midwest over 1 month.	MD vs. NP provider	NP patients were older ($P < 0.022$) and sicker at admission ($P \leq 0.001$) and discharge ($P \leq 0.001$). Charges for length of stay were lower ($P \leq 0.001$) for the physician provider group, and patients in that group had shorter stays ($P = 0.001$). Readmission and mortality rates were similar for both MD and NP groups. The authors conclude that NPs provide effective care to hospitalized geriatric patients, particularly to those who are older and sicker.
Mundinger 2000[24]	NP outcomes in primary care after an urgent or urgent care visit.	Level 2. Randomized clinical trial between August 1995 and October 1997 with patient interviews at 6 months after initial appointment and health services utilization.	Four community-based primary care clinics (17 physicians) and 1 primary care clinic (7 NPs) at an urban academic medical enter, N = 1,316.	NP practice with the same degree of independence as MDs, compared to MD process outcomes.	No significant differences were found in patients' health status at 6 months. Physiologic status for patients with diabetes or asthma were no different. For hypertensive patients, the diastolic value was significantly lower for NP patients (82 vs.88 mg Hg; $P < 0.04$). No significant differences were found in health services utilization after 6 months or 1 year. There were no differences in satisfaction ratings following the initial appointment. Satisfaction ratings at 6 months differed for 1 of 4 dimensions measured (provider attributes), with MD rates higher(4.2 vs. 4.5 on a scale where 5 = excellent; $P = 0.05$). Authors conclude that primary care outcomes of NPs are comparable to MDs when NPs have the same level of authority, responsibilities, productivity, and administrative requirements.
Lenz 2004[25]	2-year followup of outcomes on patients followed by NPs and MDs	Level 2. Randomized clinical trial (of same sample in Mundinger, 2000)	N = 406 adults	Health status, disease-specific physiologic measures, satisfaction or use of specialist, emergency or inpatient services.	Results consistent with 6-month findings (see Mundinger, 2000). The body of evidence suggests that the quality of primary care delivered by NPs is equivalent to that of MDs.

CNM = clinical nurse midwife; CRNA = clinical registered nurse anesthetist; CNS = clinical nurse specialist; NP = nurse practitioner.

Chapter 44. Tools and Strategies for Quality Improvement and Patient Safety

Ronda G. Hughes

Background

The necessity for quality and safety improvement initiatives permeates health care.[1, 2] Quality health care is defined as "the degree to which health services for individuals and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge"[3] (p. 1161). According to the Institute of Medicine (IOM) report, *To Err Is Human*,[4] the majority of medical errors result from faulty systems and processes, not individuals. Processes that are inefficient and variable, changing case mix of patients, health insurance, differences in provider education and experience, and numerous other factors contribute to the complexity of health care. With this in mind, the IOM also asserted that today's health care industry functions at a lower level than it can and should, and it put forth the following six aims of health care: effective, safe, patient-centered, timely, efficient, and equitable.[2] The aims of effectiveness and safety are targeted through process-of-care measures, assessing whether providers of health care perform processes that have been demonstrated to achieve the desired aims and avoid those processes that are predisposed toward harm. The goals of measuring health care quality are to determine the effects of health care on desired outcomes and to assess the degree to which health care adheres to processes based on scientific evidence or agreed to by professional consensus and is consistent with patient preferences.

Because errors are caused by system or process failures,[5] it is important to adopt various process-improvement techniques to identify inefficiencies, ineffective care, and preventable errors to then influence changes associated with systems. Each of these techniques involves assessing performance and using findings to inform change. This chapter will discuss strategies and tools for quality improvement—including failure modes and effects analysis, Plan-Do-Study-Act, Six Sigma, Lean, and root-cause analysis—that have been used to improve the quality and safety of health care.

Measures and Benchmarks

Efforts to improve quality need to be measured to demonstrate "whether improvement efforts (1) lead to change in the primary end point in the desired direction, (2) contribute to unintended results in different parts of the system, and (3) require additional efforts to bring a process back into acceptable ranges"[6] (p. 735). The rationale for measuring quality improvement is the belief that good performance reflects good-quality practice, and that comparing performance among providers and organizations will encourage better performance. In the past few years, there has been a surge in measuring and reporting the performance of health care systems and processes.[1, 7–9] While public reporting of quality performance can be used to identify areas needing improvement and ascribe national, State, or other level of benchmarks,[10, 11] some providers have been sensitive to comparative performance data being published.[12] Another audience for public reporting, consumers, has had problems interpreting the data in reports and

has consequently not used the reports to the extent hoped to make informed decisions for higher-quality care.[13–15]

The complexity of health care systems and delivery of services, the unpredictable nature of health care, and the occupational differentiation and interdependence among clinicians and systems[16–19] make measuring quality difficult. One of the challenges in using measures in health care is the attribution variability associated with high-level cognitive reasoning, discretionary decisionmaking, problem-solving, and experiential knowledge.[20–22] Another measurement challenge is whether a near miss could have resulted in harm or whether an adverse event was a rare aberration or likely to recur.[23]

The Agency for Healthcare Research and Quality (AHRQ), the National Quality Forum, the Joint Commission, and many other national organizations endorse the use of valid and reliable measures of quality and patient safety to improve health care. Many of these useful measures that can be applied to the different settings of care and care processes can be found at AHRQ's National Quality Measures Clearinghouse (http://www.qualitymeasures.ahrq.gov) and the National Quality Forum's Web site (http://www.qualityforum.org). These measures are generally developed through a process including an assessment of the scientific strength of the evidence found in peer-reviewed literature, evaluating the validity and reliability of the measures and sources of data, determining how best to use the measure (e.g., determine if and how risk adjustment is needed), and actually testing the measure.[24, 25]

Measures of quality and safety can track the progress of quality improvement initiatives using external benchmarks. Benchmarking in health care is defined as the continual and collaborative discipline of measuring and comparing the results of key work processes with those of the best performers[26] in evaluating organizational performance. There are two types of benchmarking that can be used to evaluate patient safety and quality performance. Internal benchmarking is used to identify best practices within an organization, to compare best practices within the organization, and to compare current practice over time. The information and data can be plotted on a control chart with statistically derived upper and lower control limits. However, using only internal benchmarking does not necessarily represent the best practices elsewhere. Competitive or external benchmarking involves using comparative data between organizations to judge performance and identify improvements that have proven to be successful in other organizations. Comparative data are available from national organizations, such as AHRQ's annual National Health Care Quality Report[1] and National Healthcare Disparities Report,[9] as well as several proprietary benchmarking companies or groups (e.g., the American Nurses Association's National Database of Nursing Quality Indicators).

Quality Improvement Strategies

More than 40 years ago, Donabedian[27] proposed measuring the quality of health care by observing its structure, processes, and outcomes. Structure measures assess the accessibility, availability, and quality of resources, such as health insurance, bed capacity of a hospital, and number of nurses with advanced training. Process measures assess the delivery of health care services by clinicians and providers, such as using guidelines for care of diabetic patients. Outcome measures indicate the final result of health care and can be influenced by environmental and behavioral factors. Examples include mortality, patient satisfaction, and improved health status.

Twenty years later, health care leaders borrowed techniques from the work of Deming[28] in rebuilding the manufacturing businesses of post-World War II Japan. Deming, the father of Total

Quality Management (TQM), promoted "constancy of purpose" and systematic analysis and measurement of process steps in relation to capacity or outcomes. The TQM model is an organizational approach involving organizational management, teamwork, defined processes, systems thinking, and change to create an environment for improvement. This approach incorporated the view that the entire organization must be committed to quality and improvement to achieve the best results.[29]

In health care, continuous quality improvement (CQI) is used interchangeably with TQM. CQI has been used as a means to develop clinical practice[30] and is based on the principle that there is an opportunity for improvement in every process and on every occasion.[31] Many in-hospital quality assurance (QA) programs generally focus on issues identified by regulatory or accreditation organizations, such as checking documentation, reviewing the work of oversight committees, and studying credentialing processes.[32] There are several other strategies that have been proposed for improving clinical practice. For example, Horn and colleagues discussed clinical practice improvement (CPI) as a "multidimensional outcomes methodology that has direct application to the clinical management of individual patients"[33] (p. 160). CPI, an approach lead by clinicians that attempts a comprehensive understanding of the complexity of health care delivery, uses a team, determines a purpose, collects data, assesses findings, and then translates those findings into practice changes. From these models, management and clinician commitment and involvement have been found to be essential for the successful implementation of change.[34–36] From other quality improvement strategies, there has been particular emphasis on the need for management to have faith in the project, communicate the purpose, and empower staff.[37]

In the past 20 years, quality improvement methods have "generally emphasize[d] the importance of identifying a process with less-than-ideal outcomes, measuring the key performance attributes, using careful analysis to devise a new approach, integrating the redesigned approach with the process, and reassessing performance to determine if the change in process is successful"[38] (p. 9). Besides TQM, other quality improvement strategies have come forth, including the International Organization for Standardization ISO 9000, Zero Defects, Six Sigma, Baldridge, and Toyota Production System/Lean Production.[6, 39, 40]

Quality improvement is defined "as systematic, data-guided activities designed to bring about immediate improvement in health care delivery in particular settings"[41] (p. 667). A quality improvement strategy is defined as "any intervention aimed at reducing the quality gap for a group of patients representative of those encountered in routine practice"[38] (p. 13). Shojania and colleagues[38] developed a taxonomy of quality improvement strategies (see Table 1), which infers that the choice of the quality improvement strategy and methodology is dependent upon the nature of the quality improvement project. Many other strategies and tools for quality improvement can be accessed at AHRQ's quality tools Web site (www.qualitytools.ahrq.gov) and patient safety Web site (www.patientsafety.gov).

Table 1. Taxonomy of Quality Improvement Strategies With Examples of Substrategies

QI Strategy	Examples
Provider reminder systems	• Reminders in charts for providers • Computer-based reminders for providers • Computer-based decision support
Facilitated relay of clinical data to providers	• Transmission of clinical data from outpatient specialty clinic to primary care provider by means other than medical record (e.g., phone call or fax)

QI Strategy	Examples
Audit and feedback	• Feedback of performance to individual providers • Quality indicators and reports • National/State quality report cards • Publicly released performance data • Benchmarking – provision of outcomes data from top performers for comparison with provider's own data
Provider education	• Workshops and conferences • Educational outreach visits (e.g., academic detailing) • Distributed educational materials
Patient education	• Classes • Parent and family education • Patient pamphlets • Intensive education strategies promoting self-management of chronic conditions
Patient reminder systems	• Materials and devices promoting self-management
Promotion of self-management	• Postcards or calls to patients
Organizational change	• Case management, disease management • TQM, CQI techniques • Multidisciplinary teams • Change from paper to computer-based records • Increased staffing • Skill-mix changes
Financial incentives, regulation, and policy	Provider directed: • Financial incentives based on achievement of performance goals • Alternative reimbursement systems (e.g., fee-for-service, capitated payments) • Licensure requirements Patient directed: • Copayments for certain visit types • Health insurance premiums, user fees Health system directed: • Initiatives by accreditation bodies (e.g., residency work hour limits) • Changes in reimbursement schemes (e.g., capitation, prospective payment, salaried providers)

Note: Reprinted with permission from AHRQ[38] (pp. 17–18).

Quality improvement projects and strategies differ from research: while research attempts to assess and address problems that will produce generalizable results, quality improvement projects can include small samples, frequent changes in interventions, and adoption of new strategies that appear to be effective.[6] In a review of the literature on the differences between quality improvement and research, Reinhardt and Ray[42] proposed four criteria that distinguish the two: (1) quality improvement applies research into practice, while research develops new interventions; (2) risk to participants is not present in quality improvement, while research could pose risk to participants; (3) the primary audience for quality improvement is the organization, and the information from analyses may be applicable only to that organization, while research is intended to be generalizable to all similar organizations; and (4) data from quality improvement is organization-specific, while research data are derived from multiple organizations.

The lack of scientific health services literature has inhibited the acceptance of quality improvement methods in health care,[43, 44] but new rigorous studies are emerging. It has been asserted that a quality improvement project can be considered more like research when it involves a change in practice, affects patients and assesses their outcomes, employs

randomization or blinding, and exposes patients to additional risks or burdens—all in an effort towards generalizability.[45–47] Regardless of whether the project is considered research, human subjects need to be protected by ensuring respect for participants, securing informed consent, and ensuring scientific value.[41, 46, 48]

Plan-Do-Study-Act (PDSA)

Quality improvement projects and studies aimed at making positive changes in health care processes to effecting favorable outcomes can use the Plan-Do-Study-Act (PDSA) model. This is a method that has been widely used by the Institute for Healthcare Improvement for rapid cycle improvement.[31, 49] One of the unique features of this model is the cyclical nature of impacting and assessing change, most effectively accomplished through small and frequent PDSAs rather than big and slow ones,[50] before changes are made systemwide.[31, 51]

The purpose of PDSA quality improvement efforts is to establish a functional or causal relationship between changes in processes (specifically behaviors and capabilities) and outcomes. Langley and colleagues[51] proposed three questions before using the PDSA cycles: (1) What is the goal of the project? (2) How will it be known whether the goal was reached? and (3) What will be done to reach the goal? The PDSA cycle starts with determining the nature and scope of the problem, what changes can and should be made, a plan for a specific change, who should be involved, what should be measured to understand the impact of change, and where the strategy will be targeted. Change is then implemented and data and information are collected. Results from the implementation study are assessed and interpreted by reviewing several key measurements that indicate success or failure. Lastly, action is taken on the results by implementing the change or beginning the process again.[51]

Six Sigma

Six Sigma, originally designed as a business strategy, involves improving, designing, and monitoring process to minimize or eliminate waste while optimizing satisfaction and increasing financial stability.[52] The performance of a process—or the process capability—is used to measure improvement by comparing the baseline process capability (before improvement) with the process capability after piloting potential solutions for quality improvement.[53] There are two primary methods used with Six Sigma. One method inspects process outcome and counts the defects, calculates a defect rate per million, and uses a statistical table to convert defect rate per million to a σ (sigma) metric. This method is applicable to preanalytic and postanalytic processes (a.k.a. pretest and post-test studies). The second method uses estimates of process variation to predict process performance by calculating a σ metric from the defined tolerance limits and the variation observed for the process. This method is suitable for analytic processes in which the precision and accuracy can be determined by experimental procedures.

One component of Six Sigma uses a five-phased process that is structured, disciplined, and rigorous, known as the define, measure, analyze, improve, and control (DMAIC) approach.[53, 54] To begin, the project is identified, historical data are reviewed, and the scope of expectations is defined. Next, continuous total quality performance standards are selected, performance objectives are defined, and sources of variability are defined. As the new project is implemented, data are collected to assess how well changes improved the process. To support this analysis, validated measures are developed to determine the capability of the new process.

Six Sigma and PDSA are interrelated. The DMAIC methodology builds on Shewhart's plan, do, check, and act cycle.[55] The key elements of Six Sigma is related to PDSA as follows: the plan phase of PDSA is related to define core processes, key customers, and customer requirements of Six Sigma; the do phase of PDSA is related to measure performance of Six Sigma; the study phase of PDSA is related to analyze of Six Sigma; and the act phase of PDSA is related to improve and integrate of Six Sigma.[56]

Toyota Production System/Lean Production System

Application of the Toyota Production System—used in the manufacturing process of Toyota cars[57]—resulted in what has become known as the Lean Production System or Lean methodology. This methodology overlaps with the Six Sigma methodology, but differs in that Lean is driven by the identification of customer needs and aims to improve processes by removing activities that are non-value-added (a.k.a. waste). Steps in the Lean methodology involve maximizing value-added activities in the best possible sequence to enable continuous operations.[58] This methodology depends on root-cause analysis to investigate errors and then to improve quality and prevent similar errors.

Physicians, nurses, technicians, and managers are increasing the effectiveness of patient care and decreasing costs in pathology laboratories, pharmacies,[59–61] and blood banks[61] by applying the same principles used in the Toyota Production System. Two reviews of projects using Toyota Production System methods reported that health care organizations improved patient safety and the quality of health care by systematically defining the problem; using root-cause analysis; then setting goals, removing ambiguity and workarounds, and clarifying responsibilities. When it came to processes, team members in these projects developed action plans that improved, simplified, and redesigned work processes.[59, 60] According to Spear, the Toyota Production System method was used to make the "following crystal clear: which patient gets which procedure (output); who does which aspect of the job (responsibility); exactly which signals are used to indicate that the work should begin (connection); and precisely how each step is carried out"[60] (p. 84).

Factors involved in the successful application of the Toyota Production System in health care are eliminating unnecessary daily activities associated with "overcomplicated processes, workarounds, and rework"[59] (p. 234), involving front-line staff throughout the process, and rigorously tracking problems as they are experimented with throughout the problem-solving process.

Root Cause Analysis

Root cause analysis (RCA), used extensively in engineering[62] and similar to critical incident technique,[63] is a formalized investigation and problem-solving approach focused on identifying and understanding the underlying causes of an event as well as potential events that were intercepted. The Joint Commission requires RCA to be performed in response to all sentinel events and expects, based on the results of the RCA, the organization to develop and implement an action plan consisting of improvements designed to reduce future risk of events and to monitor the effectiveness of those improvements.[64]

RCA is a technique used to identify trends and assess risk that can be used whenever human error is suspected[65] with the understanding that system, rather than individual factors, are likely

the root cause of most problems.[2, 4] A similar procedure is critical incident technique, where after an event occurs, information is collected on the causes and actions that led to the event.[63]

An RCA is a reactive assessment that begins after an event, retrospectively outlining the sequence of events leading to that identified event, charting causal factors, and identifying root causes to completely examine the event.[66] Because it is a labor-intensive process, ideally a multidisciplinary team trained in RCA triangulates or corroborates major findings and increases the validity of findings.[67] Taken one step further, the notion of aggregate RCA (used by the Veterans Affairs (VA) Health System) is purported to use staff time efficiently and involves several simultaneous RCAs that focus on assessing trends, rather than an in-depth case assessment.[68]

Using a qualitative process, the aim of RCA is to uncover the underlying cause(s) of an error by looking at enabling factors (e.g., lack of education), including latent conditions (e.g., not checking the patient's ID band) and situational factors (e.g., two patients in the hospital with the same last name) that contributed to or enabled the adverse event (e.g., an adverse drug event). Those involved in the investigation ask a series of key questions, including what happened, why it happened, what were the most proximate factors causing it to happen, why those factors occurred, and what systems and processes underlie those proximate factors. Answers to these questions help identify ineffective safety barriers and causes of problems so similar problems can be prevented in the future. Often, it is important to also consider events that occurred immediately prior to the event in question because other remote factors may have contributed.[68]

The final step of a traditional RCA is developing recommendations for system and process improvement(s), based on the findings of the investigation.[68] The importance of this step is supported by a review of the literature on root-cause analysis, where the authors conclude that there is little evidence that RCA can improve patient safety by itself.[69] A nontraditional strategy, used by the VA, is aggregate RCA processes, where several simultaneous RCAs are used to examine multiple cases in a single review for certain categories of events.[68, 70]

Due the breadth of types of adverse events and the large number of root causes of errors, consideration should be given to how to differentiate system from process factors, without focusing on individual blame. The notion has been put forth that it is a truly rare event for errors to be associated with irresponsibility, personal neglect, or intention,[71] a notion supported by the IOM.[4, 72] Yet efforts to categorize individual errors—such as the Taxonomy of Error Root Cause Analysis of Practice Responsibility (TERCAP), which focuses on "lack of attentiveness, lack of agency/fiduciary concern, inappropriate judgment, lack of intervention on the patient's behalf, lack of prevention, missed or mistaken MD/healthcare provider's orders, and documentation error"[73] (p. 512)—may distract the team from investigating systems and process factors that can be modified through subsequent interventions. Even the majority of individual factors can be addressed through education, training, and installing forcing functions that make errors difficult to commit.

Failure Modes and Effects Analysis

Errors will inevitably occur, and the times when errors occur cannot be predicted. Failure modes and effects analysis (FMEA) is an evaluation technique used to identify and eliminate known and/or potential failures, problems, and errors from a system, design, process, and/or service before they actually occur.[74–76] FMEA was developed for use by the U.S. military and has been used by the National Aeronautics and Space Administration (NASA) to predict and evaluate potential failures and unrecognized hazards (e.g., probabilistic occurrences) and to

proactively identify steps in a process that could reduce or eliminate future failures.[77] The goal of FMEA is to prevent errors by attempting to identifying all the ways a process could fail, estimate the probability and consequences of each failure, and then take action to prevent the potential failures from occurring. In health care, FMEA focuses on the system of care and uses a multidisciplinary team to evaluate a process from a quality improvement perspective.

This method can be used to evaluate alternative processes or procedures as well as to monitor change over time. To monitor change over time, well-defined measures are needed that can provide objective information of the effectiveness of a process. In 2001, the Joint Commission mandated that accredited health care providers conduct proactive risk management activities that identify and predict system weaknesses and adopt changes to minimize patient harm on one or two high-priority topics a year.[78]

HFMEA. Developed by the VA's National Center for Patient Safety, the health failure modes and effects analysis (HFMEA) tool is used for risk assessment. There are five steps in HFMEA: (1) define the topic; (2) assemble the team; (3) develop a process map for the topic, and consecutively number each step and substep of that process; (4) conduct a hazard analysis (e.g., identify cause of failure modes, score each failure mode using the hazard scoring matrix, and work through the decision tree analysis);[79] and (5) develop actions and desired outcomes. In conducting a hazard analysis, it is important to list all possible and potential failure modes for each of the processes, to determine whether the failure modes warrant further action, and to list all causes for each failure mode when the decision is to proceed further. After the hazard analysis, it is important to consider the actions needed to be taken and outcome measures to assess, including describing what will be eliminated or controlled and who will have responsibility for each new action.[79]

Research Evidence

Fifty studies and quality improvement projects were included in this analysis. The findings were categorized by type of quality method employed, including FMEA, RCA, Six Sigma, Lean, and PDSA. Several common themes emerged: (1) what was needed to implement quality improvement strategies, (2) what was learned from evaluating the impact of change interventions, and (3) what is known about using quality improvement tools in health care.

What Was Needed To Implement Quality Improvement Strategies?

Substantial and strong leadership support,[80–83] involvement,[81, 84] consistent commitment to continuous quality improvement,[85, 86] and visibility,[87] both in writing and physically, [86] were important in making significant changes. Substantial commitment from hospital boards was also found to be necessary.[86, 88] The inevitability of resource demands associated with changing process required senior leadership to (1) ensure adequate financial resources[87–89] by identifying sources of funds for training and purchasing and testing innovative technologies[90] and equipment;[91] (2) facilitate and enable key players to have the needed time to be actively involved in the change processes,[85, 88, 89] providing administrative support; [90] (3) support a time-consuming project by granting enough time for it to work;[86, 92] and (4) emphasize safety as an organizational priority and reinforce expectations, especially when the process was delayed or results were periodically not realized.[87] It was also asserted that senior leaders needed to understand the impact of high-level decisions on work processes and staff time,[88] especially when efforts were

underway to change practice, and that quality improvement needed to be incorporated into systemwide leadership development.[88] Leadership was needed to make patient safety a key aspect of all meetings and strategies,[85, 86] to create a formal process for identifying annual patient safety goals for the organization, and to hold themselves accountable for patient safety outcomes.[85]

Even with strong and committed leadership, some people within the organization may be hesitant to participate in quality improvement efforts because previous attempts to create change were hindered by various system factors,[93] a lack of organization-wide commitment,[94] poor organizational relationships, and ineffective communication.[89] However the impact of these barriers were found to be lessened if the organization embraced the need for change,[95] changed the culture to enable change,[90] and actively pursued institutionalizing a culture of safety and quality improvement. Yet adopting a nonpunitive culture of change took time,[61, 90] even to the extent that the legal department in one hospital was engaged in the process to turn the focus to systems, not individual-specific issues.[96] Also, those staff members involved in the process felt more at ease with improving processes, particularly when cost savings were realized and when no layoff policies were put in place to protect job security even when efficiencies were realized.[84]

The improvement process needed to engage[97] and involve all stakeholders and gain their understanding that the investment of resources in quality improvement could be recouped with efficiency gains and fewer adverse events.[86] Stakeholders were used to (1) prioritize which safe practices to target by developing a consensus process among stakeholders[86, 98] around issues that were clinically important, i.e., hazards encountered in everyday practice that would make a substantial impact on patient safety; (2) develop solutions to the problems that required addressing fundamental issues of interdisciplinary communication and teamwork, which were recognized as crucial aspects of a culture of safety; and (3) build upon the success of other hospitals.[86] In an initiative involving a number of rapid-cycle collaboratives, successful collaboratives were found to have used stakeholders to determine the choice of subject, define objectives, define roles and expectations, motivate teams, and use results from data analyses.[86] Additionally, it was important to take into account the different perspectives of stakeholders.[97] Because variation in opinion among stakeholders and team members was expected[99] and achieving buy-in from all stakeholders could have been difficult to achieve, efforts were made to involve stakeholders early in the process, solicit feedback,[100] and gain support for critical changes in the process.[101]

Communication and sharing information with stakeholders and staff was critical to specifying the purpose and strategy of the quality initiative;[101] developing open channels of communication across all disciplines and at all levels of leadership/staff, permitting the voicing of concerns and observations throughout the process of creating change;[88] ensuring that patients and families were appropriately included in the dialogue; ensuring that everyone involved felt that he or she was an integral part of the health care team and was responsible for patient safety; sharing lessons learned from root-cause analysis; and capturing attention and soliciting buy-in by sharing patient safety stories with staff and celebrating successes, no matter how small.[85] Yet in trying to keep everyone informed of the process and the data behind decisions, some staff had difficulty accepting system changes made in response to the data.[89]

The successful work of these strategies was dependent upon having motivated[80] and empowered teams. There were many advantages to basing the work of the quality improvement strategies on the teamwork of multidisciplinary teams that would review data and lead change.[91]

These teams needed to be comprised of the right staff people,[91, 92] include peers,[102] engage all of the right stakeholders (ranging from senior managers to staff), and be supported by senior-level management/leadership.[85, 86] Specific stakeholders (e.g., nurses and physicians) had to be involved[81] and supported to actually make the change, and to be the champions[103] and problem-solvers within departments[59] for the interventions to succeed. Because implementing the quality initiatives required substantial changes in the clinician's daily work,[86] consideration of the attitude and willingness of front-line staff for making the specific improvements[59, 88, 104] was needed.

Other key factors to improvement success were implementing protocols that could be adapted to the patient's needs[93] and to each unit, based on experience, training, and culture.[88] It was also important to define and test different approaches; different approaches can converge and arrive at the same point.[81] Mechanisms that facilitated staff buy-in was putting the types and causes of errors in the forefront of providers' minds, making errors visible,[102] being involved in the process of assessing work and looking for waste,[59] providing insight as to whether the improvement project would be feasible and its impact measurable,[105] and presenting evidence-based changes.[100] Physicians were singled out as the one group of clinicians that needed to lead[106] or be actively involved in changes,[86] especially when physician behaviors could create inefficiencies.[84] In one project, physicians were recruited as champions to help spread the word to other physicians about the critical role of patient safety, to make patient safety a key aspect of all leadership and medical management meetings and strategies.[85]

Team leaders and the composition of the team were also important. Team leaders that emphasized efforts offline to help build and improve relationships were found to be necessary for team success.[83, 93] These teams needed a dedicated team leader who would have a significant amount of time to put into the project.[84] While the leader was not identified in the majority of reports reviewed for this paper, the team on one project was co-chaired by a physician and an administrator.[83] Not only did the type and ability of team leaders affect outcomes, the visibility of the initiative throughout the organization was dependent upon having visible champions.[100] Multidisciplinary teams needed to understand the numerous steps involved in quality improvement and that there were many opportunities for error, which essentially enabled teams to prioritize the critical items to improve within a complex process and took out some of the subjectivity from the analysis. The multidisciplinary structure of teams allowed members to identify each step from their own professional practice perspective, anticipate and overcome potential barriers, allowed the generation of diverse ideas, and allowed for good discussion and deliberations, which together ultimately promoted team building.[100, 107] In two of the studies, FMEA/HFMEA was found to minimize group biases by benefiting from the diversity within multidisciplinary composition of the team and enabling the team to focus on a structured outline of the goals that needed to be accomplished.[107, 108]

Teams needed to be prepared and enabled to meet the demands of the quality initiatives with ongoing education, weekly debriefings, review of problems solved and principles applied,[84] and ongoing monitoring and feedback opportunities.[92, 95] Education and training of staff [95, 80, 95, 101, 104] and leadership [80] about the current problem, quality improvement tools, the planned change in practice intervention, and updates as the project progressed were key strategies.[92] Training was an ongoing process [91] that needed to focus on skill deficits[82] and needed to be revised as lessons were learned and data was analyzed during the implementation of the project.[109] The assumption could not be made that senior staff or leadership would not need training.[105] Furthermore, if the team had no experience with the quality tools or successfully creating change, an additional

resource could have been a consultant or someone to facilitate the advanced knowledge involved in quality improvement techniques.[106] Another consideration was using a model that intervened at the hospital-community interface, coupled with an education program.[97]

The influence of teamwork processes enabled those within the team to improve relationships across departments.[89] Particular attention needed to be given to effective team building,[110] actively following the impact of using the rapid-cycle (PDSA) model, meeting frequently, and monitoring progress using outcome data analysis at least on a monthly basis.[86] Effective teamwork and communication, information transfer, coordination among multiple hospital departments and caregivers, and changes to hospital organization culture were considered essential elements of team effectiveness.[86] Yet the impact of team members that had difficulty in fully engaging in teamwork because of competing workloads (e.g., working double shifts) was dampened.[97] Better understanding of each other's role is an important project outcome and provides a basis for continuing the development of other practices to improve outcomes.[97] The work of teams was motivated through continual sharing of progress and success and celebration of achievements.[87]

Teamwork can have many advantages, but only a few were discussed in the reports reviewed. Teams were seen as being able to increase the scope of knowledge, improve communication across disciplines, and facilitate learning about the problem.[111] Teams were also found to be proactive, [91] integrating tools that improve both the technical processes and organizational relationships,[83] and to work together to understand the current situation, define the problem, pathways, tasks, and connections, as well as to develop a multidisciplinary action plan.[59] But teamwork was not necessarily an easy process. Group work was seen as difficult for some and time consuming,[111] and problems arose when everyone wanted their way,[97] which delayed convergence toward a consensus on actions. Team members needed to learn how to work with a group and deal with group dynamics, confronting peers, conflict resolution, and addressing behaviors that are detrimental.[111]

What Was Learned From Evaluating the Impact of Change Interventions?

As suggested by Berwick,[112] the leaders of the quality improvement initiatives in this review found that successful initiatives needed to simplify;[96, 104] standardize;[104] stratify to determine effects; improve auditory communication patterns; support communication against the authority gradient; [96] use defaults properly; automate cautiously; [96] use affordance and natural mapping (e.g., design processes and equipment so that the easiest thing to do is the right thing to do); respect limits of vigilance and attention; [96] and encourage reporting of near hits, errors, and hazardous conditions.[96] Through the revision and standardization of policies and procedures, many of these initiatives were able to effectively realize the benefit of making the new process easier than the old and decrease the effect of human error associated with limited vigilance and attention.[78, 80–82, 90–92, 94, 96, 102, 103, 113, 114]

Simplification and standardization were found to be effective as a forcing function by decreasing reliance on individualized decisionmaking. Several initiatives standardized medication ordering and administration protocols,[78, 87, 101, 103, 106–108, 109, 114–116] realizing improvements in patient outcomes, nurse efficiency, and effectiveness.[103, 106, 108, 109, 114–116] One initiative used a standardized form for blood product ordering.[94] Four initiatives improved pain

assessment and management by using standardized metrics and assessment tools.[80, 93, 100, 117] In all of these initiatives, simplification and standardization were effective strategies.

Related to simplification and standardization is the potential benefit of using information technology to implement checks, defaults, and automation to improve quality and reduce errors, in large part to embedding forcing functions to remove the possibility of errors.[96, 106] The effects of human error could be mitigated by using necessary redundancy, such as double-checking for certain types of errors; this was seen as engaging the knowledge and abilities of two skilled practitioners [61, 101] and was used successfully to reduce errors associated with dosing.[78] Information technology was successfully used to (1) decrease the opportunity for human error through automation;[61] (2) standardize medication concentrations[78] and dosing using computer-enabled calculations,[115, 116] standardized protocols,[101] and order clarity;[116] (3) assist caregivers in providing quality care using alerts and reminders; (4) improve medication safety (e.g., implementing bar coding and computerized provider order entry); and (5) track performance through database integration and indicator monitoring. Often workflow and procedures needed to be revised to keep pace with technology.[78] Using technology implied that organizations were committed to investing in technology to enable improvement,[85] but for two initiatives, the lack of adequate resources for data collection impacted analysis and evaluation of the initiative.[93, 97]

Data and information were needed to understand the root causes of errors and near errors,[99] to understand the magnitude of adverse events,[106] to track and monitor performance,[84, 118] and to assess the impact of the initiatives.[61] Reporting of near misses, errors, and hazardous conditions needs to be encouraged.[96] In part, this is because error reporting is generally low and is associated with organizational culture[106] and can be biased, which will taint results.[102] Organizations not prioritizing reporting or not strongly emphasizing a culture of safety may have the tendency to not report errors that harm patients or near misses (see Chapter 35. "Evidence Reporting and Disclosure"). Using and analyzing data was viewed as critical, yet some team members and staff may have benefited from education on how to effectively analyze and display findings.[106] Giving staff feedback by having a transparent process[39] of reporting findings[82] was viewed as a useful trigger that brought patient safety to the forefront of the hospital.[107] It follows then that not having data, whether because it was not reported or not collected, made statistical analysis of the impact of the initiative[115] or assessing its cost-benefit ratio not possible.[108] As such, multi-organizational collaboration should have a common database.[98]

The meaning of data can be better understood by using measures and benchmarks. Repeated measurements were found to be useful for monitoring progress,[118] but only when there was a clear metric for measuring the degree of success.[83] The use of measures could be used as a strategy to involve more clinicians and deepened their interest, especially physicians. Using objective, broader, and better measures was viewed as being important for marking progress, and provided a basis for "a call to action" and celebration.[106] When measures of care processes were used, it was asserted that there was a need to demonstrate the relationship between specific changes to care processes and outcomes.[61]

When multiple measures were used, along with better documentation of care, it was easier to assess the impact of the initiative on patient outcomes.[93] Investigators from one initiative put forth the notion that hospital administrators should encourage more evaluations of initiatives and that the evaluations should focus on comprehensive models that assess patient outcomes, patient satisfaction, and cost effectiveness.[114] The assessment of outcomes can be enhanced by setting realistic goals, not unrealistic goals such as 100 percent change,[119] and by comparing organizational results to recognized State, regional, and national benchmarks.[61, 88]

The cost of the initiative was an viewed as important factor in the potential for improvement, even when the adverse effects of current processes were considered as necessitating rapid change.[106] Because of this, it is important to implement changes that are readily feasible[106] and can be implemented with minimal disruption of practice activities.[99] It is also important to consider the potential of replicating the initiative in other units or at other sites.[99] One strategy to improve the chances of replication is to standardize processes, which will most likely incur some cost.[106] In some respects, the faster small problems were resolved, the faster improvements could be replicated throughout the entire system.[84, 106] Recommendations that did not incur costs or had low costs and could be demonstrated to be effective were implemented expeditiously.[93, 107] A couple of investigators stated that their interventions decreased costs and patients' length of stay,[103] but did not present any data to verify those statements. It was also purported that the costs associated with change will be recouped either in return on investment or in reduced patient risk (and thus reduced liability costs).[61]

Ensuring that those implementing the initiative receive education is critical. There were several examples of this. Two initiatives that targeted pain management found that educating staff on pain management guidelines and protocols for improving chronic pain assessment and management improved staff understanding, assessment and documentation, patient and family satisfaction, and pain management.[80, 93] Another initiative educated all staff nurses on intravenous (IV) site care and assessment, as well as assessment of central lines, and realized improved patient satisfaction and reduced complications and costs.[109]

Despite the benefits afforded by the initiatives, there were many challenges that were identified in implementing the various initiatives:

- Lack of time and resources made it difficult to implement the initiative well.[82]
- Some physicians would not accept the new protocol and thwarted implementation until they had confidence in the tool.[103]
- Clear expectations were lacking. [86]
- Hospital leadership was not adequately engaged.[86]
- There was insufficient emphasis on importance and use of measures.[86]
- The number and type of collaborative staffing was insufficient.[86]
- The time required for nurses and other staff to implement the changes was underestimated.[120]
- The extent to which differences in patient severity accounted for results could not be evaluated because severity of illness was not measured.[89]
- Improvements associated with each individual PDSA cycle could not be evaluated.[89]
- The full impact on the costs of care, including fixed costs for overhead, could not be evaluated.[89]
- Failure to consider the influence of factors such as fatigue, distraction, time pressures.[82]
- The Hawthorne effect may have caused improvements more so than the initiative.[118]
- Many factors were interrelated and correlated.[96]
- There was a lack of generalizability because of small sample size.[93, 119]
- Addressing some of the problems created others (e.g., implementing computerized physician order entry (CPOE)).[110]
- Targets set (e.g., 100 percent of admissions) may have been too ambitious and were thus always demanding and difficult-to-achieve service improvements.[119]

Despite the aforementioned challenges, many investigators found that it was important to persevere and stay focused because introducing new processes can be difficult, [84, 100] but the reward of quality improvement is worth the effort.[84] Implementing quality improvement initiatives was considered time consuming, tedious, and difficult for people who are very action oriented; it required an extensive investment of resources (i.e., time, money, and energy);[94] and it involved trial and error to improve the process.[91] Given theses and other challenges, it was also important to celebrate the victories.[84]

Other considerations were given to the desired objective of sustaining the changes after the implementation phase of the initiative ended.[105] Investigators asserted that improving quality through initiatives needed to be considered as integral in the larger, organizationwide, ongoing process of improvement. Influential factors attributed to the success of the initiatives were effecting practice changes that could be easily used at the bedside;[82] using simple communication strategies; [88] maximizing project visibility, which could sustain the momentum for change;[100] establishing a culture of safety; and strengthening the organizational and technological infrastructure.[121] However, there were opposing viewpoints about the importance of spreading the steps involved in creating specific changes (possibly by forcing changes into the redesign of processes), rather than only relying on only adapting best practices.[106, 121] Another factor was the importance of generating enthusiasm about embracing change through a combination of collaboration (both internally and externally)[103] and healthy competition. Collaboratives could also be a vehicle for encouraging the use of and learning from evidence-based practice and rapid-cycle improvement as well as identifying and gaining consensus on potentially better practices.[86, 98]

What Is Known About Using Quality Improvement Tools in Health Care?

Quality tools used to define and assess problems with health care were seen as being helpful in prioritizing quality and safety problems[99] and focusing on systems,[98] not individuals. The various tools were used to address errors and growing costs[88] and to change provider practices.[117] Several of the initiatives used more than one of the quality improvement tools, such as beginning with root-cause analysis then using either Six Sigma, Toyota Production System/Lean, or Plan-Do-Study-Act to implement change in processes. Almost every initiative included in this analysis performed some type of pretesting/pilot testing.[92, 99] Investigators and leaders of several initiatives reported advantages of using specific types of quality tools. These are discussed as follows:

Root-cause analysis was reported to be useful to assess reported errors/incidents and differentiate between active and latent errors, to identify need for changes to policies and procedures, and to serve as a basis to suggest system changes, including improving communication of risk.[82, 96, 102, 105]

Six Sigma/Toyota Production System was reported to have been successfully used to decrease defects/variations[59, 61, 81] and operating costs[81] and improve outcomes in a variety of health care settings and for a variety of processes.[61, 88] Six Sigma was found to be a detailed process that clearly differentiated between the causes of variation and outcome measures of process.[61] One of the advantages of using Six Sigma was that it made work-arounds and rework difficult because the root causes of the preimplementation processes were targeted.[59, 88] Additionally, investigators reported that the more teams worked with this strategy, the better they

became at implementing it and the more effective the results.[84] Yet it was noted that to use this strategy effectively, a substantial commitment of leadership time and resources was associated with improved patient safety, lowered costs, and increased job satisfaction.[84] Six Sigma was also an important strategy for problem-solving and continuous improvement; communicating clearly about the problem; guiding the implementation process; and producing results in a clear, concise, and objective way.[59]

Plan-Do-Study-Act (PDSA) was used by the majority of initiatives included in this analysis to implement initiatives gradually, while improving them as needed. The rapid-cycle aspect of PDSA began with piloting a single new process, followed by examining results and responding to what was learned by problem-solving and making adjustments, after which the next PDSA cycle would be initiated. The majority of quality improvement efforts using PDSA found greater success using a series of small and rapid cycles to achieve the goals for the intervention, because implementing the initiative gradually allowed the team to make changes early in the process[80] and not get distracted or sidetracked by every detail and too many unknowns.[87, 119, 122] The ability of the team to successfully use the PDSA process was improved by providing instruction and training on the use of PDSA cycles, using feedback on the results of the baseline measurements,[118] meeting regularly,[120] and increasing the team's effectiveness by collaborating with others, including patients and families,[80] to achieve a common goal.[87] Conversely, some teams experienced difficulty in using rapid-cycle change, collecting data, and constructing run charts,[86] and one team reported that applying simple rules in PDSA cycles may have been more successful in a complex system.[93]

Failure modes and effects analysis (FMEA) was used to avoid events and improve or maintain the quality of care.[123] FMEA was used prospectively to identify potential areas of failure[94] where experimental characterization of the process at the desired speed of change could be assessed,[115] and retrospectively to characterize the safety of a process by identifying potential areas of failure, learning about the process from the staff's point of view.[94] Using a flow chart of the process before beginning the analysis got the team to focus and work from the same document.[94] Information learned from FMEA was used to provide data for prioritizing improvement strategies, serve as a benchmark for improvement efforts,[116] educate and provide a rationale for diffusion of these practice changes to other settings,[115] and increase the ability of the team to facilitate change across all services and departments within the hospital.[124] Using FMEA facilitated systematic error management, which was important to good clinical care in complex processes and complex settings, and was dependent upon a multidisciplinary approach, integrated incident and error reporting, decision support, standardization of terminology, and education of caregivers.[116]

Health failure modes and effects analysis (HFMEA) was used to provide a more detailed analysis of smaller processes, resulting in more specific recommendations, as well as larger processes. HFEMA was viewed as a valid tool for proactive analysis in hospitals, facilitating a very thorough analysis of vulnerabilities (i.e., failure modes) before adverse events occurred.[108] This tool was considered valuable in identifying the multifactoral nature of most errors[108] and the potential risk for errors,[111] but was seen as being time consuming.[107] Initiatives that used HFMEA could minimize group biases through the multidisciplinary composition of the team[78, 108, 115] and facilitate teamwork by providing a step-by-step process,[107] but these initiatives required a paradigm shift for many.[111]

Evidence-Based Practice Implications

From the improvement strategies and projects assessed in this review, several themes emerged from successful initiatives that nurses can use to guide quality improvement efforts. The strength of the following practice implications is associated with the methodological rigor and generalizability of these strategies and projects:

1. The importance of having strong *leadership* commitment and support cannot be overstated. Leadership needs to empower staff, be actively involved, and continuously drive quality improvement. Without the commitment and support of senior-level leadership, even the best intended projects are at great risk of not being successful. Champions of the quality initiative and quality improvement need to be throughout the organization, but especially in leadership positions and on the team.
2. A *culture of safety and improvement* that rewards improvement and is driven to improve quality is important. The culture is needed to support a quality infrastructure that has the resources and human capital required for successfully improving quality.
3. Quality improvement teams need to have the right *stakeholders* involved.
4. Due to the complexity of health care, *multidisciplinary teams and strategies* are essential. Multidisciplinary teams from participating centers/units need to work closely together, taking advantage of communication strategies such as face-to-face meetings, conference calls, and dedicated e-mail listservs, and utilize the guidance of trained facilitators and expert faculty throughout the process of implementing change initiatives when possible**.**
5. Quality improvement teams and stakeholders need to *understand the problem and root causes*. There must be a consensus on the definition of the problem. To this end, a clearly defined and universally agreed upon metric is essential. This agreement is as crucial to the success of any improvement effort as the validity of the data itself.
6. Use a *proven, methodologically sound approach* without being distracted by the jargon used in quality improvement. The importance given to using clear models, terms, and process is critical, especially because many of the quality tools are interrelated; using only one tool will not produce successful results.
7. *Standardizing care processes* and ensuring that everyone uses those standards should improve processes by making them more efficient and effective—and improve organizational and patient outcomes.
8. *Evidence-based practice* can facilitate ongoing quality improvement efforts.
9. Implementation plans need to be *flexible* to adapt to needed changes as they come up
10. Efforts to change practice and improve the quality of care can have *multiple purposes*, including redesigning care processes to maximize efficiency and effectiveness, improving customer satisfaction, improving patient outcomes, and improving organizational climate.
11. *Appropriate use of technology* can improve team functioning, foster collaboration, reduce human error, and improve patient safety.
12. Efforts need to have *sufficient resources*, including protected staff time.
13. *Continually collect and analyze data and communicate results* on critical indicators across the organization. The ultimate goal of assessing and monitoring quality is to use findings to assess performance and define other areas needing improvement.
14. *Change takes time*, so it is important to stay focused and persevere.

Research Implications

Given the complexity of health care, assessing quality improvement is a dynamic and challenging area. The body of knowledge is slowly growing in this area, which could be due to the continued dilemma as to whether a quality improvement initiative is just that or whether it meets the definition of research and employs methodological rigor—even if it meets the requirements for publication. Various quality improvement methods have been used since Donabedian's seminal publication in 1966,[27] but only recently has health care quality improvement used the Six Sigma methodology and published findings; when it has, it has been used only on a single, somewhat isolated component of a larger system, making organizational learning and generalizability difficult. Because of the long standing importance of quality improvement, particularly driven by external sources (e.g., CMS and the Joint Commission) in the past few years, many quality improvement efforts within organizations have taken place and are currently in process, but may not have been published and therefore not captured in this review, and may not have necessarily warranted publication in the peer-reviewed literature. With this in mind, researchers, leaders and clinicians will need to define what should be considered generalizable and publishable in the peer-reviewed literature to move the knowledge of quality improvement methods and interventions forward.

While the impact of many of the quality improvement projects included in this analysis were mentioned in terms of clinical outcomes, functional outcomes, patient satisfaction, staff satisfaction, and readiness to change, cost and utilization outcomes and measurement is important in quality improvement efforts, especially when variation occurs. There are many unanswered questions. Some key areas are offered for consideration:

- How can quality improvement efforts recognize the needs of patients, insurers, regulators, patients, and staff and be successful?
- What is the best method to identify priorities for improvement and meet the competing needs of stakeholders?
- What is the threshold of variation that needs to be attained to produce regular desired results?
- How can a bottom-up approach to changing clinical practice be successful if senior leadership is not supportive or the organizational culture does not support change?

In planning quality improvement initiatives or research, researchers should use a conceptual model to guide their work, which the aforementioned quality tools can facilitate. To generalize empirical findings from quality improvement initiatives, more consideration should be given to increasing sample size by collaborating with other organizations and providers. We need to have a better understanding of what tools work the best, either alone or in conjunction with other tools. It is likely that mixed methods, including nonresearch methods, will offer a better understanding of the complexity of quality improvement science. We also know very little about how tailoring implementation interventions contributes to process and patient outcomes, or what the most effective steps are that cross intervention strategies. Lastly, we do not know what strategies or combination of strategies work for whom and in what context, why they work in some settings or cases and not others, and what the mechanism is by which these strategies or combination of strategies work.

Conclusions

Whatever the acronym of the method (e.g., TQM, CQI) or tool used (e.g., FMEA or Six Sigma), the important component of quality improvement is a dynamic process that often employs more than one quality improvement tool. Quality improvement requires five essential elements for success: fostering and sustaining a culture of change and safety, developing and clarifying an understanding of the problem, involving key stakeholders, testing change strategies, and continuous monitoring of performance and reporting of findings to sustain the change.

Search Strategy

To identify quality improvement efforts for potential inclusion in this systematic review, PubMed and CINAL were searched from 1997 to present. The following key words and terms were used: "Failure Modes and Effects Analysis/FMEA," "Root Cause Analysis/RCA," "Six Sigma," "Toyota Production System/Lean," and "Plan Do Study Act/PDSA." Using these key words, 438 articles were retrieved. Inclusion criteria included reported processes involving nursing; projects/research involving methods such as FMEA, RCA, Six Sigma, Lean, or PDSA; qualitative and quantitative analyses; and reporting patient outcomes. Projects and research were excluded if they did not involve nursing on the improvement team, did not provide sufficient information to describe the process used and outcomes realized, nursing was not directly involved in the patient/study outcomes, or the setting was in a developing country. Findings from the projects and research included in the final analysis were grouped into common themes related to applied quality improvement.

Evidence Table. Quality Methods

Source	Quality or Safety Issue Related to Clinical Practice	Design Type	Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Failure Modes and Effects Analysis (FMEA)						
Adachi 2005[78]	Medication safety	Quality improvement	Medication errors, targeting wrong dose errors (Level 4)	422-bed hospital in California	FMEA used to develop strategies – Standard order sets were revised, items from the formulary were removed, and the use of unapproved abbreviations was eliminated. – Used IV pumps with enhanced safety features.	1 year after medication strategies were implemented, medication errors associated with IV infusion were reduced slightly (from 59 to 46), and error related to IV pumps decreased from 41% of dosing errors to 22%. Errors related to wrong drug concentration were completely eliminated.
Apkon 2004[115]	Medication safety	Quality improvement	Infusion drug errors (Level 4)	11-bed pediatric intensive care unit (ICU) in a children's hospital	None	Standardization of the infusion delivery process, with the combined effect of prolonging infusion hang times from 24 to 72 hours, shifting preparation to the pharmacy, and purchasing premanufactured solutions resulted in 1,500 fewer infusions prepared by nurses per year; process changes preferred by nurses and patients.

Source	Quality or Safety Issue Related to Clinical Practice	Design Type	Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Burgmeier 2002[94]	Blood transfusion	Quality improvement	Errors associated with blood products administered to patients (Level 4)	1 hospital in Ohio	Following the FMEA, implemented the following changes: a standardized form listing choices for blood products and documenting medical necessity, form is faxed to the blood bank; used a blood-barrier system; required staff training; and changes in policies and procedures.	Following the new process changes for blood transfusions, no outcome errors were reported within the first 3 months. New process continued to be assessed, finding more failures to be addressed, and data are aggregated and reported monthly. Flowcharting before beginning the FMEA process itself was important. FMEA process was time consuming, tedious, and difficult.
Day 2006[124]	Dialysis treatment	Quality improvement	Risks for error in the process of administering dialysis (Level 4)	1 hospital in Utah	None	Risk factors included inconsistent nephrology consult/dialysis communication process; dialysis technicians performing beyond their scope of work; scheduling treatments for chronic dialysis patients without a formal consult/order; nurses inconsistently involved in dialysis process; nurses not reviewing dialysis orders or treatment plan before treatment; and lack of a formal handoff report before treatment.

Source	Quality or Safety Issue Related to Clinical Practice	Design Type	Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Esmail 2005[107]	Medication safety	Quality improvement	Systematic analysis for improvement in the ordering and administration of potassium chloride and potassium phosphate using HFMEA (Level 4)	4 adult ICUs in 3 hospitals in Canada	Implemented standardized protocol for potassium chloride and potassium phosphate.	Using the HFMEA, recommendations were made for the hospital and ICUs, including who, where, and how the drugs should be mixed, and identifying and developing standard labels for look-alike and sound-alike products. HFMEA helped prioritize the critical steps of a complex medication process (from ordering to administration), making it more objective. While the process took time to conduct, it was instrumental in discovering that the vials of intravenous potassium needed to be stored and packaged differently.
Gering 2005[123]	Patient transfer	Pretest and post-test, quality improvement	Adverse events (Level 3)	2 VA medical centers	A series of strategies to merge patients into one facility	Nurses were critical in the actual move of patients from one hospital to the next. After integration, there were no disruptions in patient care, operating room (OR) cancellations decreased, there were no MRSA infections, and clinic wait times decreased.
Kim 2006[116]	Medication safety, CPOE	Pretest, post-test study	Medication order errors (Level 3)	Pediatric oncology patients in 1 academic medical center in Maryland	Implementation of a CPOE system	After CPOE implementation, there was a decrease in improper dosing, incorrect dosing calculations, missing cumulative dose calculations, and incomplete nursing checklists. There was no difference in the likelihood of improper dosing on treatment plans, and a higher likelihood of not matching medication orders to treatment plans.
Papastrat 2003[111]	Medication safety	Changing practice project	Error detection associated with medication administration (Level 4)	First-semester baccalaureate nursing students at 1 university in Pennsylvania	New teaching method	Problem-based learning enabled students to use findings from topic-specific research to develop solutions for clinical problems. Students applied knowledge to clinical settings.

Source	Quality or Safety Issue Related to Clinical Practice	Design Type	Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Semple 2004[92]	Patient monitoring	Quality improvement	Response time (Level 4)	1 unit with telemetry in a hospital in Connecticut	Procedure changes to enable nurse to respond to telemetry alarms	Problem areas were identified as the nurses' inability to see critical alarm screen color change, hear critical alarms, and to know when their patient's alarm is sounding. A series of changes were implemented to enable nurse response. Response to telemetry alarms decreased from 12 minutes to 1.57 minutes.
Singh 2004[107]	Error risk detection	Pretest, post-test study	Perceived type/cause of error (Level 3)	1 academic rural primary care practice with 32 staff members	Implementation of electronic medical record	Perceived risk of errors decreased in nurse-physician and physician-chart interactions, but hazards increased in physician-patient interaction in the assessment stage as well as nurse-chart interactions.
Singh 2007[99]	Error risk detection	Quality improvement	Perceived type/cause of error (Level 4)	2 primary care practices serving rural populations in New York	None	Nurses perceived being in a hurry, fatigued, stressed, or ill as well as not using available resources for help as the most prevalent type and cause of errors. Hazard scores at site 2 were consistently higher, indicating that staff perceived greater frequency and/or severity of the errors in their practice.
Smith 2005[87]	Medication safety	Quality improvement	Medication errors and adverse drug events (ADEs) (Level 4)	1 hospital in Illinois	Pharmacist staffing on patient care units to review orders and stock medications reduced errors by 45%; adult IV medications were standardized, and nonstandard doses were prepared by the pharmacy.	There was a significant (a 66% drop in the FMEA score) reduction in ADEs.

Source	Quality or Safety Issue Related to Clinical Practice	Design Type	Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
van Tilburg 2006[108]	Medication safety, CPOE	Quality improvement	Errors associated with chemotherapy (Level 4)	Pediatric oncology patients in a hospital in the Netherlands	None	Because changes in ordered prescriptions could be made without being noticed by the nurse, a standardized procedure for changes in chemotherapy treatment schedules was made. Because of administration errors, the procedure was changed so that only pediatric oncologists were allowed to administer vincristine via peripheral IV access.
Weir 2005[101]	Medication safety	Quality improvement	ADEs associated with patient-controlled analgesia (PCA) (Level 4)	1 hospital and clinics in California	None	Areas needing change included using a standard IV PCA dosage or concentration protocol; adding the patient's age to CPOE medication order screen; handwritten orders; PCA pumps programmed incorrectly; and monitoring patients using PCAs. 71% of ADEs were associated with PCA programming error, followed by human factors (15%), equipment problems (9%), and ordering errors (5%).
Plan-Do-Study-Act (PDSA)						
Baird 2001[103]	Medication safety	Quality improvement	Patient outcomes and reduced costs in the ICU (Level 4)	Physicians, nurses, and clinical pharmacists in a 115 adult ICU beds in 1 large medical center in Texas	Using a new heparin administration protocol in ICU	Initial findings with 10 patients found that 90% of patients received optimal bolus doses (compared to 8.6% of the historical patients) and all received optimal infusion doses (compared to 3.4% of historical patients). Patients received better heparin therapy because they received the right loading dose, reached a therapeutic level of the drug more quickly, and maintained the therapeutic level. Nursing efficiency improved with fewer dose changes and laboratory tests. Medication and laboratory test costs decreased as did the patient's length of stay.

Source	Quality or Safety Issue Related to Clinical Practice	Design Type	Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Bolch 2005[97]	Care transitions	Quality improvement	Patients having a documented discharge plan, patients screened for risk, patients receiving followup care within 10 days of discharge (Level 4)	Patients ages ≥ 65, admitted to a hospital in South Australia	Modified the nursing assessment/risk assessment tool	Improvements in the initiation and followup of discharge planning resulted in more documented discharge plans, increased risk assessment, increased referrals to community services, and improved communication between hospital staff and community providers.
Buhr 2006[80]	Pain management	Quality improvement	Improved assessment and management of chronic pain (Level 4)	Patients and nurses (licensed practical nurses (LPNs), certified nursing assistants (CNAs), and registered nurses (RNs)) in 1 nursing home in North Carolina	Increased knowledge of chronic pain assessment and management through education. Implemented updated policies and procedures, and used new tools for pain assessment and management. Revised standing orders for pain management.	Pain assessment and management understanding improved in staff, especially in the CNAs. Patient and family satisfaction increased, and feeling that pain was adequately addressed increased.
Docimo 2000[89]	Throughput in emergency department (ED)	Quality improvement	Time in ED for minor illnesses and injuries (Level 4)	1 ED in 1 hospital in Maryland	Improved both the processes and relationships of hospital staff using PDSA cycles	Nonacute patients were fast-tracked to an average time of 1 hour, 47 minutes by not waiting behind higher-acuity patients for registration. Physician assistants, nurses, and technicians reported improved working conditions and team spirit.
Dodds 2006[119]	Practice variation	Quality improvement	Length of stay, reduced variation in process of care (Level 4)	Patients with chronic obstructive pulmonary disease (COPD)	Redesigned service delivery by using a continuous quality improvement methodology and PDSA cycles	Decrease in average length of stay. Increase in the numbers of patients admitted directly to the emergency medical unit and transferred to the respirator department. Improved the management of patient information and communication with patients.

Source	Quality or Safety Issue Related to Clinical Practice	Design Type	Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Dunbar 2006[100]	Pain management Practice variation	Quality improvement	Frequency of painful procedures, managing pain associated with painful procedures (Level 4)	11 neonatal ICUs	Implemented evidence-based practices for pain management and sedation in neonates using PDSA cycles	The combination of using collaborative quality improvement techniques and local quality improvement efforts resulted in better patient outcomes.
Eisenberg 2002[109]	IV incidents	Quality improvement	IV care patient outcomes (Level 4)	4 community hospitals	Education of all staff nurses on IV site care and assessment, as well as assessment of central line, total parenteral nutrition (TPN**)**. Revised 35 IV policies into 5, revised documentation flow sheets, and provided a resource manual.	Reductions in complications and costs. Improved patient satisfaction. No formal complaints about IV care.

Source	Quality or Safety Issue Related to Clinical Practice	Design Type	Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Erdek 2004[93]	Pain management	Prospective study	Pain management and assessment (Level 4)	2 surgical ICUs in 1 hospital in Maryland	Implemented 4 PDSA cycles, including educating staff on pain management, modifying pain scales at patients' bedsides, residents documenting pain scores for past 24 hours, and creating expectation that pain > 3 is a defect.	Pain assessment improved from 42% to 71%, and pain management improved from 59% to 97%. Documentation of pain assessment improved among nurses.
Farbstein 2001[106]	Medication safety	Quality improvement	Types of medication administration errors (Level 4)	6 improvement projects in hospitals in Massachusetts	Implementation of best practices, using PDSA to assess impact	The results presented from the 6 improvement projects included faster therapeutic anticoagulation for patients receiving heparin; fewer look-alike/sound-alike errors; fewer PCA administration adverse events; safer administration of coumadin; improved patient information on their medication; and improved processing of the morning dispensing of medications in the pharmacy. The investigators described success factors of medication safety projects as using data to measure outcomes; using forcing functions built into the process; pacing changes sequentially, not all at one time; low cost of changes; using a consultant to mentor team leaders; and using reported errors to assess implementation impact.

Source	Quality or Safety Issue Related to Clinical Practice	Design Type	Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Horbar 2003[98]	Neonatal intensive care	Quality improvement	Improved quality and safety of neonatal intensive care (Level 4)	34 centers	Implemented, applying 4 key habits for improvement using rapid-cycle PDSA	Developed 51 potentially better practices that were implemented by multidisciplinary neonatal ICU teams in identifying, testing, and implementing change in practice.
Horner 2005[117]	Pain management	Pretest and post-test study	Improved pain assessment and management of residents (Level 3)	9 nursing homes in North Carolina	Chart audit and data feedback on quality indicators, provider education, and technical support for systems change using PDSA	The number of residents receiving pain assessments increased from 8% to 29%. Residents receiving nonpharmacological pain treatments increased from 31% to 42%. Residents with daily moderate or excruciating pain had increased probability of pain medication use.
Leape 2006[86]	Medication reconciliation, communicating critical test results	Quality improvement	Implementation of safe practices (Level 4)	58 hospitals (88%) in Massachusetts	Institute for Healthcare Improvement model for improvement to care practices	Participating hospitals did so because of the following factors: the intrinsic appeal of the practice, access to experts, and the availability of implementation strategies. Project success was associated with active engagement of senior management, physician engagement, increased use of PDSA cycles, participation in collaborative meetings.
Pronovost 2000[83]	Access to care	Quality improvement	Number of ambulance bypass hours (Level 4)	1 hospital in Maryland	PDSA to act on identified root causes, targeting bed sharing for patients needing ICU care that were managed in the ED	Significant reduction in hours with an estimated $6 million in additional hospital revenue. Success was achieved by teams integrating tools that improved processes and collaborative relationships.
Salvador 2003[114]	Medication safety	Quality improvement	Safety of hospital-based antenatal home care for high-risk women (Level 4)	Physicians, nurses, and clinical pharmacists in 115 adult ICU beds in 1 large medical center in Texas	Using a new heparin administration protocol in ICU	New heparin protocol resulted in better patient care, improved nursing efficiency and work satisfaction, and reduced costs by $885 on average. There were no differences in maternal or newborn health outcomes.

Source	Quality or Safety Issue Related to Clinical Practice	Design Type	Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
van Tiel 2006[118]	Health care associated infections	Quality improvement	Compliance with infection control measures (Level 4)	1 ICU and OR in a 715-bed university hospital in the Netherlands	Instruction and training of nursing and medical staff on PDSA cycles	Not wearing a face mask during procedures decreased to 0%; not wearing jewelry decreased to 33%. Improved compliance with wound care, including hand washing before and after wound care and the use of disposable surgical wound sets.
Warburton 2004[120]	Adverse outcomes in EDs	Quality improvement	Detect patients at risk for adverse outcomes, provide a plan of care, and target care services (Level 4)	1 small hospital in Canada	Implementation of the Elder Alert program using PDSA cycles	Process evaluation audits and regular meetings of providers and academic collaborators were essential improvement tools. Screening criteria had to be adapted to the patient population.
Wojciechowski 2006[122]	PDSA	Quality improvement	Increasing access to patient education resources (Level 4)	1 rehabilitation facility in a city in the Midwest	Implementation of a new patient education system for medication and disease information using PDSA cycles	Designing a new Web-based patient education system benefits from a process promoting change incrementally and collaboration.
Root-Cause Analysis (RCA)						
Gowdy 2003[90]	Patient falls	Quality improvment	Incidence of inpatient falls (Level 4)	1 hospital in North Carolina	Implemented an action plan to prevent patient falls	RCA identified risks for falls associated with confusion, gait disturbance, and self-toileting. Inpatient fall rate decreased from 6.1 to 2.6 falls per 1,000 patient days (a 43% decrease during the study period).
Luther 2002[104]	Adverse events	Quality improvement	Incidence of ADEs, ventilator-acquired pneumonia, central-venous-catheter-related bloodstream infections (Level 4)	2 hospitals in Texas	Increased staffing levels and improved education. Conducted RCA to identify issues needing to be addressed by leadership and staff.	Adverse events targeted by nurses using protocols decreased ADEs by 45%, ventilator-acquired pneumonia from 47.8/1,000 ventilator days to 10.9/1,000, and decreased central-venous-catheter-related bloodstream infections from the 90th to the 50th percentile of the National Nosocomial Infection Surveillance System. Implementation of protocols decreased length of stay from 8.1 to 4.5 days.

Source	Quality or Safety Issue Related to Clinical Practice	Design Type	Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Middleton 2007[105]	Root causes of errors	Cross-sectional study	Adoption of recommendations detected from RCA (Level 4)	12 physicians (86% response rate) and 17 nurses (100% response rate) in Sydney, Australia	None	Nurses were more likely than physicians to view RCA recommendations as "relevant to the causal statement," "understandable," "achievable," and "measurable." Physicians and nurses involved in the RCA were significantly more likely to believe that the RCA recommendations would "eliminate" or "control" future risks. Some recommendations rated as "relevant to the causal statement" by nurses were significantly less likely to also be rated as "achievable."
Mills 2005[82]	Patient falls	Quality improvement	Incidence of falls and major injuries due to falls (Level 4)	100 VA acute and long-term care facilities	Aggregate RCA was used to support implementation of fall prevention strategies.	61.4% of strategies were fully implemented, and 20.9% were partially implemented. 34% of the facilities reported a reduction in the number of falls, and 38.9% reported a reduction in major injures related to falls. The impact of the interventions could have been hampered by making specific clinical changes without changing policies and providing staff education.
Mutter 2003[95]	Medication safety	Quality improvement	Frequency of medication administration errors (Level 4)	1 451-bed acute care hospital in New Jersey	After assessing causes of errors, established a nonpunitive environment to encourage error reporting and interviewed providers who reported errors.	Improvement requires constant and continual assessment of errors. Rapid-cycle improvement was used to decrease medication administration errors and to inform changes.

Source	Quality or Safety Issue Related to Clinical Practice	Design Type	Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Plews-Ogan 2004[102]	Voluntary reporting of near miss/adverse events	Cross-sectional study	Error reporting (Level 4)	1 ambulatory site of a large teaching hospital	System analysis and redesign using RCA.	Two-thirds of the 70 recommended recommendations were level 1, 23% level 2 (i.e., involving more complex interventions usually requiring significant groundwork), and 10% level 3 (i.e., involving other services). Using RCA increased error reporting as system issues were addressed, not through individual blame. RCA identified the underlying causes of reported errors, and improvements were made on an ongoing basis.
Rex 2000[96]	Medication safety	Quality improvement	Rates of ADEs (Level 4)	1 hospital in Texas	Implemented policy changes to use forcing or constraining functions and better personnel support	RCA identified environmental factors (e.g., patient acuity, change of shit) and staffing issues (e.g., new staff). ADEs decreased by 45%. Implementing blame-free RCA enabled identification and prioritization of performance improvement initiatives and focus on systems issues.

Source	Quality or Safety Issue Related to Clinical Practice	Design Type	Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Willeumier 2004[85]	Medication safety Health care associated infections	Quality improvement	Rates of medication error reporting and ventilator-associated pneumonia (VAP) rates (Level 4)	8-hospital system in northern Illinois	Improved medication availability, standardized nursing reassessment of medications, reinforced the 5 rights of medication administration, provided medication information, revised medication policies, and standardized nursing documentation of medication administration. Redesigned oral hygiene processes, used head positioning, and used collection and culture techniques for better diagnosis.	Identified strategies based on proactive risk assessment (a composite of RCA and FMEA). Medication error reporting increased and VAP rates decreased. Greatest challenges were implementing and sustaining a culture of safety, the complexity of the health care system, underreporting of patient safety events, and medical staff's acceptance of the disclosure policy. Improvement is dependent upon the involvement of leadership, communication with staff, and the use of the appropriate technology.
Six Sigma						
Germaine 2007[91]	Surgical site infections OR patient throughput	Quality improvement	OR turnover (Level 4)	1 hospital in Michigan	Implemented OR turnaround protocol	Turnover decreased from 34 minutes to an average of 18 minutes, allowing volume to increase by 5%. Surgical site infections decreased from 2.14% to 1.07%.

Source	Quality or Safety Issue Related to Clinical Practice	Design Type	Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Guinane 2004[81]	Groin injury in cardiac catheterization patients	Quality improvement	Groin injury rates (Level 4)	A team of physicians, nurses, and administrators involved in the care of cardiac catheterization patients in 1 hospital	Implemented groin management process to decrease injury rates, reduce the cost of care, and improve customer satisfaction	Groin injuries decreased from 4% to less than 1% (e.g., 41,666 defects to 8,849.5 defects) – sigma value improved from 3.23 to 3.87. Length of stay that exceeded the specified upper limit decreased from 16% of the time to only 3% of the time. Operating costs that exceeded the specified upper limit decreased from 18% to 3% of the time.
Johnson 2005[125]	Chest pain management	Quality improvement	Time for diagnosis and evidence-based treatment of patients with chest pain	1 hospital in New York	Implemented an algorithm, preprinted orders, and use of cardiac nurse practitioners from presentation in ED through discharge	Increases in diagnosis of cardiac disease, cardiac catheterization, and stenting/bypass surgery, especially in women, Latinos, and patients > 60 years old.
Pexton 2004[113]	Surgical site infections	Quality improvement	Rate of colon and vascular surgical site infections (Level 4)	1 medical center in West Virginia	A preoperative order set with a checklist including recommended antibiotics and weight-based dosages, education of team members, physician report cards, and anesthetists and nurses prompting surgeons to use antibiotics.	Surgical site infection rates decreased by 91% (2.86 sigma), with an estimated potential annual savings of more than $1 million.

Source	Quality or Safety Issue Related to Clinical Practice	Design Type	Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Toyota Production System (TPS)/Lean						
Aldarrab 2006[126]	Emergency care of patients with ST-elevation myocardial infarction (MI)	Quality improvement	Patients with appropriate reperfusion and adjunctive pharmacological treatment (Level 4)	3-site tertiary/quaternary facility in Canada	Implementation of evidence-based guidelines for ST-elevation in MI patients	An RCA was used to understand current processes and to assess what could be standardized. Targets were achieved in terms of using the appropriate reperfusion strategy, meeting the median time of < 30 minutes for thrombolytic therapy and 90 minutes for percutaneous coronary intervention, appropriate thrombolytic and adjunctive treatment use. It was noted that without continued reinforcement of the new protocol, the process would regress to prior levels of performance.
Furman 2007[39]	Error reporting	Quality improvement	Near-miss error reports (Level 4)	1 medical center in Virginia	Implemented an error reporting system, including a 24-hour hotline	Nurses reported 44% of the near misses, physicians 8%, managers 20%, nonclinical staff 23%. Over a period of 3 years, the number of error reports increased because there was a transparent discussion and feedback process.
Jimmerson 2005[88]	Medication safety Access to medical equipment	Quality improvement	Efficiency of testing patient's glucose level at the bedside (Level 4)	1 medical-surgical ICU in a hospital in Utah	Installed glucometers in each room in the ICU	Reduced time to do glucose check from 17 to 4 minutes. Improved ability to consistently implement the protocol. No unlabeled specimens at risk of erroneous identification. Fewer RN interruptions and frustration.
Nowinski 2006[121]	Medication administration	Quality improvement	Medication administration errors (Level 4)	1 hospital in Pennsylvania	Revised and streamlined medication administration process based on finding from an RCA	Rapid, substantial, and continuing improvements in patient care were achieved. Nursing staff reported higher levels of satisfaction.

Source	Quality or Safety Issue Related to Clinical Practice	Design Type	Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Printezis 2007[59]	Using TPS in health care	Literature review	Reviewed five quality improvement projects to reduce medical errors in hospitals (Level 4)	Improvement projects in hospitals	None	Simple pathways of root causes lead to better operational performance. Organizing principles of TPS improve reliability and effectiveness of health care delivery systems. Problem-solver on projects should not be a consultant, but someone who is a stakeholder. Many problems are associated with relationships with other departments. TPS makes work-around and rework difficult to continue. TPS helps staff learn and identify waste in daily activities. Front-line staff need to be enthusiastic about making improvements. Clear, concise, and objective communication is key.
Thompson 2003[84]	Medication administration	Quality improvement	Missing medications Complexity of the medication administration process (Level 4)	Pharmacy and nursing units at 1 hospital in Pennsylvania	Implemented: specific	Rapid, substantial, and continuing improvements in medication administration processes were achieved. Nursing staff reported higher levels of satisfaction, associated with workflow improvements.

Chapter 45. AHRQ Quality Indicators

Marybeth Farquhar

What Are the AHRQ Quality Indicators?

The Quality Indicators (QIs) developed and maintained by the Agency for Healthcare Research and Quality (AHRQ) are one response to the need for multidimensional, accessible quality measures that can be used to gage performance in health care. The QIs are evidence based and can be used to identify variations in the quality of care provided on both an inpatient and outpatient basis. These measures are currently organized into four modules: the Prevention Quality Indicators (PQIs),[1] the Inpatient Quality Indicators (IQIs),[2] the Patient Safety Indicators (PSIs),[3] and the Pediatric Quality Indicators (PDIs).[4] A brief description of each module appears in Table 1.

Table 1. The AHRQ Quality Indicators modules

Prevention Quality Indicators (PQIs): These indicators identify ambulatory care sensitive conditions, defined as conditions for which good outpatient care can potentially prevent the need for hospitalization, or for which early intervention can prevent complications or more severe disease.
Inpatient Quality Indicators (IQIs): These indicators reflect quality of care inside hospitals and include inpatient mortality; utilization of procedures for which there are questions of overuse, underuse, or misuse; and volume of procedures for which there is evidence that a higher volume of procedures is associated with lower mortality.
Patient Safety Indicators (PSIs): These indicators focus on potentially preventable instances of complications and other iatrogenic events resulting from exposure to the health care system.
Pediatric Quality Indicators (PDIs): These indicators reflect the quality of care for children younger than 17 years of age and neonates inside hospitals (provider-level indicators) and identify potentially avoidable hospitalizations among children (area-level indicators).

Origins and History

In 1994, in response to requests for assistance from State-level data organizations and hospital associations with hospital inpatient data collection systems, the AHRQ developed a set of measures that used hospital administrative data provided by the Healthcare Cost and Utilization Project (HCUP), an ongoing Federal-State-private sector partnership that was established to develop uniform databases. As a result, these measures, called the HCUP Quality Indicators, were developed to take advantage of readily available administrative data and quality measures that had been previously reported in the literature.[5] The original HCUP Quality Indicators included 33 measures that could identify avoidable adverse outcomes such as in-hospital mortality and complications of procedures; the use of specific inpatient procedures thought to be overused, underused, or misused; and ambulatory care sensitive conditions. These

indicators identified potential quality-of-care problems and served as the starting point for further investigation.

In 1998, under contract with AHRQ, researchers at the University of California, San Francisco (UCSF) and the Stanford University Evidence-Based Practice Center (EPC) reviewed and revised the original set of measures.[5] This revision served to expand the HCUP Quality Indicators by (1) identifying quality indicators reported in the literature and in use by health care organizations, (2) evaluating both the HCUP Quality Indicators and other indicators using literature reviews and empirical methods, and (3) incorporating risk adjustment. The revised set, now known as the AHRQ QIs, originally included two modules: the PQIs released in April 2002, and the IQIs released in June 2002. Other modules were eventually added based on requests from the user community; specifically, the PSIs were released in May 2003, and the most recent set of measures, the PDIs, were added to the existing QI modules in February 2006. An additional module, the Neonatal Quality Indicators (NQIs), is currently under development and will be released in the near future.

Development of the AHRQ Quality Indicators

The AHRQ QIs were developed from an extensive, iterative process that included interviews from a broad spectrum of organizations that represented QI users and potential users, literature reviews that identified possible quality measures, evaluation of the candidate measures as well as evaluation of several risk-adjustment methods for use with the potential measures, empirical analysis, and validation. The process can be roughly divided into two phases: the first identifies candidate measures or indicators, and the second analyzes the potentially viable measures or indicators.

During development of the QIs, the UCSF-Stanford EPC used the Institute of Medicine's definition of care quality to guide the development process: "the degree to which health services for individuals and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge."[6] Based on this definition, six key questions were developed to direct the selection of measures for further evaluation. They were:

- Which indicators currently in use or described in the literature could be defined using hospital discharge data?
- What are the quality relationships reported in the literature that could be used to define new indicators using hospital discharge data?
- What evidence exists for indicators not well represented in the current set of indicators—pediatric conditions, chronic disease, new technologies, and ambulatory care sensitive conditions?
- Which indicators have literature-based evidence to support face validity, precision of measurement, minimum bias, and construct validity of the indicator?
- What risk-adjustment method should be suggested for use with the recommended indicators, given the limits of administrative data and other practical concerns?
- Which indicators perform well on empirical tests of precision of measurement, minimum bias, and construct validity?

Identifying Candidate Indicators

In the first phase of development, the UCSF-Stanford EPC conducted interviews with individuals affiliated with hospital associations, business coalitions, State data groups, Federal agencies, and academia about topics related to quality measurement. The interviews provided background information on measure use, suggested new indicators for potential development, and provided the names of additional individuals within the field who could be contacted for an interview. The interviews also suggested new risk-adjustment methods and assisted in framing the evaluation of potential indicators. With this information and relevant literature, the team developed a framework in which to evaluate the performance of the candidate measure. Table 2 provides an overview of the criteria used to evaluate the potential measures as well as a brief description of each.

Table 2. Criteria used to evaluate potential Quality Indicators

Face validity: An adequate quality indicator must have sound clinical or empirical rationale for its use. It should measure an important aspect of quality that is subject to provider or health care system control.
Precision: An adequate quality indicator should have relatively large variation among providers or areas that is not due to random variation or patient characteristics. This criterion measures the impact of chance on apparent provider or community health system performance.
Minimum bias: The indicator should not be affected by systematic differences in patient case mix, including disease severity and comorbidity. In cases where such systematic differences exist, an adequate risk-adjustment system should be possible using available data.
Construct validity: The indicator should be related to other indicators or measures intended to measure the same or related aspects of quality. For example, improved performance on measures of inpatient care (such as adherence to specific evidence-based treatment guidelines) ought to be associated with reduced patient complication rates.
Fosters real quality improvement: The indicator should be robust to possible provider manipulation of the system. In other words, the indicator should be insulated from perverse incentives for providers to improve their reported performance by avoiding difficult or complex cases, or by other responses that do not improve quality of care.
Application: The indicator should have been used in the past or have high potential for working well with other indicators. Sometimes looking at groups of indicators together is likely to provide a more complete picture of quality.

Source: Agency for Healthcare Research and Quality. *Refinement of the HCUP Quality Indicators*[5] (p. 30).

The research team also undertook a literature review that was structured in two phases. The first phase identified potential measures within the literature that were applicable to comparisons among providers or among geographic areas. In addition, potential indicators were identified using the various established databases of measures such as those from the Joint Commission for the Accreditation of Healthcare Organizations, Healthy People 2010, and so on. In the second phase of the literature review, the team performed an initial screen of the candidate indicators for

relevance and accuracy. If an indicator met the criteria as described in Table 2, it received a comprehensive literature review and empirical evaluation.

The next phase of development was to identify potential risk-adjustment models for each of the selected candidate measures. Users of the QIs preferred a risk-adjustment system that was (1) open with published logic; 2) cost effective with data collection costs minimized and with any additional data collection being well justified; (3) designed using a multiple-use coding system, such as those used for reimbursement; and (4) officially recognized by government, hospital groups, or other organizations. In general, the All Patient Refined-Diagnosis Related Groups (APR-DRGs) tended to fit more of the user preferences than other alternatives considered. In addition, the APR-DRGs were reported to perform as well as or better than other risk-adjustment systems for several conditions.[7–9] The APR-DRGs are used in various AHRQ QIs; however, this method is not used with the PDIs, which use a novel and specialized risk-adjustment system that includes the data element Present on Admission (POA), the AHRQ Clinical Classification System, and stratification.

Analyzing Potential Indicators

The next step in the development process was empirical testing of all potential indicators. The primary datasets used were the HCUP Nationwide Inpatient Sample (NIS) and the State Inpatient Database (SID). The NIS is the largest all-payer inpatient care database in the United States, consisting of approximately 8 million hospital stays per year, specifically it consists of discharges of about a 20 percent stratified sample of community hospitals in the country. The SID consists of the universe of inpatient discharge abstracts in participating States, translated into a uniform format. This database encompasses about 90 percent of all community hospital discharges in the nation. More recently, the Kids' Inpatient Database was used to develop the AHRQ PDIs. This database, currently the only all-payer inpatient care database for children in the United States, contains 2–3 million hospital discharges. For more information about these databases, please go to the AHRQ website at www.ahrq.gov/data/hcup.

The data from these databases were used to test each evaluation criterion that was assessed empirically i.e., precision, bias, and construct validity. The results of the candidate indicators were compared, and those indicators that performed poorly were eliminated. Bias tests were conducted to determine the need for risk adjustment, and then finally, construct validity was evaluated to provide evidence of the nature of the relationship between potential indicators.

The next phase of indicator development used multi-disciplinary clinician panel reviews. The team solicited nominations from professional clinical organizations and hospital associations, that were selected based on the applicability of the specialty or subspecialty to the candidate indicators. Nominees were chosen based on meeting certain criteria. For example, nominees were required to spend at least 30 percent of their work time on patient care, including hospitalized patients. The panelists were selected so that each group had a diverse membership in terms of clinical practice characteristics and settings.

The members of the panel were given a number of documents to evaluate the candidate measures. The documents provided included information about administrative data; coding from the *International Classification of Diseases, Ninth Revision, Clinical Modification* (ICD-9-CM); assignment of DRGs and Major Diagnostic Categories (MDCs); and specific definitions for adverse events or complications, preventability, and medical error. Candidate measure information incorporated exclusion and inclusion criteria, the clinical rationale for the indicator, and the specification criteria. A summary of literature-based evidence and empirical rates based

on the NIS were provided for reference as well. Finally the panelists were given a list of potential questions regarding indicator definitions that the team planned to explore. Each panelist completed a 10-item questionnaire that asked them to determine the candidate indicator's ability to screen out conditions present on admission, to identify conditions with high potential for preventability, to identify medical errors, or to evaluate access to high-quality outpatient care. Panelist were also asked to consider potential sources of bias, reporting or charting problems, potential ways of gaming the indicator, and possible adverse effects of implementing the measure. Finally, panelists were invited to suggest changes to the candidate indicator.

After the questionnaires were returned, the team convened a series of conference calls with the panelists to discuss their opinions regarding the candidate measures. Using a modified version of the RAND/UCLA method developed in the 1980s. The RAND/UCLA Appropriateness Method[10] is used to synthesize the best available scientific evidence and expert opinion on health care issues. This method is a way to reach formal agreement on how the current science is interpreted by care givers in the real world. For the development of the QIs, the primary goal of the interaction was to allow for and encourage varied opinions about the appropriateness of an indicator. For our purposes, consensus was not the goal of the discussion, and agreement and disagreement on every indicator under consideration was noted. Following each conference call, modifications were made to each indicator as suggested by the panelists. The revised indicators were then redistributed to the panelists, along with questionnaires, and instructions to reevaluate and again rate each indicator based on their current opinion after the conference call discussions. Once the final round of questionnaires was received, the team calculated median scores to determine the degree of agreement among panelists. In addition, the team calculated scores indicating the level of acceptability of the indicator and the dispersion of ratings across the panel. The following criteria covered in the questionnaire were used to summarize the panel's options on each indicator:

- Overall usefulness of the indicator, both for internal quality improvement purposes and comparisons between hospitals
- Likelihood that the indicator measures a complication and not a comorbidity (specifically, present on admission)
- Preventability of complication
- Extent to which a complication is due to medical error
- Likelihood that a complication that occurs is charted
- Extent that the indicator is subject to bias (systematic differences, such as case mix, that could affect the indicator in a way not related to quality of care)

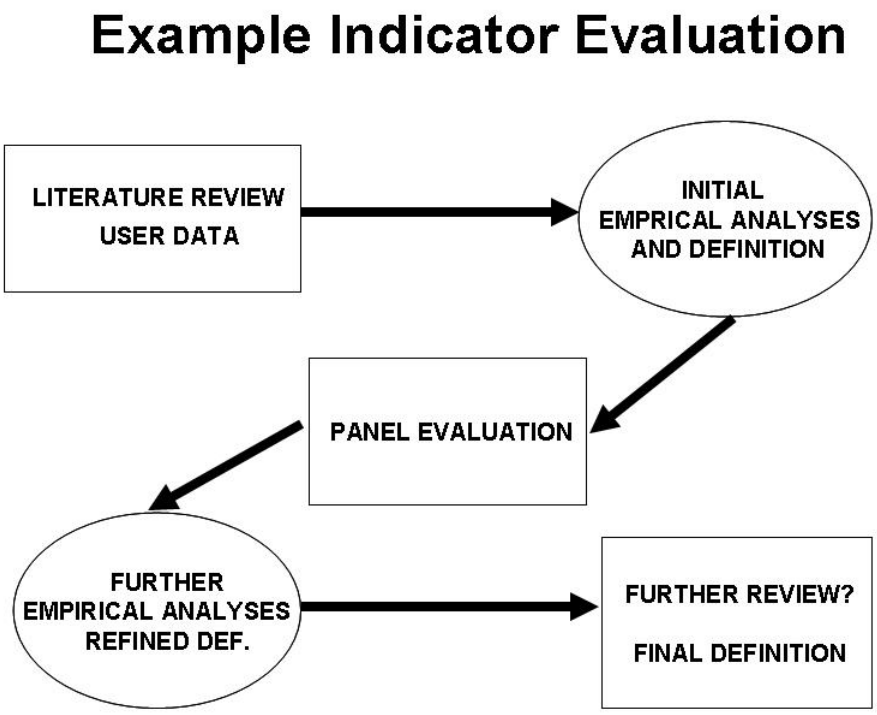
For area-level indicators, panelists provided feedback on the following areas:

- Overall usefulness of the indicator, both internally within an area and for comparisons between areas
- Extent to which an event reflects poor access to quality outpatient care
- Consistency in terminology for charting the principal diagnosis
- Extent that the indicator is subject to bias

The next step in the development process involved peer review of the candidate measures. Nominations were sought for clinicians, policy advisors, professors, researchers, and managers in quality improvement to participate on this panel. The group was instructed to provide comments on the indicators with constructive suggestions for content and presentation enhancements.

Once the panel reviews and evaluations were complete, the candidate indicators could go through further empirical testing to refine their definitions. After that, the indicator may undergo further clinical and peer review, which can occur over several rounds until the definition of the indicator is finalized. As with any measure of performance, the process of refinement is ongoing and becomes part of the measure maintenance activities of the measure developer. Figure 1 provides a graphic account of the basic development process.

Figure 1. The AHRQ Quality Indicator development and evaluation process



As a measure developer, AHRQ maintains these measures and on an annual basis, provides revisions to the measures, including ICD-9-CM and DRG code updates, an update to the reference population used in calculating the QIs, and refinement of the specifications based on additional evidence in the literature and user input. Literature reviews are completed on one QI module every year, which allows time for new research to be completed and subsequently published in peer reviewed journals.

What We Know About the AHRQ Quality Indicators

Measuring performance is central to improving the quality of health care. Performance measurement conveys the message of importance—that is, what is important is measured, while what is not measured is considered less important by many. The AHRQ QIs are measures of health care quality that make use of readily available hospital inpatient administrative data. The structure of the indicators consists of definitions based on ICD-9-CM diagnosis and procedure

codes. Inclusion and exclusion criteria are based upon DRGs: sex, age, procedure dates, and admission type. The numerator is equal to the number of cases flagged with the complication or situation of interest, for example, postoperative sepsis, avoidable hospitalization for asthma, and death. The denominator is equal to the number of patients considered to be at risk for that complication or situation, for example, elective surgical patients, county population from census data, and so on. The QI rate is equal to the numerator divided by the denominator. As with any type of performance measure, regardless of its data source, there are advantages to using certain measures as well as limitations associated with using them. What is presented below is a review of the data source used by the QIs as well as a review of the indicators by module. The strengths and limitations of the QIs are also discussed.

The AHRQ QIs and Their Data Sources

There are several sources of data that can be used to measure performance, and these data sources can be grouped into the following categories: administrative data (also known as billing or claims data), medical record information, patient-derived data (i.e., surveys);[11] confidential reports from providers, and direct observation. All categories of data have strengths and weaknesses and each data source should be evaluated for comprehensiveness or the completeness of data elements as they pertain to individuals, and inclusiveness or the extent to which populations are represented in a particular geographic area.[12] The AHRQ QIs use data derived from administrative databases, which is considered a "by-product" of care delivery, i.e., reimbursement to hospitals or physicians or determining insurance eligibility of patients.[9]

While administrative data were not originally intended to be used in research, these types of databases are often used by researchers in their studies and clearly offer some important advantages, such as the ability to track study subjects over time. Administrative data are also relatively inexpensive to collect and readily available to researchers, administrators, and others. Additional advantages include the large sample sizes associated with this type of data, the ease of collection without interference with the care of the patient, the population-based characteristic of administrative data, and identifiers associated with the data that permit observations across sites and settings of care. The AHRQ QIs can be used with any administrative data set and largely rely on the ICD-9-CM codes for diagnosis and procedures from individual hospitalization data, which are derived from the 2004 Uniform Bill (UB-04). Other information such as patient identifiers, hospitalization descriptors, admission types, insurance information, and charge data can be found on this form. Thus by putting together the range of ICD-9-CM codes and supplementary codes such as E codes* and V codes,† and from a creative and clinically informed use of these codes, a picture of a patient's clinical status and risk factors begins to form (see Table 3).

* These are external causes of injury and poisoning that capture how the injury or poisoning happened, the intent, and the place where the event occurred.

† These are supplementary classification codes that document factors influencing health status and contact with heath services, including such areas as health hazards related to communicable diseases, the need for isolation due to other potential health hazards and prophylactic measures, and persons with conditions influencing their health status, etc.

Table 3: Characteristics and Uses of Hospital Administrative Data

• Used to bill and pay for hospital services and contain information from the discharge claim.
• Standardized format, which is available electronically from all hospitals that bill for services.
• Used for health care quality research, evaluation, public reporting, and quality improvement.
• Typical data elements include patient gender, age, diagnoses, procedures, length of stay, admission source, discharge status, total charges, primary payer, and hospital identifier.
• Depending on the data source, other data elements that may be available include patient race, county or ZIP Code of residence, secondary payer, detailed charges, and identifier of primary physician or surgeon.
• Data format and quality may differ across hospitals or data organizations, such as the number of diagnosis and procedure codes available and the sequencing of the codes, the audits or edits applied to the data before and after submission, and the data values accepted.

The AHRQ QIs are valuable because they are based on widely available data that can be used to assess quality. Theses QI indicators also have uniform definitions and standardized algorithms that can be used with virtually any administrative data set, which allows for comparisons across States, regions, communities, and hospitals.

As with any data source used to assess performance, there are a number of drawbacks to using administrative data to examine the quality of care delivered by health care providers. Despite the large number of ICD-9-CM codes available and the implied detail they contain, these codes do not have operational clinical definitions assigned, which make assignment by coders somewhat variable. While coders are generally formally trained in coding methods and instructed to use the terminology in the medical record, clinicians seldom use a consistent lexicon in their charting. Thus, the meaning of codes without a clinical context, or without the considerations of disease progression, and the interaction of comorbidities can provide an inaccurate clinical picture—limiting the usefulness of the data. Yet despite this limitation, data availability, coding systems, and coding practices are improving, which enhance our ability to identify quality problems as well as success stories, which can be further identified and studied.

The AHRQ QI Modules

Prevention Quality Indicators (PQIs)

The AHRQ PQIs are one set of quality measures that can be used to identify potential problems; follow trends over time; and ascertain disparities across regions, communities, and providers. This module focuses on preventive care services—outpatient services that assist individuals with either staying healthy or managing chronic illness. In these instances, inpatient data can provide information on admissions for ambulatory sensitive conditions that evidence suggests could have been avoided, at least in part through better outpatient care. For example, patients with diabetes may be hospitalized due to complications for their disease if their conditions have not been adequately monitored or if they do not receive education that would allow them to self-manage the disease. There are currently 14 PQIs, listed in Table 4 that measure rates of admissions to the hospital.

Table 4: AHRQ Prevention Quality Indicators

- Diabetes short-term complication admission rate
- Perforated appendix admission rate
- Diabetes long-term complication admission rate
- Chronic obstructive pulmonary disease admission rate
- Hypertension admission rate
- Congestive heart failure admission rate
- Low birth weight rate
- Dehydration admission rate
- Bacterial pneumonia admission rate
- Urinary tract infection admission rate
- Angina admission without procedure
- Uncontrolled diabetes admission rate
- Adult asthma admission rate
- Rate of lower-extremity amputation among patients with diabetes

Factors such as poor environmental conditions or lack of patient adherence to treatment regimes can result in hospitalization. However, the PQIs provide a good starting point to assess quality of services within a community. The POIs can be used to provide a picture of health care in the community by identifying unmet needs, monitoring how well complications are being avoided in the outpatient setting, assessing access to health care, and comparing the performance of local health care systems across communities.

The PQIs represent the current state of the art in assessing the health care system as a whole, but particularly in the area of ambulatory care, for example, in preventing medical complications for both acute illness and chronic conditions. The PQIs are valuable when calculated at the population or area level and when used by organizations such as public health groups, State data organizations, health plans, large health systems, and other organizations concerned with the health of populations. The PQIs are risk adjusted for age and gender and provide information about potential problems in the community that may require further analysis. The PQIs help answer questions such as

- Does the admission rate for diabetes complications in my community suggest a problem in the provision of appropriate outpatient care to this population?
- How does the admission rate for congestive heart failure vary over time and from one region of the country to another?

These are just a few of the questions that the PQIs can address to assist those health care providers with responsibility for the health of a particular population. The PQIs allow for comparisons across States, regions, and local communities over time. The PQIs do not measure hospital quality, but reflect the care provided in the community.

Despite their strengths, there are several considerations when using these indicators. Differences in PQI rates can explain some of the variation across areas but not all. The complexity of the relationship between socioeconomic status and PQI rates makes it difficult to

delineate how much of the observed relationships are due to true access to care issues, difficulties in potentially underserved populations, or other patient characteristics unrelated to quality of care that vary systematically by socioeconomic status. Second, the evidence related to potentially avoidable hospital admissions is limited for each indicator because many of the indicators have been developed as parts of sets. Finally, despite the relationships demonstrated at the patient level between higher quality ambulatory care and lower rates of hospital admission, few studies have directly addressed the question of whether effective treatments in outpatient settings would reduce the overall incidence of hospitalizations.

The Inpatient Quality Indicators (IQIs)

The AHRQ IQIs provide information about the quality of medical care delivered in a hospital. This measure set represents the state of the art in measuring the quality of hospital care using inpatient administrative data. The IQIs include measures in the areas of inpatient mortality; utilization of procedures for which there are questions of overuse, underuse, or misuse; and volume of procedures for which there is evidence that a higher volume is associated with lower mortality.

The IQIs that focus on volume are proxy measures of quality and represent counts of admissions in which these procedures were performed. They are based on evidence suggesting that hospitals that perform more of certain procedures—for example, those that are intensive, high-technology, or highly complex—may have better outcomes for those procedures. The provider-level volume IQIs are:

- Esophageal resection volume
- Pancreatic resection volume
- Abdominal aortic aneurysm (AAA) repair volume
- Coronary artery bypass graft (CABG) volume
- Percutaneous transluminal coronary angioplasty (PTCA) volume
- Carotid endarterectomy (CEA) volume

The mortality indicators for inpatient procedures cover procedures for which mortality has been shown to vary across institutions and for which there is evidence that high mortality may be associated with poorer quality of care. The mortality indicators for inpatient surgical procedures are:

- Esophageal resection mortality rate
- Pancreatic resection mortality rate
- AAA repair mortality rate
- CABG mortality rate
- PTCA mortality rate
- CEA mortality rate
- Craniotomy mortality rate
- Hip replacement mortality rate

When evaluating mortality rates, the corresponding volumes should be examined in conjunction with the mortality rate because that provides more information about the care delivered. For example, esophageal resection is a complex surgery, and studies have noted that providers with higher volumes have lower mortality rates. These results suggest that providers with higher volumes have some characteristics, either structurally or with regard to processes that influence mortality.

The mortality indicators for inpatient conditions cover conditions for which mortality has been shown to vary substantially across institutions and for which evidence suggests that high mortality may be associated with deficiencies in the quality of care. The mortality indicators for inpatient medical conditions are:

- Acute myocardial infarction (AMI) mortality rate
- AMI mortality rate, without transfer cases
- Congestive heart failure mortality rate
- Acute stroke mortality rate
- Gastrointestinal hemorrhage mortality rate
- Hip fracture mortality rate
- Pneumonia mortality rate

Also included in the IQIs are utilization indicators that examine procedures whose use varies significantly across hospitals and for which questions have been raised about overuse, underuse, or misuse. High or low rates for these indicators are likely to represent inappropriate or inefficient delivery of care. The procedure utilization indicators are:

- Cesarean section delivery rate
- Primary cesarean delivery rate
- Vaginal birth after cesarean (VBAC) rate, all
- VBAC rate, uncomplicated
- Laparoscopic cholecystectomy rate
- Incidental appendectomy in the elderly rate
- Bilateral cardiac catheterization rate

There are currently 28 IQIs that are measured at the provider or hospital level, as well as 4 area-level indicators that are suited for use at the population or regional level. These 4 indicators, which are utilization measures, include:

- CABG area rate
- Hysterectomy area rate
- Laminectomy or spinal fusion area rate
- PTCA area rate

The IQIs can be used by a variety of stakeholders in the health care arena to improve quality of care at the level of individual hospitals, the community, the State, or the Nation. The IQIs represent advancement in assessing quality of care using hospital administrative data. While these data are relatively inexpensive and convenient to use and represent a rich data source that can provide valuable information, like other data sources that have various limitations, the data should be used carefully when assessing and interpreting the quality of health care within an institution.

The Patient Safety Indicators (PSIs)

The PSIs are a set of quality measures that use hospital inpatient discharge data to provide a perspective on patient safety.[13] Specifically, the PSIs identify problems that patients experience through contact with the health care system and that are likely amenable to prevention by implementing system level changes. The problems identified are referred to as complications or adverse events. There are currently 27 PSIs that are defined on two levels: the provider level and the area level. They are risk adjusted using a model that incorporates DRGs (with and without

complications aggregated); a modified comorbidity index based on a list developed by Elixhauser and colleagues;[14] and age, sex, and age-sex interactions.

At the provider level, the PSIs present a picture of patient safety within a hospital and provide information about the potentially preventable complication for patients who received their initial care and experienced the complication of care within the same hospitalization. The PSIs use secondary diagnosis ICD-9-CM codes to detect complications and adverse events. The measure set covers a variety of areas such as selected postoperative complications, selected technical adverse events, technical difficulty with procedures, and obstetric trauma and birth trauma. The 20 provider-level PSIs include:

- Postoperative pulmonary embolism or deep vein thrombosis
- Postoperative respiratory failure
- Postoperative sepsis
- Postoperative physiologic and metabolic derangements
- Postoperative abdominopelvic wound dehiscence
- Postoperative hip fracture
- Postoperative hemorrhage or hematoma
- Decubitus ulcer
- Selected infections due to medical care
- Iatrogenic pneumothorax
- Accidental puncture or laceration
- Foreign body left in during procedure
- Birth trauma—injury to neonate
- Obstetric trauma—vaginal delivery with instrument
- Obstetric trauma—vaginal delivery without instrument
- Obstetric trauma—cesarean section delivery
- Complications of anesthesia
- Death in low-mortality DRGs
- Death among surgical inpatients with treatable serious complications (previously known as Failure to rescue)
- Transfusion reaction (AB/Rh)

The area-level PSIs capture all cases of the potentially preventable complications that occur in a given area (e.g., metropolitan service areas or counties), either during hospitalization or resulting in subsequent hospitalizations. They are specified to include the principal diagnosis, as well as secondary diagnoses, for the complications of care. The measurement specifications add cases where a patient's risk of the complication occurred in a separate hospitalization. The seven area-level PSIs are:

- Foreign body left in during procedure
- Iatrogenic pneumothorax
- Selected infections due to medical care
- Postoperative wound dehiscence in abdominopelvic surgical patients
- Accidental puncture or laceration
- Transfusion reaction
- Postoperative hemorrhage or hematoma

Widespread consensus exists that health care organizations can reduce patient injuries by improving the environment for safety—from implementing technical changes, such as electronic

medical record systems, to improving staff awareness of patient safety risks. Clinical process interventions also present strong evidence for reducing the risk of adverse events related to a patient's exposure to hospital care. These PSIs can be used to better prioritize and evaluate local and national initiatives. Some potential actions, after an in-depth analysis of the system and process of care, include the following:

- Review and synthesize the evidence base and best practices from scientific literature.
- Work with the multiple disciplines and departments involved in care of surgical patients to redesign care based on best practices with an emphasis on coordination and collaboration.
- Evaluate information technology solutions.
- Implement performance measurements for improvement and accountability.

The ability to assess all patients at risk for a particular patient safety problem, along with the relative low cost of collecting the data, are particular strengths of the datasets that use administrative data. However, many important areas of interest, such as adverse drug events, cannot currently be monitored well using administrative data and using this data source to identify patient safety events tends to favor specific types of indicators. For example, the PSIs cited in this chapter contain a large proportion of surgical indicators, rather than medical or psychiatric measures, because medical or psychiatric complications are often difficult to distinguish from comorbidities that are present on admission. In addition, medical populations tend to be more heterogeneous than surgical populations, especially elective surgical populations, making it difficult to account for case mix.

While PSIs may be more applicable to patient safety when limited to elective surgical admissions, the careful use of administrative data holds promise to identify problems for further analysis and study. The limitations of this measure set include those inherent with the use of administrative data, clinical accuracy of the discharged-based diagnosis coding, and indicator discriminatory power. Specifically,

- Administrative data are unlikely to capture all cases of a complication, regardless of the preventability, without false positives and false negatives (sensitivity and specificity).
- When the codes are accurate in defining an event, the clinical vagueness inherent in the description of the code itself (e.g., hypotension) may lead to a highly heterogeneous pool of clinical states represented by that code.
- Incomplete reporting is an issue in the accuracy of any data source used for identifying patient safety problems, as medical providers might fear adverse consequences as a result of full disclosure in potentially public records such as discharge abstracts.
- The heterogeneity of clinical conditions included in some codes, lack of information about event timing available in these datasets, and limited clinical detail for risk adjustment all contribute to the difficulty in identifying complications that represent medical error or that may be at least in some part preventable. These factors may exist for other sources of patient safety data as well. For example, they have been raised in the context of the Joint Commission's implementation of a sentinel event program geared to identifying serious adverse events that may be related to underlying safety problems.

Yet, despite these issues, the PSIs are a useful tool to identify areas in patient safety that need monitoring and/or intervention for improved patient care.

The Pediatric Quality Indicators (PDIs)

The AHRQ PDIs are a set of quality measures that use hospital administrative data and involve many of the same challenges associated with measure development for the adult population. These challenges include the need to carefully define indicators, establish validity and reliability, detect bias, design appropriate risk adjustment, and overcome challenges of implementation and use. However, as a special population, children require special tailoring of quality measures and risk-adjustment methodologies. The AHRQ PDIs, developed through careful, ongoing research efforts, provide a risk-adjusted tool to identify quality problems for hospitalized children as well as assess the rate of potentially preventable hospitalizations. The AHRQ PDIs currently consist of 18 indicators defined as both provider- and area-level measures. The 13 provider-level PDIs are:

- Accidental puncture and laceration
- Decubitus ulcer
- Foreign body left in during procedure
- Iatrogenic pneumothorax in neonates
- Iatrogenic pneumothorax in non-neonates
- Pediatric heart surgery mortality
- Pediatric heart surgery volume
- Postoperative hemorrhage or hematoma
- Postoperative respiratory failure
- Postoperative sepsis
- Postoperative wound dehiscence
- Selected infections due to medical care
- Transfusion reaction

Existing risk-adjustment strategies for pediatric patients were not suitable for use with the AHRQ PDIs. Most available schemes apply to specific clinical groups and utilize clinical data not available in administrative databases. The APR-DRG methodology, used for risk adjustment in the adult population, was considered for use in the pediatric population. However, using the APR-DRGs could not adjust for complications in the pediatric population because it resulted in over-adjustment. As a result, different risk adjustment strategies were investigated for potential incorporation into the PDIs. Three important risk-adjustment factors of significance to the pediatric population were identified: (1) reason for admission (including principal procedure), (2) comorbidities, and (3) age and gender. Using a modified-DRG risk adjustment combined with comorbidity adjustment based on the AHRQ Clinical Classification System and age and gender adjustment, the AHRQ PDIs include a novel and specialized risk-adjustment system. They also include stratification, another approach to accounting for case mix. Stratification allows hospitals to identify which segment of the pediatric population accounts for any elevation in rates, creating more user-friendly measures. Tailored stratification schemes are available for six of the PDIs: accidental puncture and laceration, decubitus ulcer, iatrogenic pneumothorax, postoperative hemorrhage or hematoma, postoperative sepsis, and selected infections due to medical care. Despite these efforts to account for risk, it is anticipated that further research on pediatric risk adjustment will be important for assessing quality appropriately.

In addition to the provider-level indicators, the PDIs also include five area-level indicators:

- Asthma admission rate
- Diabetes short-term complication rate
- Gastroenteritis admission rate
- Perforated appendix admission rate
- Urinary tract infection admission rate

These indicators track potentially preventable hospitalizations and allow policymakers to target specific groups that appear to be developing more severe disease requiring hospitalization. Higher-than-anticipated rates may reflect poor access to care (e.g., from lack of insurance or too few primary care physicians), barriers to timely care (e.g., clinics that require daytime appointments), barriers to adherence to medical advice (e.g., language barriers), cultural influences that preclude seeking early treatment, or higher prevalence of poor health behaviors (e.g., smoking). Interventions may address any of these factors.

Area-level indicators are prone to bias due to cultural factors that may be outside of a health system's control. For instance, an area with a high number of illegal immigrants may have patients presenting with more advanced disease, because patients delay seeking care for fear of deportation. In addition, factors such as smoking or obesity may be more prevalent in certain areas. Risk adjustment should include these factors, and an adjustment for socioeconomic status, as a proxy, and has been included in these PDIs. However, risk adjustment for socioeconomic groups may mask true differences in access to good quality care. For this reason, risk-adjusted rates should be considered alongside raw, unadjusted rates.

Current Uses of the AHRQ Quality Indicators

There are a number of uses of the AHRQ QIs, ranging from internal quality improvement to pay-for-performance (P4P) initiatives. (See Table 5 for a list of organization types and associated uses of the QIs.) Each use has certain caveats associated with it, but the AHRQ QIs are one set of many performance measures that can be used for these purposes. Although the QIs were not originally developed for hospital-specific comparative quality reporting, they have been and are being used for public reporting and P4P initiatives. When various users began to apply the AHRQ QIs for public reporting and other initiatives, AHRQ undertook an analysis to determine their appropriateness for these new uses. The Agency concluded that these measures can be used for these purposes, with certain understandings. This analysis resulted in a document that provided detailed information about the use of the QIs for hospital comparative reporting and P4P—*Guidance for Using the AHRQ Quality Indicators for Hospital-Level Public Reporting or Payment,*[15] which is available on the Web at http://www.qualityindicators.ahrq.gov. This document is currently being updated to reflect the current state of the evidence of the AHRQ QIs in relation to public reporting and will include an evidence based reporting template that has been tested with the various stakeholder groups including consumers, providers, and others.

Decisions on how and whether to use the AHRQ QIs or any other measure set is a local matter and depends on various local issues such as data availability and data quality, legislative mandates, confidentiality issues and data use agreements, and resources, to name a few. AHRQ will continue to provide evidence that will inform and further clarify hospital-specific public reporting issues and other issues related to transparency.

Table 5. Users of AHRQ QIs

Type of Organization	Type of Use

Quality Improvement

Originally, the AHRQ QIs were designed as an internal quality improvement tool to assist hospitals to identify and target potential areas for interventions. The ability to track quality of care for a wide range of patients is an important consideration for quality improvement. Hospitals, health care systems, and hospital associations use the AHRQ QIs for internal quality improvement, specifically to initiate case finding, root-cause analyses, and cluster identification, as well as to evaluate the impact of local interventions and to monitor performance over time.

Yet, as with any quality measures, these indicators must be used with care, because the administrative data on which the measures are based are not collected for research purposes or for measuring quality of care, but for billing purposes. While these data are relatively inexpensive to collect, convenient to use, and represent a rich source of information that provides valuable insights, they are one view of the multi-dimensional concept of quality. Our health care system currently uses a "hybrid" model derived from multiple sources, both electronic and paper records, to result in performance information. While not the only use of administrative data, it can as a sole data source, be used by individual hospitals to launch investigations into reasons for identified quality problems. Further study may:

- Reveal real quality problems for which quality improvement programs can be initiated.
- Uncover problems in data collection that can be remedied through stepped-up efforts to code more diligently.
- Determine that additional clinical information is required to understand the quality issues, beyond what can be obtained through billing data alone.

Overall, the AHRQ QIs are a valuable tool that takes advantage of readily available data to identify quality-of-care problems. Hospitals may use existing data to identify indicators with higher-than-expected rates, flagging potential quality concerns. These areas of concern may be investigated further to identify the underlying cause of the poorer-than-expected performance. In some cases, incorrect coding practices may be identified; in other cases, closer examination of system-level factors may be in order. Interventions may be devised to improve performance, and hospitals may track their own performance over time to identify areas for improvement.

Public Reporting and Pay for Performance

The AHRQ QIs are currently being used in several public reporting and pay for performance (P4P) initiatives at the national, State, and regional levels. At the national level, for example, they are used in tracking the quality of health care in the United States in the *National Healthcare Quality Report*[16] and *National Healthcare Disparities Report*[17] produced annually by AHRQ. These reports focus on four dimensions of quality—effectiveness, safety, timeliness, and patient centeredness—and are available on the AHRQ Web site. Other uses of the QIs include surveillance of trends over time at the State and community level as well as assistance in tracking disparities across areas, when the data are available.

Several organizations have incorporated the AHRQ QIs in reports on quality that allow for comparisons of individual hospitals. Organizations such as the Colorado Health and Hospital Association, the Texas Health Care Information Council, the Niagara Health Quality Coalition, and Norton Healthcare are a few. Many of these reports are Web based and are routinely updated. For a more complete list of organizations that use the AHRQ QIs for public reporting, see Table 6.

Table 6: Organizations Using the AHRQ QIs for Public Reporting

Organization Name	Type of Report	Description	QIs used
AFSCME Council 31[18]	One-time report	The union published a report on quality at Resurrection Health Care hospitals after complaints about quality from workers.	IQIs 15–20
California Office of Statewide Health Planning & Development[19]	Interactive tool and periodic written reports	A Web site includes an interactive tool for hospital comparison on selected IQIs and other risk-adjusted mortality indicators.	IQIs 1, 2, 4–7, 21–23, 33, 34; PDI 7
Chicago Department of Public Health[20]	Periodic report	Chicago runs a Web site providing a health profile, including PQIs, of community areas in the city.	PQIs (all except 2, 9)
Colorado Health and Hospital Association[21]	Periodic report	Hospital reports are shared among hospitals and published on a Web site.	IQIs 4–7, 12–20, 30, 31
Connecticut Office of Health Care Access[22]	One-time report	Databook on preventable hospitalizations.	PQIs (all)
Excellus Blue Cross/Blue Shield[23]	Interactive tool	Online hospital comparison tool for health plan members only.	Unspecified (members only)
Exempla Hospital System[24]	Periodic report	Exempla publishes quality information on its hospitals on its Web site. (The same results are also reported by the Colorado Health and Hospital Association.)	IQIs 12–20, 30, 31
Florida State Center for Health Statistics[25]	Interactive tool	Online hospital comparison tool.	PSIs 3, 6–8, 12, 13; IQIs 8–20, 32
Georgia Partnership for Health and Accountability[26]	Periodic report	A periodic report on health in Georgia includes a chapter on avoidable hospitalizations.	PQIs 3, 5, 8, 10, 11, 15
Massachusetts Dept. of Health and Human Services[27]	Interactive tool	Online hospital comparison tool.	IQIs 14, 16–21, 32–34
Missouri Department of Health and Senior Services[28]	Periodic report	Comparison of hospital surgery volume to help consumers choose a hospital.	IQIs 1, 2, 4–7; PDI 7
Niagara Health Quality Coalition and Alliance for Quality Health Care[29]	Interactive tool	Online hospital comparison tool.	IQIs 1–25
Norton Healthcare[30]	Interactive tool	Health system publishes quality data for its hospitals on its Web site.	PSIs 1–6, 8–16, 18–20; IQIs 1, 2, 4–9, 11–20, 22–24, 30, 31, 34; PDIs 2–9, 11, 13
Ohio Department of Health[31]	Periodic report	Online comparison of avoidable hospitalizations by county.	PQIs 1, 4, 5, 7, 8, 11, 14, 15
Oregon[32,33]	Interactive tool	Online hospital comparison tool and a report on Oregon's safety net by the Safety Net Advisory Council.	IQIs 11, 12, 15–17, 19, 20, 30; PQIs 3, 5, 8, 10, 11, 12, 15
Rhode Island[34]	One-time report	Report on hospital procedure volumes. Future reports on IQIs and PSIs in preparation.	IQIs 1–7
Texas Health Care Information Collection[35]	Interactive tool	Online hospital comparison tool.	IQIs 1–14, 16–20, 22–25, 30–33; PQIs (all)

Organization Name	Type of Report	Description	QIs used
The Alliance (Wisconsin)[36]	Periodic report	QualityCounts report on hospital safety performance. The report is based on AHRQ PSIs but modifies them for reporting.	PSIs 3, 6, 7, 8, 12, 17; IQI 33
Utah Department of Public Health[37, 38]	Periodic report	Web site providing health information for geographic areas. Three PQIs are included with numerous health status and other measures. State-level IQI results are presented on a one-page poster, available online.	PQIs 4, 11, 1+3+14 combined; IQIs (all)
Vermont Department of Banking, Insurance, Securities & Health Care Administration[39]	Periodic report	Online hospital comparison report.	IQIs 1, 2, 4–9, 11, 12, 30, 31; PDIs 6, 7

Note: Public reporting is defined as a publicly available report that compares AHRQ QI results between hospitals (IQIs and PSIs) or geographic areas such as counties (PQIs). No public reporting of the area-based IQIs or PSIs was identified. Not all of the public reports identified in this table are intended to influence consumers' choice of provider.
One-time reports are published comparisons that are not labeled as an ongoing activity.
Periodic reports are published comparisons, updated periodically, that are in static format (e.g., documents available as PDF files online).
Interactive tools are online comparisons that allow users to create customized reports (e.g., selection of providers or indicators of interest).

Source: Hussey PS, Mattke S, Morse L, et al. *Evaluation of the Use of AHRQ and Other Quality Indicators.* Santa Monica, CA: Rand Health; October 2006.

Organizations such as the Centers for Medicare & Medicaid Services and Anthem Blue Cross and Blue Shield of Virginia have incorporated selected AHRQ QIs into P4P demonstration projects or similar initiatives. These projects reward providers for superior performance based on a combination of performance measures, including the AHRQ QIs. Results from the Centers for Medicare & Medicaid Services demonstration project indicate that tying payment to performance may provide some incentive to improve the quality of care.

There are a number of factors to be considered when using the AHRQ QIs for public reporting and payment purposes. Factors related to data source and measurements raise important issues such as:

- Very low or low volume (small cell size) could impact patient confidentiality and also limit the ability to reliably identify quality differences.
- Measures may not be applicable to the majority of hospitals or applicable only to hospitals with specific services (e.g., cardiac surgery, obstetrics).
- Volume is a proxy measure; volume may be manipulated leading to concerns about appropriate utilization.
- Potential confounding bias or the impact may be impaired by skewed distribution not completely eliminated by risk adjustment or carefully constructed operational definitions.
- Benchmarking or the correct rate may not be clear.
- Many procedures are currently done on an outpatient basis or observation status.
- The indicator may require data not present in all administrative datasets, or risk adjustment may be inadequate when based only on data available from ICD-9-CM codes.
- Coding may vary across hospitals; some hospitals code more thoroughly than others, making fair comparisons across hospitals difficult.

However even with these limitations, codes, coding systems, and coding practices are improving and are often subject to auditing or monitoring for accuracy. Coders are becoming more aware of the importance of properly coding the data and how they are used in relation to quality improvement, public reporting, P4P and other initiatives.

Ideally, in public reporting and P4P initiatives, the results of the performance measures should be made available to those hospitals participating, along with information on averages for peer groups, for the State, and for the Nation.

It is important when using not only the AHRQ QIs but all measures used for purposes such as comparative reporting, purchasing, or payment to continually assess and evaluate them and provide feedback to the measure developer for measure refinement and improvement purposes. The process of measure development and maintenance is constant, and measure developer like AHRQ welcome input from uses in an effort to continue to refine and enhance the measures.

Research

A number of the AHRQ QIs have been used in health care research projects. On the whole, researchers use the indicators because of the quality and level of detail of the AHRQ documentation of the QIs as well as the fact that these measures capture important aspects of clinical care[40] (p. v). The AHRQ QIs, their documentation, and the related software reside in the public domain and are downloadable from the AHRQ Web site, free of charge. The QIs can be used with readily available administrative data, which researchers have ready access to in the

form of HCUP. Further, researchers appreciate the fact that they can dissect indicator results and relate them back to individual records, which helps to gain a better understanding of the logic used in the measures, which, in turn, assists in distinguishing data quality issues from actual quality problems[40] (p. vii). Topics of studies using the AHRQ QIs include an analysis examining the association between the Joint Commission accreditation scores and the AHRQ IQIs and PSIs,[41] the effect of resident physician work hour limits on surgical patient safety,[42] and the determination of whether persons with Alzheimer's disease were at greater risk for in-hospital mortality than non-Alzheimer's patients.[43]

Table 5, which is based on an environmental scan commissioned by AHRQ and completed by Hussey and colleagues,[40] indicates that the AHRQ QIs are frequently used by researchers in their projects.

What Nurses Need To Know

Measuring performance is central to quality improvement because it provides information on current and past performance that can help guide future improvement efforts. In particular, performance measures can distinguish between good and substandard performance. Accordingly, the development and application of performance measurement is essential to improving the quality of care. It is one of the "first steps in the improvement process and involves the selection, definition, and application of performance indicators…"[44] (p. 24). Performance measurement, while not the only influence, can act as a force to promote certain issues and agendas. Performance measurement conveys the message of importance. Specifically, what is important is measured, while what is not measured is considered less important.[45] By focusing people and resources on a particular aspect of an industry, performance measurement can be a driver of change and reform.

Nurses are an integral member of the health care team and are in a unique position to detect quality-of-care issues, often providing avenues for change in processes that improve quality and safety in health care.[46–48] The AHRQ QIs are one set of performance measures that provide information about the quality of care that nurses can use to plan and implement quality-improvement strategies. The climate for quality tracking, measurement, and reporting, and linking payment to quality, has changed dramatically in the past several years. The efforts by governments, accrediting bodies, large purchasers, employer coalitions, and others to track quality at the national, state-wide, and provider level; publish comparative quality reports; launch quality improvement efforts; and use public and private purchasing power to reward better quality have accelerated. Nurses not only are members of the quality team but often lead and coordinate efforts at the local levels that provide input into these efforts. Leaders of these quality efforts often consider using administrative data because they are readily available and inexpensive relative to other data sources. Data gleaned from the AHRQ QIs can be used to track trends, identify gaps in data measurements, and assist in redesigning organizational and workflow processes. Data provide a focus for improving health care quality, which can be used to make more informed decisions about policies within given facilities, communities, or regions. National and State benchmarks of the AHRQ QIs can be used to assess and compare an individual facility's progress in a certain area. Nurses are well positioned to review performance data, interpret the results, provided additional followup as warranted, and design interventions to improve the quality of care within an organization.

There are significant challenges associated with applying administrative or clinical data sources, no matter how "good" the measure is, for which nurses should be aware of. Selecting measures and the purposes for which to use them should depend upon organizational or program needs. Implementation issues, including data availability and data quality, need to be addressed during the measure-selection process because the immediate goal is to produce usable information for quality improvement, public reporting, planning, and care redesign.

Data availability is an issue that must be addressed. Typical data sources include clinical data (e.g., medical record abstraction, laboratory data, pharmacy data, electronic medical record), administrative data (UB-04, billing, or claims data), survey data (e.g., patient experience with care, employee satisfaction), and operational data (e.g., licensure, ownership, staffing levels, type of staff). Each data source has its strengths and limitations. While clinical data is usually preferred by providers, it requires medical abstraction that is usually costly to collect. The primary benefit associated with the use of clinical data is the greater number of data elements that can be abstracted, resulting in enhanced measure definition, risk adjustment, and linkage to care processes. While there are efforts underway to expand and automate access to clinical data, automated data are not yet a reality.

Administrative data, on the other hand, are the most widely available source of information about hospital services, patient care, and patient outcomes. All hospitals generate administrative data as part of billing operations, and all payers have access to administrative data. These types of data have been shown to be useful in quality assessment and medical research, as well as for other measurement tasks such as screening for complications, identifying mortality rates, and tracking health system utilization. Like clinical data, administrative data also have limitations. Because administrative data are collected principally for billing and related administrative purposes, these data lack the depth of clinical detail that can be helpful in quality measurement; variations in coding practices may create challenges for quality evaluations; and there can be data validity issues. Since the concept of quality is multidimensional, a combination of measures derived from clinical and administrative data sources would offer a more complete picture of quality, at least in the immediate future.

Regardless of the data source, nurses involved in the quality improvement enterprise should be aware of several factors and consider them when tasked with designing and using a performance measurement system. The purpose of the measurement project should be clearly specified. Is it to drive quality improvement or public accountability? Inform consumer decisions? Pay for performance? Subsequent decisions will depend on the purpose of the measurement effort. Once the purpose has been established, the stakeholders of the project should be identified to assess expectations and to determine to what extent the available data and measures can meet their interests. In the planning stages of the project, providers who will be affected by or measured should be given the opportunity to understand the purpose of the project, why certain measures were chosen, and what will be done with the results. There should also be an opportunity to understand the methodology, including measure definitions, any risk adjustment used, and the calculation of the measures.

Audits for quality or similar mechanisms should be in place to assure accuracy and completeness. Data explorations should be completed and should focus on overall data quality and content, beginning with simple frequency distributions on key variables. Nurses and other providers reviewing the data should ask the following questions: If the program includes the objective to evaluate access or outcome by patient race, is the data element present for each case? Are data missing in a consistent manner? Is a selected procedure performed so infrequently

in any single year that examining mortality rates would best be accomplished by combining data from several years? What comparative benchmarks are available? There are benchmarks at the national, regional, and peer-group levels from sources such as the *National Healthcare Quality Report*[16] and *National Healthcare Disparities Report*,[17] HCUPnet, and other State-level or hospital-system efforts. Finally, an evaluation component should be included as part of the initiative as it provides feedback, which can inform future decisions about the measurement project.

Nurses serve as an important member of the quality team, and often provide continuity from one phase of a project to another. Many nurses serve as part of leadership teams within their organizations and can provide valuable input into designing measurement strategies and quality improvement programs that improve the quality of care overall. Additionally, nurses are well positioned to not only analyze data from measures but also to design and implement strategies that impact care delivery. Many nurses coordinate activities among multidisciplinary teams, and organize interventions across departments which can ultimately result in improved quality of care for patients.

Enhancing the AHRQ Quality Indicators

Recently, the AHRQ QIs have undergone some changes based upon newly reported research, validation testing, the NQF endorsement process, input from several professional societies, and input from the QI user community. Based upon these activities, the AHRQ has revised the ICD-9-CM codes; incorporated the data element present on admission (POA) as a requirement for the calculation of selected measures; and added the ability to stratify certain measures such as delineating emergent cases from non-emergent cases for AAA Mortality Repair. In addition, the AHRQ has worked with other organizations to harmonize measures that are similar to the QIs, and as a result of these discussions, various coding changes have been incorporated into the numerator and denominator of selected measures.

The AHRQ also convened several expert panels to develop composite measures of the QIs. These discussions resulted in five composite measures: the PQI composite (PQI 17); Mortality for Selected Conditions (IQI 36); Mortality for Selected Procedures (IQI 35); Patient Safety for Selected Indicators (PSI 28); and Pediatric Patient Safety for Selected Indicators (PDI 19). The final report for each of these composites can be accessed from the AHRQ website.

AHRQ has also developed evidence-based reporting templates for the QIs. These templates were designed to report comparative performance data generated by the QIs to consumers and others. These templates are intended to report performance to consumers, but can be useful to other stakeholders in health care. The templates were tested by several focus groups that consisted of consumers, purchasers, providers and others. The first template uses the composite measures developed by AHRQ to report performance, while the second template groups the measures into health topics. Both templates are available, along with a sponsor guide are available on the AHRQ website.

Conclusion

The AHRQ QIs are one measure set, based on administrative data that can be used to evaluate the quality of clinical services. Most of the QIs focus on health care outcomes rather than rates of processes of care followed. The measures, their extensive documentation, and

associated codes for SAS® and Windows® reside in the public domain and are available for download at no cost to the user. Furthermore, the QIs are maintained by AHRQ, which continues to refine and enhance them. Updates to the modules are done on a yearly basis and are routinely released in the first quarter of the year. AHRQ also provides technical support to users on a wide range of issues, including questions about the software package, clarifications of indicator definitions, theoretical questions on the indicators, and interpretation of performance results. The QI support team can be reached via e-mail at support@qualityindicators.ahrq.gov.

Future enhancements to the AHRQ QIs are underway and include the development of indicators specific to neonates, the development of additional indicators in areas such as hospital outpatient care, day surgery, diagnostic procedures, and emergency department care. Other planned improvements include incorporating additional clinical data elements such as lab values and do-not-resuscitate-order flag. Additional research is needed to develop evidence-based outcome measures that are sensitive to nursing practice.

"Quality of care is highly variable and delivered by a system that is too often poorly coordinated, driving up costs, and putting patients at risk."[49] (p. 1). Improving the access to and the performance of our health care system is a matter of national urgency.[50] Yet, defining what quality is in health care is not easy. Quality is a complex, multidimensional concept that suggests different things to different people.[47, 51] Consequently, competing views of quality should be balanced among patients, purchasers, managers, and health care professionals. A widely used definition of quality in health care is "the degree to which health services for individuals and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge."[6]

Regardless of how quality is defined, the only way to know whether the quality of health care is improving is to measure the performance of those that deliver it. Performance measures and performance measurement systems provide a tool to determine if quality exists. Currently there is a proliferation of performance measures, and development of these measures shows no sign of abating. While there is a plethora of measures in areas such as cardiac care, there is a dearth or complete lack of measures in other areas such as mental health and cancer care. Better coordination among measure developers is key to reducing the measurement burden of health care organizations. With the adoption of the electronic health record, performance measurement has the potential to become a by-product of care, instead of a distinct data-gathering activity.

The AHRQ QIs are one set of performance measures that cover a broad array of conditions and that use an inexpensive, readily available data source. While these measures do have certain limitations, these measures have been and are being used in a variety of initiatives that have contributed to improved quality of care within the United States.

Acknowledgements

As with any large, complex endeavor, the AHRQ Quality Indicators are supported by a team of researchers, clinicians, and others that work to constantly refine and improve the measures. There are a number of individuals that work on the QIs and contribute to their development and testing that should be acknowledged here, however, I would like to specifically acknowledge Jeffrey Geppert, J.D., of Battelle Memorial Institute; Patrick Romano, M.D., M.P.H., of the University of California; Sheryl M. Davies, M.A., and Kathryn M. McDonald, M.M., of Stanford University for their diligence and continued support of the program. I would also like to thank my colleagues at AHRQ for their suggestions and words of encouragement, but in particular,

Mamatha Pancholi, the QI Project Officer, for her support and phenomenal focus over the past two years. I am honored and privileged to be part of an incredible team.

Chapter 46. Magnet Environments for Professional Nursing Practice

Vicki A. Lundmark

Background

In hospital settings, nurses fulfill two roles. Based upon expert knowledge, nurses provide care to the ill or prevent illness. Nurses also maintain and manage the environment surrounding the delivery of care, which has increasingly involved coordinating the care activities provided by other health care providers. Of three reports published since the year 2000 by the Institute of Medicine,[1–3] the 2004 report on patient safety was the first to emphasize the connection between nursing, patient safety, and quality of care. The report specifically noted the importance of organizational management practices, strong nursing leadership, and adequate nurse staffing for providing a safe care environment. The report also noted how frequently the patient safety practices identified by the literature "were the same as those recommended by organizations studying the nursing shortage, worker safety, and patient satisfaction"[3] (p. 317).

While it seems logical to assume that safe and effective patient care depends on the presence of "an organizational context that enables the best performance from each health professional"[4] (p. 186), remarkably little knowledge has accumulated about how the organization and delivery of nursing services influences patient outcomes. One explanation for this situation is that health services research so firmly turned its focus to organization/environment and organization/market questions following the rise of health economics and health maintenance organizations (HMOs) in the 1970s that it was caught somewhat unprepared when quality issues began to emerge in the latter part of the 1990s. As a result, few conceptual tools exist "to address the heart of quality concerns: the internal work processes and arrangements inside health care organizations . . . that contribute to variations in quality"[5] (p. 318).

Another limiting factor has been the inherent challenges of measuring organizational practice environments and the complexity of nursing's effects on patient outcomes. Improved theoretical frameworks and greater methodological rigor will be needed to guide and advance the nursing research on patient outcomes.[6, 7] Nursing research has already been leading the way in this effort, which may not be surprising given the deep knowledge nurses have of the internal workings of health care organizations.[5]

The magnet hospital concept, originating from a groundbreaking study in the early 1980s[8] that sought to explain instances of successful nurse recruitment and retention during a severe nurse shortage, provides one framework for specifying the organizational and practice environment conditions that support and facilitate nursing excellence. The purpose of this chapter is to summarize the magnet research evidence related to nurse or patient outcomes.

Magnet Hospitals and the Attraction and Retention of Professional Nurses

The original magnet study began in 1981 when the American Academy of Nursing appointed a task force to investigate the factors impeding or facilitating professional nursing practice in

hospitals. The four researchers on the task force were working from the knowledge that despite a nursing shortage for a large number of hospitals, a certain number "had succeeded in creating nursing practice organizations that serve as 'magnets' for professional nurses; that is, they are able to attract and retain a staff of well-qualified nurses and are therefore consistently able to provide quality care"[8] (p. 2). Therefore, the research goal was set to explore the factors associated with success in attracting and retaining professional nurses.

Through an extensive nominating process, 41 hospitals from across the country were selected to participate in the study based upon their known reputations as being good places for nurses to work and the evidence they submitted to document a relatively low nurse turnover rate.[9] Subsequently, a series of group interviews was held with representatives from each hospital. Two interviews were conducted in each of eight geographically dispersed locations. In the morning, one of the task force researchers interviewed the chief nurse executives from the participating hospitals in that area. Then, in the afternoon, a second group interview session was held with staff nurses. Each staff nurse who participated in the interviews was selected by his or her chief nurse executive.

Based upon their analysis of this interview data, the task force researchers identified and defined a set of characteristics that seemed to account for the success the 41 reputational magnet hospitals had enjoyed in attracting and keeping a staff of well-qualified nurses at a time when other hospitals around them were not able to do so. The labels given to these characteristics, which have come to be known as the forces of magnetism, are listed below in Table 1. Many of the insights they embody have a long history of study within the sociological literature related to organizational performance, leadership, worker autonomy and motivation, decentralized or participative management, work design, coordination and communication, effective groups and teams, and organizational innovation and change.[10]

Note: Order shown in the left column has been slightly rearranged for ease of comparison.

The relationship of a magnet environment to quality was recently described by one of the original task force researchers. Looking back on the original magnet study more than 20 years later, McClure wrote[12] (p. 199),

> We found that all these settings had a commonality: their corporate cultures were totally supportive of nursing and of quality patient care. What we learned was that this culture permeated the entire institution. It was palpable and it seemed to be almost a part of the bricks and mortar. Simply stated, these were good places for all employees to work (not just nurses) and these were good places for patients to receive care. The goal of quality was not only stated in the mission of these institutions but it was lived on a daily basis.

The Magnet Recognition Program® of the American Nurses Credentialing Center (ANCC)*

In the early 1990s, the American Nurses Association (ANA) initiated a pilot project to develop an evaluation program based upon the conceptual framework identified by the 1983 magnet research. The program's infrastructure was established within the newly incorporated American Nurses Credentialing Center of the ANA, and the first facility to receive Magnet recognition was named in 1994.[11] Interest in Magnet™ has been increasingly accelerating. While only about 225 organizations have achieved Magnet recognition since the program's inception, nearly two-thirds of them did so within the last 3 years, and the applicant list continues to expand.

Applicants for Magnet recognition undergo a lengthy and comprehensive appraisal process[13] to demonstrate that they have met the criteria for all of the forces of magnetism shown in the right column of Table 1. Currently, documentation or sources of evidence are required in support of 164 topics.[11] Organizations that receive high scores on written documentation move to the site-visit stage of the appraisal and a period of public comment. The philosophy of the program is that nurses function at their peak when a Magnet environment is fully expressed and embedded throughout the health care organization, wherever nursing is practiced. Magnet organizations submit annual reports and must reapply every 4 years to maintain their recognition.

In the context of a rapidly evolving health care system, ANCC has the responsibility as a credentialing body to continuously refine and improve the criteria it uses for Magnet recognition in order to "separate true magnets from those that simply want to achieve the recognition"[14] (p. 123). ANCC does so by evaluating new information from multiple sources, the scholarly research literature, expert groups convened to deliberate specific issues, and feedback from Magnet facilities and appraisers, particularly in relation to identifying effective and innovative practices.

Continuity between the original magnet research and ANCC's Magnet program is provided by the conceptual framework for the forces of magnetism. Little has changed in the essential definitions for the forces except that ANCC has revised them to reflect contemporary hospital settings and elaborated under each force a set of required documentation for applicants to submit and appraisers to evaluate. Beginning in 2005, however, an important change appeared in the

Magnet is capitalized in this chapter when it refers to the ANCC Magnet Recognition Program or to organizations that have been designated Magnet by the Magnet Recognition Program.

Magnet application process. Whereas previous application manuals had itemized evidence requirements according to ANA's *Scope and Standards for Nurse Administrators*,[15] the new manual version[11] reorganized the criteria into the framework of the forces of magnetism. This transition should help to clarify the correspondence between the elements ANCC's Magnet program evaluates in its appraisal process and the magnet characteristics that nursing and health services researchers study.

Reviewing the Evidence

Research studies were retrieved for this review by searching PubMed® and CINAHL® for articles referencing magnet or magnetism in the title or abstract. Two inclusion criteria were used. (More details can be found below, in "Search Strategy.") The articles had to (a) report findings from analyses of primary or secondary data, and (b) investigate relationships between magnet variables and nurse or patient outcomes. Nurse outcomes of interest were job satisfaction, burnout, and intention to leave[16, 17] or similar variables such as mental health. Nurse perceptions of patient care quality has been a frequently used measure in the magnet-related survey research, and one study used nurse perceptions of safety climate as the dependent variable. But studies that included patient outcome variables measured from other sources were seldom found, although patient mortality and patient satisfaction are represented in the evidence tables.

Limitations of the Research

Overwhelmingly, the magnet research has been dominated by cross-sectional survey studies with convenience samples of organizations and staff nurse respondents. The basic approaches used to capture magnet environments in the research have been to include organizations from the 1983 magnet study or with ANCC Magnet recognition in the hospital sample or to administer survey scales believed to measure magnet characteristics, traits, or factors. Usually, but not always, these approaches have been used in combination. Analyses have typically been limited to simple comparisons of survey items or subscale results between two groups.

With few exceptions, the majority of this research has suffered from two major limitations: biased sampling at both the organizational and respondent level; and a scarcity of comprehensive, valid, and reliable measures for assessing the level of magnet characteristics present in any setting. Unless magnet characteristics are measured adequately across the organizations participating in a study, the degree to which their presence differs between the comparison groups cannot be assessed. Because the organizations that have attained ANCC Magnet recognition constitute a voluntary sample, it is possible that high levels of some or many magnet characteristics may also exist in other organizations that have not chosen to apply for the recognition.

Overwhelmingly, the survey scales most frequently used to measure magnet characteristics have all derived from the Nursing Work Index (NWI). Because these scales have dominated the magnet research, it is important to understand how they are constituted and how they have evolved over time. The first version of the NWI was designed to inclusively and comprehensively reflect the findings of the 1983 magnet research study.[18] It was intended to measure four variables: work values related to staff nurse job satisfaction, work values related to perceived productivity, staff nurse job satisfaction, and perceived productivity (the perception of

an environment conducive to quality nursing care). Content validity for the instrument was assured by having three of the four original magnet researchers review it for inclusiveness.[19] The NWI consisted of 65 items and asked respondents to make three Likert-scale judgments on each item.

Aiken[20] subsequently adapted the NWI to measure only organizational features by dropping the judgment statements related to job satisfaction and perceived productivity. Compared to the NWI, the NWI-Revised (NWI-R) contained fewer items, but otherwise remained the same except that one item was modified and two more were added. Four NWI-R subscales were conceptually derived from an item subset.[21]

Two of the NWI-R subscale domains, nurse autonomy and nurse-physician relationships, are readily recognizable in comparison to the forces of magnetism listed in Table 1. The other two domains, organizational support and control over nursing practice, are represented by sets of items that could be classified across several forces of magnetism. Control over nursing practice is defined as organizational autonomy or the freedom to take the initiative in shaping unit and institutional policies for patient care. Hinshaw[22] described clinical autonomy and organizational autonomy as interactive concepts. Both types of autonomy were evident in the findings from the original magnet study.[8, 23]

Since the NWI-R was developed nearly a decade before any subsequent NWI-derived scale versions appeared, the NWI-R has been the most frequently used measure of magnet characteristics in magnet research. An advantage of this fact has been the ability to compare findings across studies. A disadvantage may have been the formation of a wide impression that the magnet hospital concept is more circumscribed than it actually is. In the literature reviewed here, the phrase most frequently used to introduce the magnet concept to readers directly cites the NWI-R subscales; magnet is said to describe hospitals where nurses have greater autonomy, control over nursing practice, and good nurse-physician relationships. Given nursing's history as a subordinated profession,[24] one can understand that these three dimensions of the magnet concept attracted the most initial attention.

In the last 5 years, three additional versions of the NWI have appeared. Except for minor changes in wording, all use items from the NWI or the NWI-R as originally written. However, each version consists of different, empirically derived scale or subscale formations. Lake[25] created the 31-item Practice Environment Scale of the NWI (PES/NWI) with five subscales and an overarching composite scale. Estabrooks and colleagues[26] created a single-factor, 26-item scale called the Practice Environment Index (PEI). Choi and colleagues[27] created the Perceived Nursing Work Environment scale (PNWE)[†] with 42 items and 7 subscales. Neither the PEI nor the PNWE measures appear in the studies reviewed here.

Research Evidence

The evidence tables in this chapter are divided into three parts. Evidence Table 1 covers the early research period and itemizes studies conducted with hospitals from the group of 41 reputational magnets that participated in the 1983 study. Evidence Table 2 includes studies that compared health care organizations with and without designation as ANCC-recognized Magnets. Finally, Evidence Table 3 itemizes studies that investigated the relationship of various magnet

[†] Subscales for the PNWE are labeled professional practice, staffing and resource adequacy, nurse management, nursing process, nurse-physician collaboration, nurse competence, and positive scheduling climate.

characteristics to outcomes. Insofar as possible, the evidence tables are arranged in chronological order to illustrate how magnet research has progressed since the concept of a magnet environment first appeared in the literature in the 1980s. In addition, each row or panel in the tables represents a single data collection event. If multiple articles were generated from a single data collection effort, they are cited together in the same panel of the table. The purpose of this arrangement is to present a clearer picture of the body of evidence as a whole, revealing that the total number of data sources (with their associated measures and methods) that have constituted the magnet research since 1983 is relatively small. In addition, this arrangement draws attention to which articles are better read as a set by anyone wishing to understand the research in detail. Methodological information related to a single data collection effort can sometimes be scattered across multiple publications.

Evidence Table 1 includes two of the most compelling studies to have come out of the magnet literature, those initiated by Aiken and her colleagues[28-35] within a decade of the publication of the original magnet study. For the Medicare mortality study[28], magnet characteristics were not directly measured. However, the use of risk adjustment techniques for predicted mortality and multivariate matched sampling methods to control for factors that might affect mortality provided strong support for concluding that the set of reputational magnet hospitals was uniquely different as a group. As Aiken has summarized it, these "findings suggest that the same factors that lead hospitals to be identified as effective from the standpoint of the organization of nursing care are associated with lower mortality"[20] (p. 72).

Guided by a conceptual framework originating in the sociology of organizations and professions,[20] the second compelling study[29-35] was formulated to examine how certain modifications to the organization of nursing in hospitals introduced by the AIDS epidemic affected patient and nurse outcomes. The AIDS epidemic in combination with high nurse vacancy rates caused a number of urban hospitals to grant "unusual discretion to nurses to redesign general medical units into dedicated AIDS units"[20] (p. 63). Since the comparison group of hospitals for this study included two reputational magnet hospitals and a third hospital believed to be magnet-comparable, the researchers were able to discern that many of the same positive results achieved in dedicated AIDS units could apparently be attained by making changes at the organizational level. Magnet characteristics (as measured by the NWI-R subscales) were associated with significantly better outcomes for nurse safety, job burnout, patient satisfaction, and mortality 30 days from admission.

The studies shown in Evidence Table 2 consistently display positive results relating magnet characteristics (as measured by the NWI-R or PES/NWI subscales) to nurse job satisfaction, burnout, intention to leave, and perceived quality of care. The exception to this finding is the mixed results shown for the nurse-physician relationship subscale. Havens's[36] study with chief nurse executives found higher levels on the NWI-R subscales to be associated with reports of higher patient care quality, less recruitment difficulty, and fewer patient/family complaints. The studies shown in the first two rows of Evidence Table 2, which demonstrated more favorable results for the ANCC Magnet group compared to the reputational magnet group, also supported the view expressed by McClure and Hinshaw that magnet status "is not a permanent institutional characteristic but rather one that requires constant nurturing"[14] (p. 119).

Evidence Table 3 lists three studies that explored the degree to which magnet characteristics could be found in hospitals outside the United States or in nonhospital settings. Thomas-Hawkins and colleagues[37] and Smith, Tallman, and Kelly[38] found that some magnet characteristics linked significantly to intentions to leave in freestanding dialysis units and to job satisfaction in rural

Canadian hospitals, respectively. Rondeau and Wagar[39] found significant associations between magnet characteristics and resident satisfaction and nurse satisfaction, turnover, and vacancy rates in long-term care organizations in western Canada.

The remaining studies shown in Evidence Table 3 are important for a number of reasons. Using multiple measures, a variety of samples and respondent groups, and more powerful analyses, Laschinger and her colleagues[40-44] have been testing a theoretical model linking structural empowerment and magnet characteristics (as measured by the NWI-R or PES/NWI) to nurse and patient outcomes with variables such as trust and burnout posited as mediators. The empowerment dimensions being measured—perceptions of formal and informal power and access to opportunity, information, support, and resources—also appear to overlay some descriptions of magnet characteristics from the original 1983 research. By testing relationships with a set of theoretically selected variables and multivariate statistical methods, the studies of Laschinger and colleagues have been progressively building knowledge about how factors in the complex nursing practice environment interact with each other to affect outcomes.

The work that will be required to explicate how the organization and delivery of nursing services functions as a mechanism to improve patient safety and the quality of care has only just begun. The literature review conducted by Lundstrom and colleagues[45] found a number of studies that start to suggest the mechanisms by which organizational and work environment factors influence worker performance and ultimately patient outcomes. However, the authors also noted, "What we do know about changes in organization and structure of hospitals and the potential for those changes to affect patient outcomes pales by comparison to what we do not know"[45] (p. 103).

Reviewing the magnet research presented in this chapter leads to similar conclusions. The evidence almost uniformly shows consistent positive relations between job satisfaction or nurse-assessed quality of care and the magnet characteristics measured by subscales of the NWI-R or PES/NWI. But the connections from those results based on staff nurse surveys to patient outcomes measured objectively by other means have seldom been studied.

In a recent systematic review of the hospital nursing environment's effect on patient mortality, Kazanjian and colleagues[6] found associations between unfavorable environment attributes and higher patient mortality rates in 19 of 27 studies. However, other studies of the same attributes showed contrary or neutral results. Too much variability existed in measures, settings, and methodological rigor across studies to permit any pooling of results. The authors concluded it would be difficult to determine "how to design optimal practice settings until mechanisms linking practice environment to outcomes are better understood"[6] (p. 111).

Evidence-Based Practice Implications

The magnet framework outlined in Table 1 specifies a set of factors important for establishing positive work environments that support professional nursing practice. As the evidence reviewed in this chapter shows, few studies have explored the relationship of magnet characteristics to patient outcomes. Since the associations found were consistently positive, this constitutes a promising body of work, but one that is just beginning to emerge. In contrast, more evidence has accumulated to demonstrate links between magnet characteristics or Magnet recognition and favorable outcomes for nurses such as lower burnout, higher satisfaction, and fewer reports of intentions to leave. The practice implications suggested by these findings have been delineated in detail by the Institute of Medicine's 2004 report on patient safety, which

included a comprehensive review of the research that clarifies how nurse outcomes reflect and interact with working conditions to affect patient safety and quality.[3]

Keeping Patients Safe: Transforming the Work Environment of Nurses cited conditions in the work environments of nurses as "the primary sources" of threats to patient safety that "must be addressed if patient safety is to be improved"[3] (p. 47). The report presented a series of recommendations for improving leadership, management, and organizational support practices that emphasizes the increased participation of employees in work design, problem-solving, and organizational decisionmaking as a "key ingredient to successful organizational change"[3] (p. 260). The report noted that high involvement in decisionmaking for nurses "has been studied under a number of constructs, including shared governance, nursing empowerment, control over nursing practice, and clinical autonomy"[3] (p. 122).

In keeping with the realization that threats to patient safety result from complex causes,[2] *Keeping Patients Safe* identified a multifactor approach to creating favorable work environments for nurses. Many of the strategies and goals described in the report correspond to the descriptions of magnet environments initially provided by McClure and colleagues[8] and currently elaborated for contemporary settings in the appraisal criteria for Magnet recognition.[11] For example, of the 27 goals the report listed as "Necessary Patient Safeguards in the Work Environment of Nurses"[3] (p. 16–17), 20 are addressed by the current evidence requirements for Magnet recognition.[11] The multidimensionality of the magnet framework reflects the highly complex, variable, multilevel, and multifaceted nature of nursing practice environments, but it also poses measurement challenges for researchers interested in studying the influence of magnet environments on outcomes.

Research Implications

Mick and Mark[5] have argued that while nursing research has contributed substantially to the knowledge about how internal structures and work processes relate to patient safety and quality outcomes in health care organizations, there is a compelling need to improve the methodological sophistication of the research and to expand the theoretical frameworks that guide it. Many of the suggestions they make for doing so are echoed in the research implications generated by this review. Greater attention needs to be paid to addressing sampling bias issues, improving critical measures, collecting objective data from sources other than nurse self-reports, and designing multilevel and longitudinal studies. As Table 1 reveals, the conceptual definition of a magnet environment encompasses many fields and disciplines from which theoretical insights may be borrowed and tested.

Taking better account of multiple organizational perspectives and hierarchical levels in the research will build knowledge about how the relationships between magnet characteristics and patient outcomes differ by role or practice location. For example, Laschinger, Almost, and Tuer-Hodes[41] found that magnet characteristics and empowerment related differently to each other and to job satisfaction for nurse practitioners than for staff nurses, and Friese's[46] results differed significantly on some magnet characteristics only for oncology nurses. Distinguishing unit locations may be particularly important. Mick and Mark have claimed that "it is the exploration of work structures and processes at the nursing unit level that is contributing to the lion's share of advancing knowledge about what does and does not have an impact on patient and organizational outcomes"[5] (p. 319).

Finally, while the NWI-R and later versions of the NWI have yielded a wealth of useful data, questions have also been raised as to the measurement adequacy of at least three of them.[47] Variable, unpredictable, contextually sensitive, and multifaceted,[25, 47] "the nursing practice environment is a complex construct to conceptualize and measure"[25] (p. 177). Yet developing, improving, and refining measures to reliably capture all of the factors of a magnet environment may be the most important next step.

Conclusion

The magnet concept defines a framework for facilitating the professional practice of nursing that has demonstrated effectiveness in attracting nurses and shows promise for contributing to optimal patient outcomes. There is a compelling need to improve the measures and methods used to research magnet characteristics and environments before the links that connect organizational context to nurse and patient outcomes can be sufficiently understood.

Search Strategy

A series of searches was carried out in October 2006 using the National Library of Medicine's PubMed database and the Cumulative Index of Nursing and Allied Health Literature (CINAHL) database. Several search terms and phrases including the word "magnet" or "magnetism" were tested in both cases. The most effective were "magnet[Title/abstract] and nursing[Title/abstract]" in PubMed and "magnet" in [TI Title] OR "magnet" in [AB Abstract or Author-Supplied Abstract] with advanced search in CINAHL. Supplementary backup searches were also performed substituting the word "magnetism" for "magnet" in CINAHL and the word "hospitals" for "nursing" in PubMed. The PubMed searches yielded 134 unique titles to review. Cross-checking the CINAHL results against the PubMed lists yielded two additional titles.

The overwhelming majority of articles identified by these searches fell into editorial, interpretive, or narrative categories—especially narratives describing how an individual organization prepared for or achieved ANCC Magnet recognition. If an abstract was ambiguous about whether the article reported results from a primary or secondary data analysis, the article itself was retrieved in order to make a determination. The article by Laschinger and Leiter[44] was previously known and not identified by the search strategy.

Evidence Table 1.[‡] Studies With Reputational Magnet Hospitals

Source	Environment Issue/Attribute Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Key Finding(s)
Kramer and Hafner 1989[19] Kramer and Schmalenberg 1987[48-51] Kramer, Schmalenberg, and Hafner 1988[52]	Nursing Work Index (NWI), 65 items designed to measure work values representing the findings from the 1983 original magnet study Other measures: • culture of excellence, 8 items suggested by Peters and Waterman[53] • locus of control • autonomy-patient advocacy • self-concept/self-esteem • role behavior scales	Cross-sectional studies	Cross-sectional survey, interviews, observations, document review Outcomes: from NWI: • job satisfaction • perceived productivity of quality patient care	1985–86 data collection 16 reputational magnets proportionate by region, 8 comparison county, community, and medical center hospitals in Virginia Survey n = 2,236 staff nurses, 1,634 in reputational magnet and 702 in comparison group; interview n = 800+ staff nurses, 632 nurse managers/executives	Staff nurses in magnet hospitals had significantly higher scores on • job satisfaction • perceived productivity of quality care Causal model testing to predict outcomes with 31 variables produced no findings.
Kramer and Schmalenberg 1991[54, 55]	Magnet factors: • perceived adequacy of staffing • image of nurses • how nursing is valued (how important, how active, how powerful) Other measures: • culture of excellence, 39 items to represent 7 attributes	Cross-sectional studies	Cross-sectional survey Outcome: Overall job satisfaction: • organizational structure (7 items) • professional practice (5 items) • management style (5 items) • quality of leadership (4 items) • professional development (3 items)	1989–90 data collection Survey n = 939 nurses in 14 reputational magnets (from 1985–86 sample), 808 nurses in comparison "panel" sampled from 5,000 *Nursing89* subscribers	Nurses in magnet hospitals had significantly more positive scores on • job satisfaction Nurses in magnet hospitals reported higher levels for • a culture of excellence • perceived adequacy of staffing • image of nursing • value of nursing

[‡] To illustrate how this research has developed and expanded over time, the evidence tables in this chapter are arranged in chronological order by the data collection date for each study, when available, or publication date.

Source	Environment Issue/Attribute Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Key Finding(s)
Aiken, Smith, and Lake 1994[28]	Status as a reputational magnet hospital	Cross-sectional studies	Cross-sectional; multivariate matched sampling procedure to control for relevant hospital characteristics (e.g., teaching status, technology availability, board certification of physicians, emergency room presence), adjusting for differences in predicted mortality for Medicare patients Outcome: Medicare mortality rate (within 30 days of admission)	1988 Medicare data 39 reputational magnet hospitals (census of all available or eligible), 195 control hospitals (5 matches for each magnet) from all nonmagnet U.S. hospitals with >100 Medicare discharges	Magnet hospitals had a 4.5% lower mortality rate (95% CI (confidence interval) = 0.9 to 9.4 fewer deaths per 1,000 discharges).
Aiken and Sloane 1997[29, 30] Aiken, Sochalski, and Lake 1997[31] Aiken, Sloane and Lake 1997[32] Aiken, Lake, Sochalski 1997[33] Aiken, Sloane, and Klocinski 1997[34] Aiken, Sloane, Lake 1999[35]	Nursing Work Index-Revised (NWI-R), 57 items, with subscales for • nurse autonomy (5 items) • control over nursing practice setting (7 items) • nurse relations with physicians (2 items) • organizational support (10 items from previous 3 subscales)	Cross-sectional studies	Cross-sectional survey, needlestick reports for a 30-day period, patient interviews, patient chart abstraction Outcomes: Nurse — • job burnout • safety (needlesticks) Patient — • satisfaction with care (multi-item scale and a single-item overall rating) • mortality 30 days from admission	1991 data collection 40 medical units, 2 in each of 20 urban hospitals located throughout U.S., 10 hospitals with dedicated AIDS units, 10 matched comparable hospitals without AIDS units (scattered-bed), 2 comparison hospitals were reputational magnets, 1 more was considered magnet based on researcher knowledge of facility Survey n = 820 RNs from all employed on units ≥16 hours per week (86% response rate); interview n = 594 patients; chart outcomes for 1,205 AIDS patients	Patients with AIDS in magnet scattered-bed units had lower odds of dying than in any other setting; higher nurse-to-patient ratios were determined to be the major explanatory factor. Patient satisfaction was highest in magnet hospitals; control over nursing practice setting was determined to be the single most important explanatory factor. Nurses in magnet hospitals sustained significantly fewer needlestick injuries. Nurses in magnet hospitals and dedicated AIDS units had significantly more positive scores for emotional exhaustion, autonomy, nurse control over resources, and nurse-physician relations.

Source	Environment Issue/Attribute Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Key Finding(s)
Scott, Sochalski, and Aiken 1999[23]		Literature review, narrative	Search method unstated.		Summarizes findings cited in this table and synthesizes insights from these and additional magnet studies to illuminate the leadership characteristics and professional practice attributes found within reputational magnet hospitals.

Evidence Table 2. Studies Comparing Health Care Organizations With and Without ANCC Magnet Recognition

Source	Environment Issue/Attribute Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Key Finding(s)
Aiken, Havens, and Sloane 2000[56] Friese 2005[46]	NWI-R single items and subscales, Aiken et al.: • nurses' autonomy • nurses' control over the practice setting • nurse relations with physicians Practice Environment Scale/Nursing Work Index (PES/NWI), Friese: • nurse participation in hospital affairs (9 items) • nursing foundations for quality of care (10 items) • nurse manager ability, leadership, and support of nurses (5 items) • staffing and resource adequacy (4 items) • collegial nurse-physician relations (3 items) Other measures: • job characteristics (hours worked, workload, supervisory responsibilities, nonnursing duties)	Cross-sectional studies	Cross-sectional, comparative multisite observational Outcomes: • perceived quality of care • job satisfaction • intent to leave • burnout (Maslach Burnout Inventory)	1998 data collection 7 ANCC Magnets (census as of study date), 13 reputational magnets (12 from Kramer et al.'s 1985–86 sample) with 2 additional teaching hospitals included in Friese's secondary analysis Aiken et al. survey n = 2,045 RNs in medical or surgical units, 1,064 in ANCC Magnet and 981 in reputational magnet group Friese analysis n = 1,956 of which 305 = oncology nurses (155 in ANCC Magnet and 150 in comparison group) and 1,651 = nononcology nurses (755 in ANCC Magnet and 896 in comparison group)	Nurses in ANCC Magnets were significantly more likely to report • higher ratings of care quality • higher job satisfaction • less frequently feeling burned out, emotionally drained, and frustrated by their job Oncology nurses in ANCC Magnets reported nearly half the exhaustion levels of oncology nurses in the 13 reputational magnets and 2 teaching hospitals. In both analyses, most NWI-related subscale scores were significantly higher for nurses in the ANCC Magnet group; exceptions were that scores for nurse-physician relations and nurse manager ability, leadership, and support differed significantly, favoring ANCC Magnets only for oncology nurses.
Havens 2001[36]	NWI-R subscale: • organizational support Other measures: • degree restructuring implemented, 9 items	Cross-sectional studies	Cross-sectional survey; comparative Outcomes: • difficulty recruiting staff RNs (1 item) • quality of patient care (global ratings and reports of complaints)	1999–2000 data collection 21 ANCC Magnets, 35 reputational magnet hospitals (census samples of both groups) Survey n = 43 chief nurse executives, 19 in ANCC Magnet and 24 in reputational magnet group	Chief nurse executives in the ANCC Magnet group reported less difficulty recruiting RNs and were significantly more likely to report • high quality patient care • fewer patient/family complaints • organizational support for autonomy, control over practice, and nurse-physician collaboration

Source	Environment Issue/Attribute Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Key Finding(s)
Upenieks 2002, 2003[57, 58]	Power and empowerment – Conditions of Work Effectiveness Questionnaire-II (CWEQ-II) 20 items: • 2 global items • 4 subscales to measure perceived access to opportunity, information, support, and resources	Cross-sectional studies	Cross-sectional survey Outcome: Job satisfaction - NWI-R subscales: • autonomy • nurse control over practice setting • relations between nurses and physicians Plus 3 researcher-designed subscales: • self-governance (7 items) • organizational structure (6 items) • education opportunities (6 items)	Convenience sample of 2 ANCC Magnets, 2 comparable comparison hospitals Survey n = 305 medical-surgical nurses	Nurses in the ANCC Magnet group had significantly higher scores on • job satisfaction • power and empowerment
Brady-Schwartz 2005[59]	Status as ANCC-recognized Magnet	Cross-sectional studies	Cross-sectional survey; quantitative, descriptive correlational Outcome: • overall job satisfaction (total McCloskey Mueller Satisfaction Scale score; subscales: extrinsic rewards, scheduling, family/ work balance, coworkers, interaction, professional opportunities, praise and recognition, control/ responsibility) • intention to leave (Anticipated Turnover Scale)	3 ANCC Magnets, 3 comparison hospitals Survey n = 470 RNs, 173 in ANCC Magnet and 297 in comparison group	Nurses in ANCC Magnet group had significantly higher overall job satisfaction, including significant subscale differences for professional opportunities, control/responsibility, and extrinsic rewards. Higher overall job satisfaction correlated with stronger perceptions of voluntarily remaining in current position.

Evidence Table 3. Studies of Magnet Characteristics

Source	Environment Issue/Attribute Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Key Finding(s)
Laschinger, Shamian, and Thomson 2001[40]	Magnet characteristics—NWI-R subscales: • nurse autonomy • nurse control over practice setting • nurses' relations with physicians Other measures: • trust and confidence in management — Interpersonal Trust at Work Scale • burnout—The Human Services Survey, 3 components (emotional exhaustion, depersonalization, decreased personal accomplishments)	Cross-sectional studies	Cross-sectional survey Outcomes: • job satisfaction • perceived quality of care • perceived quality of unit	Ontario, Canada Survey n = 3,016 staff nurses from medical-surgical settings (subsample from a stratified random sample) in 135 hospitals	Model testing with these variables explained 39–40% of the variance with either job satisfaction or nurse-assessed quality as the outcome. Magnet characteristics influenced job satisfaction and perceptions of care quality with trust in management and emotional exhaustion as important mediators. Higher levels of magnet characteristics were associated with higher levels of trust in management and lower levels of burnout.
Thomas-Hawkins, Denno, Currier 2003[37]	Magnet characteristics – PES/NWI subscales (some items adapted to reflect setting): • nurse participation in hospital affairs • nursing foundations for quality of care • nurse manager ability, leadership, and support of nurses • staffing and resource adequacy • collegial nurse-physician relations	Cross-sectional studies	Cross-sectional survey Outcome: intentions to leave job in next year (1 item)	United States 1,000 staff nurses working in freestanding hemodialysis facilities (random sample from American Nephrology Nurses' Association members)	Nurses who intended to leave their jobs reported significantly lower levels of magnet characteristics represented by all of the PES/NWI subscales except for collegial relations between nurses and physicians.

Source	Environment Issue/Attribute Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Key Finding(s)
Laschinger, Almost, and Tuer-Hodes 2003[41]	Magnet characteristics—NWI-R subscales: • nurse autonomy • nurse control over practice setting • nurses' relations with physicians Other measures: Empowerment • CWEQ-II, 4 subscales: access to opportunity, information, support, and resources • Job Activities Scale-II, 3 items: perceptions of formal power • Organizational Relationships Scale-II, 4 items: perceptions of informal power	Cross-sectional studies	Cross-sectional survey data from 3 independent studies; predictive, nonexperimental Outcomes: • Global Job Satisfaction Questionnaire (Studies 1, 3) • Nurse Job Satisfaction Questionnaire (Study 2)	Ontario, Canada Study 1: survey n = 233 randomly selected staff nurses from urban tertiary care hospitals throughout Ontario Study 2: survey n = 263 randomly selected staff nurses from 3 rural community hospitals in a western Ontario network of 8 Study 3: survey n = 55 acute care nurse practitioners from urban tertiary care hospitals throughout Ontario	For staff nurses, empowerment and magnet characteristics were significant independent predictors of job satisfaction; for nurse practitioners, the combination of empowerment and magnet characteristics significantly predicted job satisfaction. Average ratings on empowerment and magnet characteristics were moderate for staff nurses and higher for nurse practitioners. Total scores on empowerment and magnet characteristics were strongly correlated for all three samples; the most strongly related empowerment features were access to resources for staff nurses and access to information for nurse practitioners. All empowerment dimensions related significantly to perceptions of autonomy; access to resources related most strongly to control over practice environment; and informal power related most strongly to nurse-physician relationships.

Source	Environment Issue/Attribute Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Key Finding(s)
Tigert and Laschinger 2004[42]	Magnet characteristics – NWI-R subscales: • nurse autonomy • nurse control over practice setting • nurses' relations with physicians Other measures: Empowerment • CWEQ-II, 4 subscales: access to opportunity, information, support, and resources • Job Activities Scale-II, 3 items: perceptions of formal power • Organizational Relationships Scale-II, 4 items: perceptions of informal power	Cross-sectional studies	Cross-sectional, correlational survey design Outcomes: mental health • State of Mind subscale (5 items) from the Pressure Management Indicator • Emotional Exhaustion subscale (6 items) from the Maslach Burnout Inventory	Ontario, Canada; Data collected 2001 Survey n = 75 critical care nurses, a subsample of 239 nurses working in teaching hospitals (randomly selected from College of Nurses of Ontario)	The combined effects of empowerment and magnet characteristics explained 19% of the variance in burnout and 12% of the variance in state of mind. Empowerment related significantly and positively to perceptions of magnet characteristics; however, only empowerment was a significant independent predictor of emotional exhaustion, and only magnet characteristics were a significant predictor of state of mind.
Rondeau and Wagar 2006[39]	Magnet similarity represented by employer-of-choice strength (7 items, e.g., how establishment views, values, treats its nursing personnel; how staff and community view its treatment of nurses) Other magnet characteristics measures: • high involvement (high commitment) work practices (10 items) • progressive, participatory decisionmaking workplace culture (3 items) • training support (10 items)	Cross-sectional studies	Cross-sectional survey Outcomes: • resident satisfaction (3 items) • nurse turnover and vacancy rates • nurse satisfaction (3 items)	Canada Data collected 2003 Survey n = 114 nurse executives sampled from all long-term care organizations (nursing homes) in western Canada with ≥35 beds	Higher scores on magnet employer-of-choice strength were significantly associated with • higher resident satisfaction • lower turnover and vacancy rates • higher nurse satisfaction • high involvement work practices • progressive decisionmaking • nurse training opportunities and assistance

Source	Environment Issue/Attribute Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Key Finding(s)
Smith, Tallman, and Kelly 2006[38]	Magnet characteristics categories: • supportive management (5 items) • professional autonomy and responsibility (4 items) • nurse-physician working relationship (2 items) • nurse-manager working relationship (2 items)	Cross-sectional studies	Cross-sectional survey, interviews Outcome: job satisfaction (3 items from Job Diagnostic Survey)	Canada Survey n = 123 nurses in diverse clinical areas from 13 rural northwestern hospitals recruited via circulating letter/flyer	All magnet characteristics items were significantly but modestly correlated with job satisfaction except for the 2 items measuring nurse-physician relationship and 1 of the 4 autonomy items.
Armstrong and Laschinger 2006[43]	Magnet characteristics – PES-NWI subscales: • nurse participation in hospital affairs • nursing foundations for quality of care • nurse manager ability, leadership, and support of nurses • staffing and resource adequacy • collegial nurse-physician relations Other measures: Structural empowerment – CWEQ-II, 2 global items and 6 components: access to opportunity, information, support, resources, formal power, and informal power	Cross-sectional studies	Cross-sectional survey; exploratory; predictive, nonexperimental Outcome measure*:* Safety Climate Survey	Canada 40 staff nurses working in a small community hospital in central Canada	The combination of structural empowerment and magnet characteristics was a significant predictor of perceptions of patient safety climate. Overall empowerment significantly positively related to all magnet characteristics, with total empowerment most strongly related to use of a nursing model of care and good nursing leadership on the unit.

Source	Environment Issue/Attribute Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Key Finding(s)
Laschinger and Leiter 2006[44]	Magnet characteristics – PES-NWI subscales: • nurse participation in hospital affairs • nursing foundations for quality of care • nurse manager ability, leadership, and support of nurses • staffing and resource adequacy • collegial nurse-physician relations Other measures: Maslach Burnout Inventory–Human Service Scale, 3 subscales: • emotional exhaustion (9 items) • depersonalization (5 items) • personal accomplishment (8 items)	Cross-sectional studies	Cross-sectional survey Outcome measure: adverse events (nurse-reported frequency of occurrence of negative patient events in past year: • falls • nosocomial infections • medication errors • patient complaints)	Canada Survey n = 8,597 nurses (4,606 from a stratified random sample of licensing registry lists in Ontario and 3,991 from a census sample of acute care nurses in Alberta), a subset of participants in the *International Survey of Hospital Staffing and Organization of Patient Outcomes* conducted in 5 countries	With all measured components included in the model, structural equation modeling analysis showed direct and indirect effects of all environment factors on patient safety outcomes partially mediated by burnout. Both staffing adequacy and use of a nursing model of care directly affected patient safety outcomes. Staffing adequacy directly affected emotional exhaustion, and use of a nursing care model directly affected personal accomplishment. Nursing leadership played a fundamental role in relation to policy involvement, staffing adequacy, RN-MD relationships, and support for a nursing (vs. medical) model of care.

Chapter 47. Patient Safety and Health Information Technology: Role of the Electronic Health Record

Nancy Staggers, Charlene Weir, and Shobha Phansalkar

Background

An electronic health record (EHR) is a real-time, point-of-care, patient-centric information resource for clinicians[1] that represents a major domain of health information technology (HIT). More recently, an EHR has been defined as "a longitudinal electronic record of patient health information, produced by encounters in one or more care settings."[2] It includes patient information such as a problem list, orders, medications, vital signs, past medical history, notes, laboratory results, and radiology reports, among other things. The EHR generates a complete record of a clinical patient encounter or episode of care and underpins care-related activities such as decisionmaking, quality management, and clinical reporting. Some distinguish between the terms EHR and electronic medical record (EMR), with EMR focusing on ambulatory care systems. However, in practice, the terms are interchangeable. In this chapter, the term EHR relates to computerized patient health records stored within and among institutions.

This chapter first presents a review of the literature about orders management—also called computerized provider (or physician or practitioner) order entry. The next section addresses barcoding, an area closely related to orders management. Third, the chapter synthesizes the literature about the impact of orders-related clinical decision-support systems on nursing practice.

Ordering and associated functions in EHRs is a salient focus for several reasons. First, EHRs are a current centerpiece in contemporary health informatics. A nationwide emphasis exists to install these clinical systems over the next decade, largely because of a 2004 statement by President Bush that most Americans would have an EHR in 10 years.[3] Second, the benefits of EHRs are becoming more well known. For instance, a 2006 systematic review of the literature concluded that overall use of HIT increased adherence to guidelines for care, increased surveillance and monitoring of patients, yet had mixed effects for medication errors and time utilization.[4] Third, nurses in the United States are now or will be using EHRs in the near future. Understanding orders management through the EHR is imperative because the effect on nursing practice promises to be great.

Orders management is an interdisciplinary activity crossing organizational boundaries; therefore, the literature review for this topic was broad, including all care settings and providers other than nurses. The ordering process inherently involves nurses, especially in acute care settings, as recipients of medical orders and initiators of nursing orders. However, this relationship may not be acknowledged in the design of empirical studies.

The Institute of Medicine (IOM) recommended computerized orders and decision-support applications as main HIT mechanisms for increasing patient safety in the future.[5] Existing research about the nursing impact of orders, barcoding, and decision support within EHRs needs to be examined and then expanded in near-future research. This chapter reviews EHR ordering and the associated, more researched areas, and suggests EHR areas for future research. The authors chose to concentrate this section on information-intense versus technology-focused impacts.

Orders Management in EHRs

Orders for patients are the connective tissue in any EHR. They are necessarily complex, integrating patient-specific interventions across departments. Orders are written by members of the health care team, primarily physicians and nurses. Orders management crosses customary boundaries, and it is just as likely to integrate computerized applications and functions as it is to disintegrate traditions. For example, information once the purview of one department becomes shared across many disciplines. Who owns data, such as a patient's allergies or weight, becomes a topic of vigorous discussion. New work processes are crafted. Because of the complexity of orders management, computerized provider (physician) order entry (CPOE) has been a topic of research.

The genesis for the recent increase in publications in this area was the IOM's *To Err Is Human: Building a Safer Health System* report on errors in medicine. The IOM recommended information technology as a major mechanism to reduce errors.[6] Likewise, the IOM's *Crossing the Quality Chasm: A New Health System for the 21st Century*[5] had a profound message for the information technology community and recommended, among other things, the installation of CPOE and decision support to improve patient safety. In its most recent publication, *Preventing Medication Errors: Quality Chasm Series*,[7] the IOM recommends that clinicians make greater use of information technology for prescribing and dispensing medications. Thus, it is imperative to understand the practice impacts of CPOE and its related functions of barcoding and clinical decision support.

Research Evidence—CPOE

The CPOE studies were analyzed using a quality instrument specific to informatics called QUASII.[8] This instrument assesses informatics study qualities across construct, internal, external, and statistical conclusion validity areas. The CPOE studies may be divided by QUASII scores into two tiers: Tier 1 (with QUASII scores at or above 61) and Tier 2 (with scores at or below 54). No scores between 54 and 61 were observed, and studies with QUASII scores below 30 were excluded from consideration. Tier 1 includes studies that have more reported rigor in study design and controls with fewer possible threats to construct, internal, external, and statistical conclusion validity. Tier 2 includes studies with less reported rigor and increased possible threats to validity. Studies with less rigor are included here because they are often widely cited and have even dominated the literature.

The studies were sorted by dependent variables into medication errors, efficiency impacts (time and length of stay), and quality care. The studies are summarized in Tables 1 and 2. In Table 3 a sample of qualitative studies is listed to show the contrast in the types of variables examined in these studies compared to quantitative CPOE studies.

Varying Definitions of CPOE

The term CPOE is used imprecisely. Researchers have used the same term to mean orders with these differing capabilities:

- Electronic orders, including electronic transmission to appropriate ancillary departments[9]
- Electronic orders without an interface to one or more ancillary departments, requiring either order transcription to paper or order entry by others into systems with different functional capabilities[10–12]
- Orders including order sets[13]
- Orders with no order sets[14]
- Orders without capability for complex medications, such as intravenous (IV) orders, total parenteral nutrition (TPN), or complex functions such as oncology protocols
- Orders with integrated alerts, reminders, and decision support to assure order completeness and accuracy, especially for medications[15]
- Orders with no checks, alerts, reminders, or decision-support capabilities[16, 17]
- Orders without a pharmacy interface or any decision-support capabilities[18]
- Orders with or without associated clinical documentation
- Orders with full capabilities, complete decision support, documentation (especially an electronic medication administration record, or eMAR), and complete support for all orders, including complex protocols
- No description of existing capabilities

Researchers report conclusions as if the CPOE capabilities were equivalent, when these varying instantiations, in effect, amount to very different strengths of CPOE as an independent variable. In particular, the lack of appropriate departmental interfaces and integration in one study, such as a pharmacy interface in a study tracking medication error rates, is very much in contrast to a study examining medication errors using a system with an existing pharmacy interface. CPOE requiring order transcription of any kind—to a medication administration record (MAR) or foreign pharmacy system—necessarily increases errors, and these very transcription errors are typically included in the count of overall medication errors rates.

The same notion can be applied to the presence or absence of computerized decision support in its most basic form. Basic decision support can allow checking for order completeness and accuracy. If medications errors are being examined, a CPOE study of an application with no basic order checking is not equivalent to studying one with any decision support integrated into CPOE. More advanced decision support for drug-drug or drug-allergy interactions, and checks for other interactions or dosing accuracy, add yet another level to CPOE applications. Researchers are led to conflicting conclusions if this variability of functions is not taken into consideration. At best, the broad scope of CPOE systems (and lack of specific descriptions in the studies of the features of systems) leads to confusion in the interpretation of results. These differing capabilities are noted when reported by researchers.

CPOE Impacts and Variables Studied: Quantitative Studies

Sites and CPOE applications. CPOE evaluations have been concentrated at large academic medical centers, particularly at Brigham & Women's Hospital in Boston and the Ohio State University medical center in Columbus. The unique, "homegrown" systems at Brigham, Vanderbilt University in Nashville, and the Regenstrief Institute at the Indiana University School of Medicine (Indianapolis) populated earlier literature—although, more recently, vendor systems have been studied. Studies of vendor systems include the Siemens, Eclipsys, General Electric (GE), and Cerner CPOE applications, in descending order of frequency.

Medication errors and adverse drug events. The relationship of CPOE to medication errors, adverse drug events (ADEs), and subsets of those categories is reported in 12 studies (see Table 1). Of these, three systematic reviews addressed the effect of CPOE on medication errors and/or ADEs. The systematic reviews concluded that CPOE (and isolated clinical decision-support systems) can reduce medication errors.[19–21] However, since these reviews were published, researchers have published conflicting conclusions about the topic.[22, 23]

Studies on inpatient units in five different settings reported significant decreases in medication errors after CPOE implementation.[11] More specifically, all medication errors and non-missed-dose errors decreased in two sites,[10, 18] and potential and nonintercepted ADEs significantly decreased with the homegrown application at Brigham and Women's Hospital.[15] Shulman and colleagues[11] reported a lower proportion of medication errors with CPOE, and King and colleagues[18] reported a 40 percent reduction in errors. Transcription errors were reduced or entirely eliminated.[17, 20, 24]

In contrast, two researchers found no differences in rates for ADEs with CPOE.[16, 18] In the outpatient arena, no differences were found in total errors, ADEs, or rules violations,[16] although the system in this one setting lacked any order checking for completeness or accuracy and lacked basic decision support. The differences in ADE detection may be due to underpowered studies[19] and also to the differences in functionality discussed earlier and the differing definitions for ADEs. Moreover, studies used varying scales to rate errors and ADEs ranging from self-developed categorical scales of minor/major/serious to the American System of Health-Systems Pharmacists classification.

Increases in medication error rates after implementation of CPOE have also been reported. In 2005, Spencer and colleagues[12] reported an increase in one type of error (i.e., pharmacy processing) on two inpatient medicine units, while other medication errors were unchanged from pre-CPOE implementation. Unfortunately, this site had no system interface to pharmacy, and the researchers acknowledge that the increased error rate may have been related to the need to transcribe orders in the pharmacy. Without the interface or a method to ensure orders were complete and accurate, the only seeming advantage of CPOE at this site was the speed of communication to the pharmacy for transcription. Researchers in Portugal[17] concluded that CPOE eliminated their transcription errors, but other errors continued—such as right class/wrong drug, and other errors likely solvable by the basic decision support they lacked (e.g., unclear orders, missing frequency, incorrect dosages, drug interactions, and duplicative therapies).

Life-threatening errors and serious ADEs were higher in the early years at Brigham and Women's, when no decision support was installed. For example, a screen for potassium orders allowed new, potentially very serious errors to occur.[15] These potential errors were intercepted by either nursing or pharmacy before the drugs were administered. Likewise, CPOE at one institution in London created three major errors that could have resulted in harm or death of a patient had they not been intercepted.[11] Again, this site had no decision support in place to prevent a reported error of 7 mg/kg of morphine being ordered instead of 7 mg, a potential overdose of 70 times the normal range. This site also saw an increase in minor, nonintercepted errors with CPOE, from 43 for handwritten orders to 93 with CPOE. That said, with all errors combined, the overall rate of errors was lower with CPOE. However, the details behind that overall rate show increases in potential major errors if decision-support capabilities are not available. This statement is in contrast to the conclusion by Chaudhry and colleagues,[4] perhaps

because his literature review concentrated on the years before these newer studies were published.

In all studies, the researchers did not include external forces, contextual variables, or organizational forces that may have contributed to changes in medication errors. For example, several studies extended over multiple years, through changes in chief information officers, national changes about patient safety, and increased emphasis on medication errors. Especially with the more recent studies, changes in error rates could have been due to these factors as well as information technology implementations.

The variability in conclusions may also be explained by the differences in available functions, particularly the lack of pharmacy interfaces and basic decision support. Therefore, the previous researchers' conclusions about CPOE decreasing medication errors must be modified: CPOE can reduce medication errors if appropriate functions are available to prevent new errors. Transcription errors can be eliminated with electronic communication and interfaces together with structured order entry. CPOE can substantially reduce overall (and many serious) medication errors if (1) electronic communication and automatic order interfaces are in place, (2) basic order checks for completeness are present, and (3) decision support at its most basic level is available—checking for drug–drug and drug–allergy interactions and for dosing ranges.

Clinical efficiency measures—time and length of stay. Eleven studies examined the effects of CPOE on efficiency measures of time and/or hospital length of stay (LOS) (see Table 2). CPOE offers clear benefits in processing efficiency for orders management and availability of electronic laboratory and radiology results. CPOE reduced the time from order entry to results availability for laboratory and radiology orders in four sites.[13, 25–27] Another clear benefit is that CPOE decreased the time from pharmacy ordering to medication administration time.[13, 25, 26, 28]

Likely because of timely availability of results and faster order processing, patients' hospital LOS was shorter.[26, 29] One systematic review concluded that one of the benefits of CPOE is reduced LOS.[20] Other clinical efficiencies are related to use of CPOE. For example, Ohio State University hospital saw a significant improvement in the number of patients whose abnormal potassium levels were normalized within 24 hours.[24]

On the other hand, order entry itself takes longer using CPOE than with paper. A systematic review of the impact of computers on time efficiency concluded that the use of central desktops for CPOE was not efficient, consuming 98.1 percent to 328.6 percent more time per working shift.[30] CPOE took 2.2 minutes longer per patient, but after duplicative tasks were removed, the extra time per patient was shortened to an average of 0.43 min.[31] At Brigham and Women's, CPOE took 44–73 minutes longer per day, especially for entering one-time orders.[32] However, this study was done before order sets were widely used. At Regenstrief, an early CPOE application took interns 33 minutes longer during a 10-hour period.[29] Interns entered orders on microcomputers and then printed them, using them as traditional paper documents afterwards. Likewise, a more recent study at Massachusetts General Hospital[33] demonstrated an increase in medical interns' ordering time, among other time-related variables. Prior to CPOE, interns spent 2.1 percent of their time ordering; after CPOE, they spent 9 percent of their time ordering. Two of these studies were published about early CPOE applications in the 1990s, and all four measured homegrown systems. None of the studies examined time for order sets or vendor-based solutions. Of note, CPOE may take providers somewhat longer to enter orders, but efficiencies are obtained later in the orders management cycle—in nursing, ancillary departments' order processing, and in reduced time for results availability and administrative tasks.[33]

Quality care variables. Three studies examined variables not reported by others, namely the quality of documentation and one particular patient outcome (see Table 3). In one study, a significant increase occurred in the number of documented consents for do-not-resuscitate orders.[34] In another study, researchers conducted a randomized controlled trial to examine the effect of medical students' rotations in a CPOE site versus traditional sites on the quality of orders written on a fictitious patient[50] They found that the quality scores for orders during an academic examination were significantly higher for students using CPOE.

A third study produced alarming results that conflict with other, more promising benefits of CPOE. A recent article reported an increased mortality coincident to a CPOE implementation at a pediatric hospital.[14] The researchers reported a direct association between CPOE and increased mortality among pediatric patients admitted through interfacility transport. However, this facility experienced substantial workflow changes in conjunction with CPOE installation. For example, no preregistration was available, delaying order entry until full registration was completed after the patient physically arrived. This process change delayed therapies and diagnostic testing.

Important human–computer interaction issues impacted treatment times. The new ordering system required substantially more order entry time during a critical period of patient care, and the wireless bandwidth capacity was often exceeded during peak periods. Crucial aspects of work organization changed with all medications being centralized, meaning that nurses were unable to access medications locally and the pharmacy could not process medication orders until they had been activated. Sadly, when the pharmacy accessed CPOE to process an order, other clinicians were locked out of the application. The researchers also reported a decrease in face-to-face communications that provided relevant information for patient care management post-CPOE.

In this study, CPOE was likely a proxy variable for significant, but untoward, process changes in that particular institution. The lesson from this article is that work processes must be thoroughly examined before CPOE "goes live," and projected, substantial treatment delays are an excellent reason to delay going live until work design is safe for patient care. For critically ill patients in emergency departments (EDs), intensive care units (ICUs), and pediatric units, new processes cannot delay treatment. Workflow and usability analyses can preclude the kinds of impacts seen in this article.

CPOE and a Sampling of Qualitative Studies

A sampling of qualitative studies shows a contrast in variables addressed by these researchers versus the researchers of quantitative studies (see Table 4). While not usual to include as evidence, these qualitative studies provide insights for future studies and as well as interesting aspects of CPOE. Koppel and colleagues[23] interviewed 261 clinicians, including nurses, about CPOE and its perceived role in medication errors. Clinicians reported new errors with CPOE because of fragmented data and processes, lack of integration among systems, and human–computer interaction issues. For example, obtaining a summary view of all the medications a patient was receiving was difficult because providers had to scroll through multiple screens to view medications. In another example, the fit between computer and workflow processes was a problem because nurses typically charted medications at the end of a shift using global commands instead of charting at the time medications were actually given. And in another study of CPOE, Sittig and colleagues[35] found that negative emotions about CPOE prevailed for both nurses and physicians.

One study concluded that communication was broadly affected by CPOE, from interpersonal to intrainstitutional.[36] Significant impacts on team and physician-nurse communication occurred with CPOE. Nurses felt that CPOE degraded communication among the dyad of doctor and nurse, and thought that it took more effort post-CPOE to get residents to come see patients needing attention. A multisite study of the Veterans Affairs' (VA's) early CPOE application showed that nurses thought the quality of care had improved with CPOE, but the control over their jobs and roles decreased.[37]

Quantitative studies examined more easily definable and, perhaps, more simplistic variables, such as measurable medication errors and ADEs, timed processes of order entry to results posted, and mortality. The qualitative studies, on the other hand, examined richer aspects of processes and interdependent variables, such as types of errors created by CPOE, interdependent communication patterns, and perceptions of role changes. With the complexity created by orders management, both methods are needed in the future research.

Evidence-Based Practice Implications

Silence about nursing impacts cuts across the CPOE quantitative studies. Only one quantitative study mentions nursing impacts with CPOE: changes associated with CPOE resulted in medications not being available on patient units in a timely manner, resulting in missed doses.[10] Bates and colleagues acknowledged the increase in missed doses but deemed these minor, and the missed-dose errors were excluded from summary findings of the study.

Impacts of CPOE on nursing were examined in the sample of qualitative studies. The sample of qualitative studies indicated that (1) nurses at three sites in one study had negative emotional perceptions of CPOE, (2) interpersonal communication between nurses and physicians was disrupted by CPOE, and (3) nurses perceived that the quality of care improved with CPOE.

Even with few studies specifically addressing nursing issues, implications are evident. Nurses can expect improved speed for results availability with CPOE. The elapsed time from writing an order to available results is a clear and expected benefit. Although not surprising, this is a benefit to the care team and the patient. Obviously, legibility of orders and improved availability of information occurs as well, by virtue of orders being typed and available electronically. Nurses can expect more efficient treatment related to results availability and decreases in hospital LOS for patients post-CPOE.

Whether medication errors and ADEs are impacted by CPOE depends upon available application functionality. Thus, all nurses will want to be aware of available functional and technical support and their implications. If, for example, the CPOE system has no pharmacy interface or integrated decision-support capabilities, aggressive monitoring systems will need to be in place to intercept medication errors ranging from transcription errors and interaction issues (drug-drug, drug-allergy interactions) to dosage issues (dose range, right class/wrong drug, frequency) and more serious errors. If no eMAR exists, then errors associated with transcription will be present because transcription to a paper medication administration record is required. Serious medication errors can increase with CPOE if no decision support is available. As functionality increases with computerized applications and electronic transmission, provider-based error-monitoring mechanisms can be tailored down in scope. Medication errors can decrease if interfaces and appropriate documentation using an eMAR are available, along with decision-support capabilities for order accuracy, dosing issues, and interaction checking. In fact,

given the implications of CPOE without interfaces and decision support, nurses should actively support a CPOE installation only if adequate functionality will be installed.

That said, no health information technology is a panacea. When lower-level errors are solved, such as results availability and transcription errors, a new level of issues will emerge, some beneficial and some prompting concern. CPOE creates professional interdependence and slices across departmental boundaries. Thus, changes in work design, roles, and communication will occur. Work processes need to be carefully analyzed for potential detrimental changes before going live, and either the work design or the EHR design must be tailored for patient safety and quality. Nurses can expect to feel the impact of more electronic and less face-to-face communication, especially from physicians. Knowing this, alternative communication channels and opportunities can be constructed. Roles will need to be renegotiated among medicine, pharmacy, and nursing for order activation, allergy entry, weight documentation, and other interdependent issues.

Research Implications

Study descriptions and designs. Identifying and specifying the capabilities of CPOE is imperative. Future studies should indicate the exact functions in the article and abstract as well, and in the title, if at all possible. Chaudhry and colleagues.[4] noted this same issue with general HIT studies. Careful conclusions are necessary when CPOE does not provide basic functionality such as pharmacy, laboratory, or eMAR interfaces. CPOE capabilities are not equivalent, so they should be treated like the different independent variables they are. Adequate descriptions of these study characteristics are needed, at minimum.

Broadening the definition of CPOE would allow researchers to conceptualize future studies differently. The term “order entry” misrepresents the concept by implying that only the entry portion of the whole process is important. Ordering is a process starting with entry, to communication, to processing by various recipients, and then to documenting actions against specific orders. By conceptualizing ordering in this way, future studies can be designed to measure impacts across the health team.

Potential external influences need to be taken into account in study design as potential confounding variables. Studying CPOE in a natural environment is challenging research. However, rather than ignore these variables, as has been done in the past, future researchers should want to identify and control, or at least measure, these variables. This notion is stressed by Snyder and colleagues.[38] External forces outside the institution should also be considered in study conclusions—for example, the influence of national trends for increasing patient safety with concomitant information technology installations.

Future research themes. Three major themes for future research emerged: (1) nursing impacts from computerized orders management, (2) human-computer interaction issues, and (3) implementation science. The concept of CPOE needs to be expanded to encompass an orders management cycle. To date, the concept has been studied primarily as order entry in quantitative studies. The ordering process is a complex, interdependent, and interactive process composed of at least these multiple, intersecting elements: systems design, interpersonal and intersystems communication, implementation processes, and organizational structures. Thus, orders management needs to be examined in the future as the interdependent, interdisciplinary, and interactive process that it is. A few authors of qualitative studies have started that process.

Because orders management is a complex process, identifying only simple outcomes variables does not do the phenomenon justice. Multiphased studies with multiple process and outcome variables are needed to begin to understand orders management and its impact.

Nursing impacts of computerized orders management. From the nursing perspective, nearly any study of orders management with nursing impacts will be novel. Ideally, an interdisciplinary study of orders management should be crafted using both quantitative and qualitative methods. Crucial variables include the impact on workflow, cognitive processes for information synthesis across disparate systems, and patient safety issues with various vendors' CPOE applications. A standardized method for medication error reporting is needed to facilitate reporting across institutions and vendor applications. In concert with recommendations from Kaushal, Shojania, and Bates,[19] commercial products should be compared and key implementation factors identified. Mixed methods in future studies are very desirable since quantitative and qualitative methods would provide a powerful mechanism to uncover information about orders management as a complex process.

Human–computer interaction issues. A second theme of future research relates to usability and human–computer interaction impacts of orders management and clinical decisionmaking. Human-computer interaction within EHRs is a critical area to explore in HIT. For at least a decade, health informatics experts have stated that user interface design and other related areas of human–computer interaction are understudied and, in fact, an area in desperate need of attention.[39, 40] Yet, research in this area has moved at a glacial speed. In some recent literature, serious user interface issues have surfaced related to CPOE.[14, 41] In particular, the rigid, linear, structured computing processes reflected in user interfaces did not adequately address clinicians' work processes, which are nonlinear, interruptive, and flexible. These findings accentuate the need for research in user interface design.

Research in human–computer interaction is beginning in health informatics, but more is immediately needed. Two researchers outlined detrimental effects of the usability aspects of order applications.[14, 42] Patel[40] studied issues surrounding physicians' cognitive structures and stressed the importance of cognitive science to informatics. Ash and colleagues examined aspects of CPOE, such as unintended consequences of CPOE and other human-systems issues.[41, 43, 44] Staggers[45–48] studied effective screen designs as they related to the efficiency (response time) and effectiveness (accuracy) of various EHR designs. Future research needs to focus on systems usability to understand what designs facilitate safer orders management; what vendors offer safe, usable, and accurate orders management applications; how vendor applications compare in efficient and effective designs for interdisciplinary applications, such as orders management; what designs facilitate effective clinical decisionmaking; and what work design needs to be in place for successful implementation of CPOE.

Implementation science. Clinical systems implementation in health settings should be a third focus of future research. Anecdotal guidelines exist for systems implementation, but little evidence is available to guide institutions across the nation as they implement EHRs. As of late 2005, only about 20 percent of U.S. institutions had installed EHRs, HIMSS Analytics reported only 3 percent of institutions had CPOE by 2007 and none had a full EHR; therefore, research into the science of implementation can be of benefit in the future.[49] At the very least, we should uncover factors crucial for implementation success in health settings, especially from the organization and system design perspective. Funding should be made available for implementation studies outside academic medical centers and urban areas.

Evidence Table 1. CPOE Effects on Medication Errors

Source	Setting	CPOE	Study Design	Study Intervention	Key Finding(s)	Quality Score	Considerations
Bates 1998[15]	Brigham & Women's (medical and surgical units)	Homegrown	Pretest, post-test	CPOE plus team effect on nonintercepted, potential, and all adverse drug events (ADEs).	Nonintercepted serious ADEs decreased by 55%. Preventable ADEs declined 17% (not significant). Nonintercepted potential ADEs decreased 84%. CPOE plus team offer no additional benefit over CPOE only. No differences seen for all ADEs.	48	CPOE and a "team effect" were intertwined in effects.
Bates 1999[10]	Brigham & Women's (3 medical units)	Homegrown: Transcription to a paper medication administration record required	Time series (1 pretest and 3 post-tests over 4 years)	Medication errors for pre- and post-CPOE x 3.	All errors decreased. Nonmissed dose errors decreased by 81%. Nonintercepted serious errors fell 86%. Nursing workflow impacted negatively and missed-dose errors increased.	43	Study spanned 4 years, during which national trends for patient safety changed. System design changed substantially.
Cordero 2004[25]	Ohio State Univ. neonatal ICU Inpatient	Vendor (Siemens)	Pretest, post-test with controls	CPOE effect on accuracy of Gentamicin doses.	Reduced medication errors for selected NICU drugs.	77	Results for select orders only.
Gandhi 2005[16]	Brigham & Women's 4 outpatient clinics	Homegrown: CPOE without checks or decision support	Cross-sectional	Prescribing errors, potential ADEs, and rule violations.	No differences in total errors, ADEs, or rules.	74	CPOE design had no checks for missing data, dosing, frequency, interactions.

Source	Setting	CPOE	Study Design	Study Intervention	Key Finding(s)	Quality Score	Considerations
Kaushal 2003[19]	N/A	Various forms	Systematic review	Effect of CPOE and clinical decision support on medication safety.	CPOE and isolated clinical decision-support systems (CDSS) can reduce medication errors. Studies under-powered to detect differences in ADEs and have studied "homegrown" systems.	N/A	
King 2003[18]	Children's Hospital, Toronto, Inpatient	Vendor (Eclipsys). No interface with pharmacy. No decision support.	Retrospective cohort study over 6 years	Rate of medication errors on 2 CPOE medical units versus 1 medical and 2 surgical units over 3 years post-implementation.	Medication errors were 40% lower on CPOE units, but no difference for ADEs.	90	Medication study but no EHR interface to pharmacy. No decision support.
Kuperman 2003 [20]	N/A	Various forms	Systematic review	CPOE impact on LOS and medication errors.	CPOE reduces medication errors (incorrect dosing, interactions), transcription errors.	N/A	
Mirco 2005[17]	Portugal, internal medicine units, institution not named	Application not stated. Unit dose available, but no decision support or interaction checking.	Pretest, post-test, no controls reported	CPOE effect on medication errors.	CPOE eliminates transcription and patient identification errors. Errors were right class/wrong drug and unclear orders. Smaller % of errors due to frequency, incorrect dose, drug interaction, duplicative therapy, length of therapy.	37	No interaction checks or decision support available. Study spanned 2 years.
Papshev 2001[21]	Electronic prescribing in ambulatory practice	N/A	Systematic review	Electronic prescribing (including CPOE) effect on medication errors.	Reduces medication errors.	N/A	

Source	Setting	CPOE	Study Design	Study Intervention	Key Finding(s)	Quality Score	Considerations
Potts 2004[9]	Vanderbilt	Homegrown "Wiz" order system	Pre/post with controls	CPOE effect on potential ADEs, medication prescribing errors (MPE), and rules violations (RV).	Reduced ADEs, MPEs, and RVs.	60	Unique homegrown CPOE design.
Shulman 2005[11]	Univ. College in London, ICUs	Vendor (GE systems)	Time series (1 pre and 4 post over 37 weeks)	CPOE without decision support and handwritten orders effect on medication errors and type of error.	Lower proportion of errors with CPOE. Reduced major/moderate outcomes for nonintercepted and intercepted errors combined. Two errors with CPOE resulted in patient harm. Increase in minor intercepted errors with CPOE (43 versus 93).	44	Errors tracked by one ICU pharmacist. No decision support in place.
Spencer 2005[12]	U. North Carolina, Chapel Hill, 2 medicine units	Vendor (Siemens). No pharmacy interface.	Pretest, post-test with controls	Effect of CPOE without decision support and handwritten orders on medication error rates.	Increase in reported errors for pharmacy processing. Other errors unchanged. Errors include drug allergy, duplicate orders.	50	Medication errors voluntarily reported. No pharmacy interface. Errors attributed to the lack of the pharmacy interface.

Evidence Table 2. Computerized Physician Order Entry (CPOE) Effects on Process Efficiency (Time and Length of Stay)

Source	Setting	CPOE	Study Design	Study Intervention	Key Finding(s)	Quality Score	Considerations
Bates 1994[32]	Brigham & Women's (medicine and surgery house staff)	Homegrown	Pretest, post-test with no reported controls	Pre/post CPOE medicine and surgery house staff time spent in order entry activities.	CPOE takes more time (44–73 min/day), especially for one-time orders.	50	Unknown % of order sets, which speed CPOE times.
Cordero 2004[25]	Ohio State Univ. neonatal intensive care unit (NICU), inpatient	Vendor (Siemens)	Pretest, post-test with controls	CPOE effect on radiology result times for abdominal, chest films, medication turnaround times for caffeine loading doses, accuracy of Gentamicin doses.	Reduced medication and radiology turnaround times, medication errors for selected NICU drugs.	77	Results for select orders only.
Kuperman 2003[20]	N/A	Various	Systematic review	CPOE impact on length of stay (LOS).	CPOE reduces LOS.	N/A	
Lehman 2001[28]	Rush Presbyterian	Vendor (Siemens). No pharmacy interface.	Pretest, post-test with no controls	CPOE impact on pharmacy order turnaround time (order to medication delivery on unit).	Over 60% faster with CPOE.	74	Orders were printed in pharmacy and transcribed into pharmacy system.
Mekhjian 2002[26]	Ohio State Univ, transplant unit, medical intensive care unit, and surgical ICUs	Vendor (Siemens). CPOE plus eMAR.	Pretest, post-test with no controls	CPOE impact on medication turnaround times, radiology procedures, lab results.	Reductions in medication turnaround times, transcription errors. More timely results reporting for radiology and lab. Severity adjusted LOS decreased in 1 hospital but not another.	65	For selected medication orders only.
Ostbye 1997[27]	Univ. Western Ontario	Vendor (Siemens from Norway)	Quasi-experimental parallel comparison, descriptive	CPOE effects on results reporting on 2 similar surgical units.	Average time to complete and transmit lab tests decreased from 7 to 1.5 minutes. Results availability decreased by about 3 hours.	76	Good study design, but elected to not analyze data.

Source	Setting	CPOE	Study Design	Study Intervention	Key Finding(s)	Quality Score	Considerations
Overhage 2001[31]	Regenstrief Institute	Homegrown. Used in 11 primary care clinics.	Randomized controlled trial. Time-motion study.	Time for CPOE compared to paper. Perceptions about order entry.	CPOE is 2.2 min per patient longer, but when duplicative tasks are removed, only 0.43 min per patient longer. Perceptions that work is done faster, quality of care and documentation is improved.	108	Unique homegrown CPOE application.
Papshev 2001[21]	N/A	N/A	Systematic review	Electronic prescribing (including CPOE) effect on time	Can eliminate the time gap between point of care and point of service.	N/A	
Shu 2001[33]	Massachusetts General Hospital	Homegrown	Pre/post with pager reminders for time recording	CPOE impact on physician time.	Interns spent 9% of their time ordering vs. 2.1% pre-CPOE. Counterbalanced by less time spent for nursing, pharmacy and quality and efficiency changes.	54	
Tierney 1993[29]	Regenstrief (Wishard Memorial Hospital) 6 inpatient internal medicine services	Homegrown. Orders printed and not sent electronically to departments.	Randomized controlled trial with time-motion study	Effects of orders entered by interns into a computer workstation compared to paper.	Mean LOS was 0.89 day shorter. CPOE interns spent 33 minutes longer per 10-hour period (5.5 min/pt/day).	110	Orders routed to printers in pharmacy. Otherwise printed and treated like paper records.
Thompson 2004[13]	St. Paul's Hospital, Vancouver, 11-bed ICU	Vendor (Eclipsys)	Pretest, post-test	Effect of CPOE on the timeliness of urgent lab and imaging test results.	Improved test turnaround time for stat lab and radiology orders.	54	Used order sets.

Evidence Table 3: Quality Care Variables

Source	Setting	CPOE	Study Design	Study Intervention	Key Findings	Quality Score	Considerations
Han 2005[14]	Univ. Pittsburgh, inpatient pediatrics	Vendor (Cerner)	Pretest, post-test with controls	Effect of CPOE on pediatric mortality rates.	Mortality rate increased from 2.8% to 6.57%.	61	New workflows substantially delayed treatment for critically ill patients. ICU order sets not available. Unclear how CPOE was measured. Possible colinearity between CPOE and severity of illness, shock.
Salmasy & Marx 1997[34]	Urban academic center	Not stated	Pretest, post-test with controls (over 4 years)	CPOE effect on documented consents.	Increased from 75% to 90%.	74	Significant differences in patients' severity of illness. Increased national emphasis on DNR orders during the study duration.
Stair & Howell 1995[50]	Georgetown Univ. medical students on emergency medicine rotations	Not stated	Randomized controlled trial. Students randomly assigned to 4 different locations.	CPOE effect on quality of orders for an imaginary patient.	Quality scores for medical students at CPOE sites better than manual.	94	

Evidence Table 4: Qualitative and Descriptive Studies

Author(s)	Site	CPOE	Study Design	Study Intervention	Key Finding(s)
Ash 2004[41]	Sites in the Netherlands, Australia, and 4 hospitals in the United States	Various applications	Qualitative description of unintended errors	Unintended effects of patient care information systems.	Unsuitable human–computer interfaces for interrupted tasks, cognitive overloads with structured or complete information entry, work fragmentation, overcompleteness; misrepresentation of workflows as linear, clearcut and predictable, inflexibility, rigid requirements for medication orders, work-arounds, loss of communication & feedback, decision support overload, and a decrease in redundancies for error catching.
Dykstra 2002[36]	Univ. of Virginia, El Camino Hospital, Puget Sound and American Lake VA Hospitals	Various systems	Qualitative	CPOE's role on communication patterns.	Impacts on physician–nurse communication without a physical presence, availability of information for the care-team and patient increases, "black box" may mask errors.
Koppel 2005[42]	Urban tertiary care teaching hospital	Vendor (Eclipsys)	Qualitative – interviews, focus groups, observations on 261 physicians, nurses, and pharmacy leaders	CPOE's role in medication errors.	CPOE facilitated 22 medication error sources due to fragmentation of data, lack of systems integration, and human-machine interface flaws.
Sittig 2005[35]	U. Virginia, VA Hospital, El Camino hospitals with recent and long-standing CPOE installations	Various systems	Qualitative – interviews with 50 people (physicians, physician assistants, and nurse practitioners)	Emotional responses to CPOE installations.	Prevalent negative emotions. Implications for CPOE design (irrelevant alerts, slow systems, focusing making "the right thing the easiest to do").
Weir 1995[37]	VA	Homegrown	Descriptive survey	Nurses' perceptions of work, quality of care, and physician–nurse communication.	Positive impact on the quality of care, less job control.

Barcode Medication Administration in EHRs

Background

To Err Is Human focused attention on the frequency of medical errors occurring in U.S. hospitals.[6] In response, the health care industry has been counting upon the strengths of technological innovations to improve patient safety and decrease medical errors. Before the IOM report, the Harvard Medical Practice Study revealed that medication errors most frequently occurred in hospitals.[51] Medication errors can occur at any stage of the medication administration process—starting at the ordering of the drug by the physician, followed by dispensing of the drug by the pharmacist, and ultimately ending in the actual administration of the drug by the nurse to the patient. However, a 1995 study showed that 38 percent of potential and preventable ADEs occurred at the time of administration by nursing personnel.[52] Further evaluation of these errors found that wrong dose, followed by wrong route and wrong drug, were the most common administration errors.[53]

As discussed in the previous section of this chapter, the implementation of CPOE systems is targeted to eliminate errors occurring at the ordering phase. On the other hand, barcode medication administration (BCMA) systems work toward decreasing errors that arise further into the medication administration process. Integration of the two technologies, that is, BCMA systems with CPOE systems, can lead to significant improvements in patient safety and efficiency of medication administration.

National organizations leading the patient safety efforts have recognized the improvements brought about by the implementation of barcode technology in hospitals. The IOM, National Patient Safety Foundation, and the American Society of Health-System Pharmacists have recommended the implementation of BCMA systems as a means for improving patient safety. In 2004, the U.S. Food and Drug Administration (FDA) mandated the barcoding of all medications and blood components to decrease adverse events.[54] This rule requires pharmaceutical companies to provide a National Drug Code (NDC) on most prescription medications and some over-the-counter medications. Additionally, in compliance with the Joint Commission's (formerly the Joint Commission on Accreditation of Healthcare Organizations, or JCAHO) patient safety goals, all hospitals are required to implement barcoding technology for patient identification and for matching patients to their medications by 2007.[55]

Thus, BCMA systems are strongly associated with efforts to bring about a culture of safety in health care. BCMA systems particularly impact the role of nursing in the administration of medications at the bedside. In this section, the empirical evidence surrounding the use of BCMA systems is evaluated, describing the integral role it has come to play in nursing care, and suggesting future directions for research.

Use of BCMA for Medication Administration

Barcoding technology has a variety of applications in health care. It has been used previously for a broad array of applications, such as transfusion and blood bag matching,[56–59] tracking laboratory specimens,[60] and inventory control,[61–63] etc. However, the application of barcoding to medication administration is newer.

Barcode technology can be used as a stand-alone application or linked to the CPOE or EHR system in the hospital. If the BCMA system is not integrated into the EHR, there would be

limited capability to have real-time alerts to detect discrepancies of the medications administered against the orders entered by the physician or to maintain an accurate documentation of medications administered.

In an integrated EHR environment, there is a seamless flow of information following every stage of the medication administration cycle, making it possible for BCMA systems to become part of the medication process workflow. Upon admission, every patient receives a barcoded wristband. These bands identify patients as they are steered through various tests and procedures at the hospital. After examining the patient, the provider enters medications electronically into the CPOE system. Following verification, the pharmacist packages unit doses of the ordered medications into barcoded containers and sends these to the nursing floor. The barcoding on the medication containers has information regarding type of medication, recommended dosage, and the frequency of administration.

The unit doses sent by the pharmacy are stored in a medication cart, which also carries a wireless laptop computer and a hand-held scanner. In an integrated EHR environment, the barcode scanning is linked to the clinical databases via a wireless network. At the patient's bedside, nurses scan their badges, or log into the BCMA system, scan the patient's wristband, and scan the medication. The BCMA system validates whether the "five rights" of medication administration—right patient, right drug, right dose, right frequency, and right route[64]—match the order entered in the CPOE system. If there is a discrepancy, an alert is displayed on the computer screen. Once a medication is scanned it is automatically documented in the medication administration record (MAR) as having been administered to the patient. In most BCMA systems, the nurse has the capability to record missed medications or changes in the time that the medication was administered. Thus, the BCMA system not only offers real-time validation at the point of care, it can also reduce nurses' workloads by creating an automatic and accurate log of the medications administered to the patient.

Research Evidence for BCMA

The research evidence on the use of BCMA systems is limited. The majority of the studies reporting outcomes related to implementation of BCMA technology were conducted in Veterans Health Administration (VHA) facilities; the VHA is a pioneer in the implementation of barcode technology for medication administration. The BCMA system currently used at the VHA is a homegrown system that has undergone several modifications. BCMA technology was first prototyped at a Topeka, Kansas, facility in 1996. In 1999, the BCMA system was integrated with the Computerized Patient Record System (CPRS), which is the CPOE system used at the VHA.[65] By 2000, the system and the associated hardware were implemented in 92 percent of the VHA inpatient wards. The following section discusses the evidence related to key variables associated with BCMA.

Decrease in medication errors. The most commonly measured variable was the change in medication error rate. Four studies described the measurement of this variable: three showed a decrease, and one study recorded an increase in medication error rate post-BCMA implementation. Coyle and colleagues[66] described the implementation of a BCMA system at one VHA facility—some of the refinements and upgrades that the system had undergone based on nursing recommendations. The changes were made to address specific workflow issues to increase acceptance of BCMA in routine practice. A survey administered to the nursing staff evaluated the acceptance of BCMA technology after 3 years of implementation. Results showed

that 97 percent of the nursing staff agreed that BCMA had decreased the risk of medication errors. Additionally, in the first year, the medication errors decreased by 23 percent, and, by the fifth year, by 66 percent. Consistent with these results, another VHA study by Johnson and colleagues[65] compared the overall medication error rates in 1993 and 2001 and found an 86 percent decrease over this period. Anderson and Wittwer[67] conducted a similar study in a non-governmental setting and found that the medication error rate decreased to less than 50 percent of its baseline value within 6 months of implementation of the BCMA system.

Another study measuring medication error rates was conducted in the medical-surgical units of a Midwest government hospital.[68] This study examined whether there was a difference in the medication error rate 1 year before and after implementation of BCMA. The error rates at the administering and dispensing stages were specifically examined. The study showed an 18 percent increase in the medication error rate. However, this increase was explained by the ability of the BCMA system to record any discrepancies in the medication administration, such as late or missed doses, which were previously underreported or went undocumented.

Discrepancies in documentation. The documentation functionality of BCMA systems enables the creation of an accurate and complete MAR, which can then become part of the patient's EHR. However, large discrepancies exist in medication documentation, even in an electronic environment. Only one study compared the discrepancies in documentation that arise upon implementation of a BCMA system. An examination of the discrepancies between MAR and patient billing records for large-volume intravenous solutions identified three types of discrepancies.[69] Failure to document administration to a patient occurred 38 percent of the time, the rate of failure to credit the patient for returned solution was 37 percent, and the rate of administration of solution to a patient other than for whom it was dispensed was 25 percent. This study also examined the potential for BCMA technology to decrease these discrepancies in documentation. A 19-percent improvement in the consistency of documentation was observed after introducing BCMA technology.

Impact on nursing workflow. A supplementary finding of the study by Barry and colleagues[69] was that the lowest scanning rates for items were achieved by the nursing personnel, largely because BCMA has such a huge impact on the workflow of nurses. In this study, the scanning capability was available only at the nursing station, requiring nurses to return to the station each time they wanted to scan an item. Lack of consideration of nursing workflow processes can result in low rates of adoption of BCMA technology. Another study of the medication administration process from the perspective of nurses found ways to make the technology less disruptive to nurses' workflow.[70] The researchers described strategies to improve acceptance of the technology among nurses and hypothesized that a tangible measurement of this acceptance would be seen in the increase in scanning rates. Patient armband scans went up by 7 percent, and medication label scanning showed a 15-percent increase over a 5-month period. The increase in scanning rates was small, but the study lacked a clear description of what the exact intervention was, and hence it is difficult to make conclusions about why it failed to have a larger impact on the scanning rates.

Using human factors theories to guide an ethnographic evaluation, before and after implementation of a BCMA system, the analysis and process-tracing protocols derived five negative, unintended effects of introducing this technology.[71] The investigators found that BCMA technology can lead to the creation of work-arounds that might result in new paths to occurrence of ADEs. This study is the first of its kind to conduct an in-depth analysis of the

design modifications, organizational policies, and elements of training that need to be in place for BCMA technology to fit seamlessly into the nurses' workflow.

Thus, the range of variables assessing the impact of BCMA technology on the workflow of nurses is broad and complex. An example of a simplistic variable is the measurement of the nurses' acceptance of BCMA technology by number of medication and patient identification scans.[70] Complex variables surrounding nurses' workflow have been measured using conceptual frameworks derived from the human factors engineering domain, such as recognition-primed decisionmaking (RPD), human-automation interaction, workload, authority-responsibility double-binds, and mutual awareness among members of the clinical team.[71]

Use of BCMA in the outpatient setting. Only one study described the use of BCMA in the outpatient pharmacy setting.[72] This was a small feasibility study evaluating whether BCMA could be used for automatic verification of medications during dispensing. The study suggested that manual checks could be replaced by barcode technology to improve pharmacist productivity and increase cost savings; however, empirical evidence supporting these conclusions was absent.

Beyond medication error rates. Unlike CPOE systems, there is a fair amount of uniformity when describing a BCMA system. Also, contrary to CPOE interventions—which were conducted largely at urban, academic institutions—BCMA studies are primarily conducted in VA settings. However, the slow penetration of this technology has resulted in very few evaluation studies. In general, there is a paucity of empirical evidence supporting the implementation of BCMA systems. The BCMA technology is advocated as an important safeguard for reducing ADEs, but sufficient evaluation of how this technology affects the dynamics of a complex hospital setting, in ways other than the reduction of medication error rate, is lacking.

Evidence-Based Practice Implications

The implementation and adoption of BCMA systems is slow, perhaps due to disruptions in nurses' workflow. Ease of use is directly linked to technology adoption. Inpatient environments are extremely busy and require technology that can easily adapt to the needs of nurses, enabling them to adopt the new technology readily into routine care.[73] Coyle and Heinen[66] provide a good description of how nursing staff are involved in the design and modification of BCMA software at the VHA. These recommendations helped the information technology team design software to align with workflow needs. Also, there is an effort by vendors to constantly upgrade and update the equipment to make it more user-friendly. The VHA environment has reaped the benefits of involving its nursing staff in the development process and implementing staff recommendations.[71, 74] Other hospitals need to consider this strategy to improve acceptance of BCMA technology by nurses. The VHA also has a national BCMA development team that is entrusted with the responsibility of continuously evaluating and revising the technology.[71]

Impact on nursing workflow. One of the efforts recently suggested was the replacement of the laptop computer with hand-held devices. A field evaluation of usability of this technique with nurses revealed that, while this might be useful for the administration of pain medication and hanging IV fluids, it was not ideal for use with medications in general.[66] Such determinations made from actual field studies serve two purposes. First, they enable nurses to be involved in the process of development and deployment, thus fostering ownership of the technology. Second, evaluation of the technology in a naturalistic setting can help us understand the far-reaching

impact that the introduction of a new technology can have on the workflow patterns—and prevent any new threats to safety that might be introduced by the technology itself.

Changing nurses' perceptions about technology. Adoption of BCMA technology calls for a behavioral change. According to the Technology Acceptance Model,[75] such a change can be brought about by improving perceptions regarding the system, specifically perception of the ease of system use and its usability in routine practice. Tailoring interventions that are geared toward understanding nurses' perceptions will promote adoption. System training should focus on educating nurses about how BCMA serves as a safety net and aids them in preventing errors. Also, organizational policies that support a transparent environment for the reporting of errors—rather than a culture of blame—can improve nurses' perception of BCMA technology. As the nursing shortage increases in hospitals across the nation, nurses need to view safety checks, such as BCMA technology, as aids rather than impediments in their practice.

Enhancing interdisciplinary communication. A seamless integration between the CPOE and BCMA systems can enhance workflow and also build interdisciplinary communication. Information systems have the capability to serve as the common thread linking an interdisciplinary clinical team with the therapeutic decisions driving patient care. Expansion of BCMA into institutions will strengthen nurses' relationship with other members on the clinical team and help other clinical staff to better appreciate nurses' contribution to patient safety.

Research Implications

Nursing practice has undergone a dramatic transformation with the implementation of BCMA systems. BCMA increases the visibility of the nurse's role in the medication administration process and contributes to the organization's commitment to patient safety efforts. Strategies that can be employed to enhance future research efforts in this domain are discussed below.

Medication error rate. A deeper examination is needed for the most commonly evaluated variable characterizing the medication error rate. No study reports an analysis regarding the type of ADEs, such as preventable and potential (often called near misses), that occurred while a BCMA system is in use. Such an evaluation would give us a deeper understanding of the ADEs that are being missed by the system and allow us to create modifications to better capture them.

Need for evaluation of economic outcomes. The policies of the FDA mandating barcoding of medications and the regulatory efforts of other patient safety organizations will, hopefully, encourage adoption of barcode technology. Research in this domain is limited and needs to be expanded to include examination of some core outcomes related to BCMA implementation. Quantitative estimations of return on investment following BCMA implementation and economic outcomes resulting from prevention of medication errors will expedite the adoption of this technology in more hospitals.

Outcomes such as reduced length of stay, decreased number of nursing full-time equivalents needed to perform medication administration, and decreased litigation following administration of incorrect medications are important economic considerations that hospital administrators evaluate when deciding in which technology to invest their health care technology dollars. These outcomes need examination with respect to BCMA technology.

Need for nurse involvement in BCMA implementation and design. As BCMA technology gets deployed in the medication administration process, it will have serious implications for nursing practice. Several issues surrounding the nursing workflow environment

need to be examined when implementing a BCMA system. Issues ranging from the usability of the hardware and software to pragmatic issues, such as the ease of use of the barcode reader and availability of the portable computer, will determine nurses' acceptance of BCMA in their patient care routine. This offers nurse researchers unique opportunities to provide leadership in the development and design of BCMA systems. Active collaboration of nurses with information technology personnel—to provide input on the display of alerts for urgent orders, reports of missing medications, or on recording the missed medications during a shift—can be invaluable to the deployment of BCMA systems.

Sociotechnical evaluation. Evaluation of BCMA technology from a sociotechnical perspective would help gain a deeper understanding of nurses' use of BCMA systems. There is a paucity of literature measuring the sociotechnical issues of compliance with alerts, cognitive load, efficiency, productivity, and emotional aspects of using the technology.

Documentation discrepancies. Besides serving as a safety check for nurses in the medication administration process, BCMA systems also play a key role in creating electronic MARs. Discrepancies in the documentation process have also been evaluated. Such discrepancies arise when medications that have been dispensed by the pharmacy fail to be administered by nurses. The returned medications are not credited back into the patient's billing account. Thus, discrepancies arise between what is dispensed, what is administered, and ultimately what the patient is billed for. Even though documentation discrepancies have been examined, there is no evaluation of the economic impacts of these discrepancies. Such discrepancies could lead to undesirable fiscal outcomes for the hospital, which might affect adoption of these systems. A systems analysis of how these discrepancies arise and what organizational policies can be put in place to inhibit them needs to be conducted.

The implementation of barcode technology can prevent the potential or near-miss errors that would not have been detected otherwise. Nurses must take an active and visible role in the development and deployment of BCMA technology. Participation is the key solution to implementing BCMA technology.

Evidence Table 5. Studies Evaluating Barcode Medication Administration (BCMA)

Source	Setting	BCMA	Study Design	Study Intervention	Key Finding(s)	Quality Score	Considerations
Anderson 2004[67]	St. Mary's Hospital Medical Center	Vendor	Pretest, post-test	Decrease in medication error rate.	The goal of 50% decrease in medication errors in the pilot unit was exceeded within 6 months of implementation. A 44% decrease in medication errors was reported for the entire hospital.	46	Lacks description of implementation process and how medication error rate was measured.
Barry 1989[69]	2 nursing units and 2 controls in a private, not-for-profit hospital	Homegrown	Pretest, post-test with controls	Potential for using barcode technology to reduce documentation errors of IV solution administration.	Errors were traced to three primary sources: (1) failure to document administration of solution (38%), (2) failure to credit patient for IV solutions returned to the pharmacy (37%), and (3) administration of solution to the wrong patient (25%).	48	BCMA was tested specifically on IV solutions. In-service training sessions were conducted.
Coyle 2005 [66]	Various Veterans Affairs Medical Center (VAMC) hospitals	Homegrown	Time series	Survey of nursing staff perceptions about BCMA decreasing risk for medication errors. Decrease in medication errors.	After 3 years, 97% of the nursing staff agreed that BCMA could decrease the risk for medication errors, potential and actual. Medication errors decreased by 23% in the first year and by 66% after 5 years.	44	Description of nursing staff involvement in the design and modification of BCMA system to resolve workflow and software issues. Good description of BCMA functionality. Lacks description of study methodology and study subjects.
Englebright 2005[70]	85 facilities of Hospital Corporation of America	Unknown	Pretest, post-test	Frequency of scanning patient armbands and medication labels.	Patient armband scanning increased by 7%, and medication label scanning increased by 13%.	31	Lacks description of implementation process and a description of how acceptance among nurses was improved.

Source	Setting	BCMA	Study Design	Study Intervention	Key Finding(s)	Quality Score	Considerations
Hokanson 1984[72]	1 outpatient pharmacy service in an ambulatory clinic	Homegrown	Cross-sectional	Feasibility study of using BCMA in the pharmacy setting.	No dispensing errors were made.	39	The study was conducted for a limited time (36 hours) and a single clinic session.
Johnson 2002[65]	VAMC	Homegrown	Time series	Number of medication errors prevented.	Prevented 549,000 medication errors while dispensing 8 million doses, in 6 years.	57	Compared medication rates from the manual medication administration system and the electronic BCMA system.
Low 2002[68]	2 medical surgical units at a Midwest government hospital	Vendor (Tremont BCMA)	Pretest, post-test	Medication error rate 12 months pre- and postimplementation of a BCMA system.	Medication error rate increased by 18% after BCMA implementation due to enhanced reporting by BCMA system.	62	The measurement of medication error rate prior to implementation was using the incident report system, while post-BCMA implementation the system would create automatic logs if any discrepancies arose in the medication administration.
Patterson 2002[71]	Acute care and nursing home wards of three VA hospitals	Homegrown	Cross-sectional, observational study before and after implementation	To identify the negative, unintended side effects resulting from the implementation of BCMA systems that can create new paths to ADE occurrence.	Five negative side effects after BCMA implementation were identified.	98	The outcomes of this study serve as recommendations for design modification of the BCMA system in the VA.

Decision-Support Systems for Nursing

Background

Patient safety researchers view decision-support systems (DSS) as a solution to high rates of medical errors and inappropriate care. Many researchers view embedding DSS systems into well-developed, comprehensive CPOE systems as the only method to significantly impact clinical decisionmaking. Order entry with DSS harnesses the full potential of the computer to provide relevant information, guide decisions, and structure data entry.[6, 76, 77] For this section of the chapter, the main focus is on decision-support interventions for nursing that are embodied within a CPOE system that is linked to a comprehensive electronic health record (EHR). DSS interventions were considered if they were implemented in the context of an existing CPOE system or could easily be integrated into a CPOE system. Decision-support systems are software designed to support or enhance clinical decisions. This is a broad definition and includes changes in information displays, alerts, reminders, or fully developed algorithmic computerized protocols.

Research Evidence

There were two published studies on nursing-specific DSS studies conducted in a CPOE environment.[78, 79] There were many other published studies that reported early development work and validation results for DSS related directly to nursing. However, because so few were implemented, they were not eligible for inclusion here. Overall, there were 31 studies where the DSS intervention either was embedded in an EHR with CPOE or could reasonably be expected to have that capacity (see Table 6). This set of studies could be divided into two groups. The first group includes those studies targeting nursing decisionmaking directly (e.g., prevention of pressure ulcers, incontinence, triage). There were 13 studies in this group; however, only one was actually implemented in a CPOE system. The second group includes those studies largely targeting physicians, but the clinical focus could reasonably be associated with nursing. This judgment is, of course, subjective, as nursing is involved in almost all aspects of care. However, some activities have substantial nursing involvement. There were 18 studies in this second group, covering three broad areas: (1) acute care guidelines for selected topics, (2) critical care, and (3) preventive care. There were many other studies where the role of nursing might be significant, such as coagulation therapy or diabetes management. Because the nursing role was not explicated and would likely vary, these studies could not be included.

Direct decision support for nursing. Out of the 31 studies identified as relevant, 13 focused directly on nursing. Three studies concerned consultant systems for the prevention of pressure ulcers. All three were essentially qualitative or descriptive, presenting very little patient outcome data.[80–82] Decision support for the management of urinary incontinence has been studied as well. Petrucci and colleagues[83] found large increases in knowledge and decreases in episodes of urinary incontinence in a patient care unit where a consultation system was implemented, as compared to a unit in the same hospital where it had not been implemented. Three studies examined the performance of staff conducting telephone triage with the help of algorithmic decision-support systems. All found improved performance, although all three used the weakest design, a pretest, post-test evaluation.[84–86] Two other studies directly addressed alerts and reminders to nursing staff for preventive care. Both of these showed strong results, including

one study that compared standing orders with alerts directed at nursing staff to alerts directed toward physicians.[79, 87]

In another study, the effects of different forms of physiologic data displays in a neonatal ICU were examined in a CPOE environment.[78] In this study, all infants were randomly assigned during an 18-month period to one of four groups: (1) no display of trend data, (2) continuous display of trend data, (3) alternating 24-hour display of trend data starting in the first 24 hours, or (4) the same as the third group starting after the first 24 hours. The number of orders for colloid, blood gases, and ultrasound were measured, as were longer-range variables, such as total time on ventilation, total time on supplemental oxygen, length of stay, and death. No differences in patient outcomes were noted, although surveys found increased knowledge regarding neonatal physiology on the part of the staff. Because patients rather than clinicians were assigned randomly, it is highly likely that there was dispersion of the effects of the independent variable.

Finally, several studies on a clinical decision-support system (CDSS) that guides nurses in identifying patient preferences consistently found improvement in the degree that nurses were able to act in accordance with patient preferences. These studies employed a high-quality design, and although the program was never embodied in an EHR, it is conceivable that one day it might implemented with resultant, improvement in the continuity of care.[88–90]

Indirect decision support for nursing. The remaining 18 studies were selected because they used a computerized intervention that either was instituted in a CPOE environment or used a well-established EMR. In addition, these studies focused in areas where nursing would likely be highly involved. One study[79] contrasted standing orders (to the nursing staff) versus computerized reminders for preventive care for inpatients, finding nearly twice the improvement with standing orders. Three studies focused on the use of guidelines to prevent deep venous thrombi in post-surgical patients, involving both nursing and physician activities. In two of the studies, significant results were found for provider compliance using the guidelines, but no difference was found regarding patient outcomes.[91, 92] In the third study,[93] both compliance with guidelines and patient outcomes were improved.

Four other studies were conducted in critical care settings, involving mostly complex guidelines (e.g., ventilator support). In two other studies, the effects of a computerized guideline for the treatment of adult respiratory distress syndrome were the focus of the investigation. Both were conducted by investigators from the LDS hospital in Salt Lake City, which had an extensive EHR at the time, but not full-scale provider order entry. East and colleagues[94] examined the impact of the computerized guideline in a prospective multi-center randomized trial for 200 patients. No significant differences were found in survival or ICU length of stay between treatment groups. There was a significant reduction in morbidity as measured by a standard scoring system, as well as a lower incidence of over-distension lung injury. In a similar study, a pilot of the study published above at Memorial Hermann Shock Trauma ICU, McKinley and colleagues[95] randomized 67 trauma patients to either being cared for by the protocol or not. No difference was found between patients in terms of survival, length of stay, or morbidity.

In another study conducted in the outpatient setting in the VA, with a complete CPOE system, computerized guidelines for mental health screening resulted in significantly higher compliance than paper guidelines. It was not clear in the description how nurses (not including the advance practice nurses) were involved in the implementation, but they might have been the individuals actually receiving the alerts.[96]

Several studies using qualitative techniques found similar issues. Karfonta[97] used grounded theory to examine the experiences of 23 nurses and 10 physicians using DSS systems in the ICU.

Overall, all interviewees mentioned the role of DSS in assisting in forecasting the outcomes of decisions. Difficulties in learning the system, trusting the output, and understanding the technology were additional themes.[97] Lyons and colleagues[98] examined VA employees' perceptions of guideline implementation and utilization in the VA's CPOE system. Information technology issues were perceived as major barriers to effective guideline implementation. Patterson and colleagues[99] conducted a human factors qualitative analysis of the VHA clinical reminder system and noted that increased workload, training, time, and role divisions were key barriers to success.

The remaining studies all focused on preventive care reminders or hypertension followup, with only two focused mainly on nursing.[87, 100] In most cases, but not all, the studies found improved compliance. Because the studies took place in the outpatient setting, the role of the nursing staff likely varied greatly, but is not elucidated. Further analysis would have to be done to determine if an increased role of nursing in providing followup and initiating immunization was a determinant contributor of success.

Challenges with research evidence. Three main themes can be extracted from the results. First, for the most part, nursing activity is simply not addressed in these studies. Nurses make decisions every day about pain and wound management, whether a patient's symptoms are severe enough to notify a physician. Nurses often have to decide if a patient's symptom is drug related, or if a drug might interact with other drugs before they give them. In many cases, nurses have primary responsibility for patient education and family support. Few decision-support interventions have been developed for any of these high-level, decision-based actions. It is as if nursing decisionmaking is invisible and nurses are viewed as data collectors, rather than decisionmakers. In addition, one of the main roles that nurses fill in an inpatient setting is that of an intermediary between the patient and other providers. This communication role is a crucial function in ensuring quality of care. However, communication has been significantly neglected in EHR designs, as was noted earlier in this chapter and by many other authors.[101, 102] Most of the work to create DSS has focused on structured documentation, order review, or systems designed to force or track nursing actions. For example, one study examined the effectiveness of putting a signal on a nurse and tracking where they were at all times to ensure efficiency.[103] Another study examined the impact of opening locked medicine cabinets (in the room) only when medications were due, to ensure that nurses would give them on time.[104]

Second, the mechanics of providing DSS for nursing in a regular CPOE inpatient setting has not been well explicated. In many settings, the computers are located at the nursing stations, making them unavailable at the time of care. The model of having decision-support software located on computers situated at the nursing station fails to support a nurse who is constantly on the move. Development and exploratory work has been published, examining the use of portable laptops or hand-held computers, but no high-quality studies have reported on an actual implementation directed at nursing.

Third, none of the studies have examined the mechanism of action for DSS interventions. This is true of the DSS literature in general. Because DSS interventions can range from alerting a clinician about something they already know (e.g., a reminder), to alerting the staff to where a patient is in a process (tracking), to providing new information that educates and informs, it is important to measure the intended psychological effect as well as the outcome.[105, 106] Although most studies show significant increases in provider compliance, the effect is small, and the upper limits are in the low 40- or 50-percent levels.

Evidence-Based Practice Implications

The above three themes provide a framework for discussing how to link this work to practice. Because the large body of nursing activity is simply not addressed in these studies, it is difficult to identify the important practice implications. Many clinical interventions are likely designed by nursing for quality improvement purposes using the EHR, and these are not being captured in the formal research literature. In the VHA, there are substantial local initiatives led by nursing to improve patient care using the functionalities provided by the CPOE. Few, if any, are published. If they are published, the focus is on "lessons learned" rather than to provide scientific evidence of efficacy. Nurses in practice can inform themselves of the functionalities of their EHR and volunteer to serve on hospital informatics committees that make strategic decisions. Adapting the system to nursing's needs and adapting to the system is a process of whole-system transformation.[107–109]

The second issue regarding the improvement of practice is how to improve the mechanics of providing DSS for nursing in the inpatient setting, given the fact that nurses are often on the move. Some of the more effective decision support can be arrangements of lists, printouts, and other easy-to-carry tools to simplify and organize data. Most EHRs have the capacity to be customized to individual clinical needs. Nurse managers are in a unique position to evaluate their system and participate in the development of low-resource-impact, decision-support tools. Nurse managers could also be involved in technology planning, to ensure that computers are available at the bedside. In addition, interventions, such as BCMA, structure nursing documentation. But because it is linked to an information system, imbedded DSS could easily be implemented to alert nurses about possible ADEs.

Because DSS is likely to be implemented by administration, it is important that the nurse managers argue for evaluation of the system. Evaluation should focus on measuring the implementation itself, the work process changes, and the outcomes. The evaluation should be started at the same time as the implementation so that the information gleaned will not only minimize any negative impact on patient safety, but also will provide for maximum input by nursing staff during the change process. Ongoing evaluation is essentially a quality management activity and is a practical approach to clarifying the mechanisms of action—and to ensuring that the impact of DSS on nursing practice is formally addressed.

Research Implications

The three themes identified above also provide a framework for discussing future research implications. The work that needs to be addressed immediately is clarification of nursing roles in the implementation and success of DSS systems, especially those implemented in the context of CPOE systems. Most of these interventions are multidisciplinary and involve substantial process reengineering that goes largely unreported. Nurses are in a position to fully comprehend the depth of this reprocessing, and expanding our understanding in this area would be a contribution to the field as a whole. Implementation as a science is expanding, and nursing expertise is crucial.

Secondly, much more work needs to be done to delineate and clarify the actual decisions made by nursing in order to develop effective decision-support systems. This goal can be accomplished in two ways. More qualitative work is needed to describe and analyze nursing decisionmaking using recent theoretical advances in the cognitive sciences. Activity theory,[110]

goal theories,[111] and adaptive rationality[112] are areas that would be very useful as approaches to understanding nursing practice. In addition, although many studies have been published that explore decisionmaking and nursing expertise, some of which have been developed and validated, very few have been actually implemented. Nursing needs to examine the barriers that prevent the outcome of these research projects from reaching higher levels of adoption.

Finally, because the mechanism of action for DSS interventions is not examined, future advancement in the field of decision support is constrained. As described above, mechanisms are likely to be either psychological (e.g., directing attention, decreasing memory loads, or educational) and/or organizational (e.g., changing work processes and role behaviors). Designing studies that measure memory load, manipulate and test the role of attention, and directly assess learning effects as part of a DSS design would greatly advance the science.

Evidence Table 6. Decision-Support Systems Within an Electronic Health Record Related to Nursing

Source	Setting	Study Design	Study Intervention	Key Finding(s)	Quality Score
Barnett 1983[113]	Outpatient	Randomized controlled trial	Reminders for followup for hypertensive patients.	Followup was significantly improved in the group receiving the reminders, in rate of followup attempted or achieved by the responsible physician and in the repeated recording of blood pressure.	90
Barton 1990[114]	Outpatient health maintenance organization	Pretest, post-test	Postcards compared to simple reminders compared to feedback and reminders.	No changes in vaccination rates until computerized reminders were supplemented with feedback to individual providers.	48
Cannon 2000[96]	Outpatient mental health VA	Randomized controlled trial with patients randomized within providers	Computerized vs. paper reminders for screening and documentation of mood disorders using CaseWalker.	The computerized screening reminders resulted in a higher screening rates for mood disorder (86.5 vs. 61 percent, *P* = 0.008) and improved documentation.	90
Clark 2005[80]	Multilevel care in Canadian Health Region	Qualitative, descriptive	Computerized advisory management system to prevent pressure ulcers.	Evaluation indicated an increase in knowledge relating to pressure ulcer prevention, treatment strategies, resources required. Lack of visible senior nurse leadership; time required to acquire computer skills and to implement new guidelines; and difficulties with the computer system were identified as barriers.	N/A
Coe 1977[115]	Outpatient	Cluster case cohort	Blood pressure management in outpatients using computerized reminders.	No significant difference in patient outcomes.	64
Cunningham 1998[78]	Critical care	Randomized control trial	Continuous trend display vs. summative aggregated displays.	None of the short-, medium-, or long-term patient outcomes demonstrated any significant benefit from the provision of computerized physiologic trend monitoring.	102
Dale 2003[116]	Emergency services	Pretest, post-test	Consultant support for nurse triage.	More patients requiring an ambulance were seen in the emergency department for the intervention group as compared to the control (odds ratio = 2.62; 95% CI = 1.78–3.85).	90
Davidson 1984[87]	Outpatient	Pretest, post-test	Specific nurse-targeted reminders.	Significant increases in stool examination for occult blood (32% to 47%), breast examination (29% to 46%), and influenza immunization (18% to 40%).	78

Source	Setting	Study Design	Study Intervention	Key Finding(s)	Quality Score
Dexter 2004[79]	Inpatient	Randomized controlled trial	Compared standing orders to computerized reminders in a CPOE environment.	Patients with standing orders received an influenza vaccine significantly more often (42%) than those patients with reminders (30%) ($P < 0.001$). Patients with standing orders received a pneumococcal vaccine significantly more often (51%) than those with reminders (31%) ($P < 0.001$).	110
East 1999[94]	Critical care	Randomized controlled trial	Computerized guidelines for management of ventilated patients.	No significant difference in survival or ICU length of stay between the two treatment groups ($X^2 = 0.49$, $P = 0.49$) and ($F(1) = 0.88$, $P = 0.37$). There was a significant reduction in morbidity ($F(1) = 4.1$, $P = 0.04$) and severity of over-distension lung injury ($F(1) = 45.2$, $P < 0.001$).	102
Hutchison 1989[100]	Outpatient clinic	Pretest, post-test repeated measures	Printed reminders attached to charts taken from EMR.	Vaccination rate increased from 10.1% to 26.8% and no increase in influenza immunization in the comparison practice.	64
Karfonta 1999[97]	Critical care	Qualitative analysis of nurses and physicians	DSS in general.	DSS was seen to be important for forecasting decisional outcomes. Included four sub-areas: DSS learning, understanding DSS technology, creating DSS inferences, and trusting DSS-derived data. UK.	N/A
Kucher 2005[93]	Inpatient in a CPOE environment	Randomized controlled trial	Alerts given to physicians.	The rate of prophylaxis increased from 14% in the control to 33% in the intervention group. Those receiving prophylaxis had 41% less incidence of DVT than those who did not.	84

Source	Setting	Study Design	Study Intervention	Key Finding(s)	Quality Score
Lyons 2005[98]	Inpatient VA	Qualitative	Perceptions of VA clinicians regarding the role of information technology in implementing guidelines.	Eighteen themes clustered into four domains. Workplace factors were more often discussed by administrators, system design issues discussed most by nurses, and personal concerns discussed by physicians and nurses. Facilitators included guideline maintenance and charting formats. Barriers included resources, attitudes, time and workload, computer glitches, computer complaints, data retrieval, and order entry. Themes with dual designations included documentation, patient records, decision support, performance evaluation, clinical practice guidelines (CPG) implementation, computer literacy, essential data, and computer accessibility.	N/A
McKinley 2001[95]	Critical care	Randomized controlled trial	Computerized guideline to manage ventilated patients.	Outcome measures (i.e., survival, ICU length of stay, morbidity, and barotrauma) were not significantly different between groups. Fio2 > or = 0.6 and Plateau > or = 35 cm H2O exposures were less for the protocol group.	102
Mosen 2004[92]	In patient post-op in highly developed EMR system, but not complete CPOE	Pretest, post-test	Guideline to prevent post-surgical DVT (deep vein thrombosis).	The overall prophylaxis rate increased from 89.9% before implementation of the computerized reminder system to 95.0% after implementation ($P < 0.0001$). The combined 90-day rate of symptomatic DVT, pulmonary embolism (PE), and death attributable to PE remained the same (pre-1.0%; post-1.2%; odds ratio = 1.21; 95% CI = 0.67–2.20).	52
Murray 2004[116]	Outpatient in a CPOE environment	Randomized controlled trial	Computerized suggestions given to (1) physicians, (2) pharmacists, (3) both, or (4) none.	No significant differences found between groups in terms of quality of life, hospitalizations, ER visits, cost, or blood pressure (BP).	110
Patterson 1998[91]	Inpatient in a CPOE environment	Pretest, post-test	Computerized algorithm with protocols for prevention of DVTs.	The preintervention rate of DVT prophylaxis over a 3-month period was 85.2% (785 of 921 eligible cases). For the 3 months following the introduction of the computerized reminder, compliance with DVT prophylaxis increased to 99.3%.	64

Source	Setting	Study Design	Study Intervention	Key Finding(s)	Quality Score
Patterson 2004[99]	Outpatient use of clinical reminders in the VA CPOE system	Qualitative	Human factors analyses were conducted on users across multiple settings and roles.	Significant barriers and issues were identified, including time, workload, nonrelevance, ease of use, training, complicated procedures for refusal, etc.	N/A
Petrucci 1991[83]	Nursing home in a non-CPOE environment	Case control	Disease management consultation for urinary incontinence.	The number of wet occurrences of patients residing on units where nurses consulted UNIS decreased significantly; F (2,9) = 34.67. The knowledge of urinary incontinence also improved significantly when nurses consulted UNIS; F (2,157) = 19.46.	54
Rogers 1982[117]	Outpatient in a non-CPOE environment	Randomized controlled trial	Alerts to manage hypertension, obesity, and renal disease, using printouts only.	Decreased BP, decreases in hospitalization and length of stay.	84
Ruland 1999[88]	Inpatient unit for the elderly	Quasi-experimental nonrandom assignment; groups selected in tandem.	Use of a systematic protocol for eliciting patient preferences given to nurses in experimental group.	Patients whose nurse was given their personal preferences reported care more congruent with their preferences.	68
Ruland 2002[89]	Inpatient	Randomized controlled trial	Use of a hand-held computerized decision support.	Nurses' use of CHOICE made nursing care more consistent with patient preferences (F = 11.4; $P < 0.001$) and improved patients' preference achievement (F = 4.9; $P < 0.05$).	78
Ruland 2003[90]	Outpatient	Randomized controlled trial	Use of a computerized system that collects patient preferences.	Patient reports of topics addressed during the consultations showed greater congruence in the experimental group as compared to control group.	108
Schriger 1997[118]	Emergency services	Time series	Guidelines for treatment of occupational body fluid exposures.	Mean % documentation of essential items increased from 57% to 98% in the intervention phase, and aftercare instruction increased from 31% at baseline to 93% during the intervention phase, but both decreased to baseline when the computer system was removed. Compliance with guidelines increased from 63% to 96% during the intervention phase. Percentage of charges increased from 44% to 81% during the intervention phase and decreased to 36% following the intervention.	78

Source	Setting	Study Design	Study Intervention	Key Finding(s)	Quality Score
Schriger 2000[119]	Emergency services	Time series	Guidelines for care of febrile children.	Percentage of 21 essential history and physical examination items increased from 80% during the baseline period to 92% in the intervention phase (13% increase; 95% CI = 10–15%). Mean percentage documentation of 10 items in the aftercare instructions increased from 48% at baseline to 81% during the intervention phase (33% increase; 95% CI = 28–38%). All decreased to baseline when the computer system was removed.	68
Slovis 1985[85]	Emergency services	Pretest, post-test	Triage DSS using flip charts; users were not clinicians.	The DSS system shortened the average response time from 14.2 minutes to 10.4 minutes for the most urgent cases ($P < 0.05$); resulted in a significant increase in the use of advanced life support units for this group ($P < 0.02$).	44
Strachan 2001[86]	Emergency services	Pretest, post-test	Triage	Effective triage went from 20% to 32%.	44
Tang 1999[120]	Outpatient CPOE environment.	2-yr prospective case control	Reminders for immunization.	Used physician volunteers for CPOE. Compliance rates for the computer-based patient record system (CPR) user group increased 78% from baseline ($P < 0.001$), whereas rates for the paper records (PR) user group did not change significantly ($P = 0.18$).	64
Willson 1995[81]	Inpatient	Pretest, post-test	Implementation of AHCPR guideline on pressure ulcers.	Comparison of computerized protocol with a previously implemented paper protocol. Very little data.	N/A
Zielstorff 1997[82]	Inpatient unit	Case control	Pressure ulcer DSS for nurses used by nurse volunteers; no data on usage.	Dependent variables were knowledge and decisionmaking results from simulations. No patient data provided.	N/A

Conclusion

Across the sections in this chapter, several themes are apparent. First, nursing and nursing impacts are nearly absent in the current empirical studies of work on EHR orders and clinical decision support within ordering systems. Future research is needed to understand the impact of that technology on the role of nurses and workflow methods that are effective for nurses in a computerized orders environment. Nursing clearly participates in the orders process; yet, the assessment of that role is missing to date. More important, nurses and pharmacists serve in roles as protectors against errors in patient care. The counts of intercepted errors speak to this role in a simplistic way. More complex variables and expanded research is needed on this topic. With CDSS, nurses are studied as invisible partners in the care process rather than as decisionmakers themselves. Yet, nurses make thousands of care decisions a day. Borrowing methods from psychology, future researchers could expand the cognitive work in this area.

BCMA is the exception to the absent nursing voice. In BCMA, nurses are integral to the success of the application. Medication error reduction with BCMA is apparent. Additionally, the VHA has effectively included nurses in the design and implementation of technology-assisted medication administration. However, technology assistance in medication administration represents a lower-level cognitive process than, say, decisionmaking about symptom assessment or an independent care intervention. Thus, future research on decision support for higher cognitive processes and the nurse as a full-fledged decisionmaker is warranted.

There are several limitations to this work. A strong effort was made to have well-defined inclusion criteria to make the studies as homogeneous as possible and to allow valid comparisons. However, the inclusion criteria have limited this analysis to implemented solutions, narrowing the possible CDSS applications in particular. Likewise, studies were excluded from areas such as imaging and psychiatry; in the future these areas could be examined. Our results included some qualitative work, not usually considered as evidence, but included here to better describe the phenomena at hand. An analysis without qualitative studies would perhaps come to different conclusions.

Studies in sociotechnical and human-computer interaction are needed in each of these areas. This would help us understand the complex processes inherent in technology design and adoption. Interdisciplinary examinations are needed in future research to understand interdependent roles. With technology becoming an omnipresent participant on today's health care teams, traditional roles on a health care team have been altered. For example, computerized orders management changes roles, and role renegotiation must take place. New process and new issues emerge with complex technologies like CPOE; this interdependence needs to be systematically evaluated in the future. The research in HIT integrative functions is just beginning. Future opportunities are many for areas of great impact to nursing.

Search Strategies

CPOE Search Strategies

A broad search of the literature from 1976 through the end of 2005 was undertaken as part of a larger study to locate articles dealing with the practice impacts of clinical computing applications. Searches were conducted in PubMed®, CINAHL, Cochrane, PsychInfo, DARE, INSPEC, CENTRAL, and HTA databases. The search strategy is located in appendix A. The

search yielded 63,731 references with 1,023 abstracts rated as having empirical data. Abstracts were coded for relevancy and sorted into categories (e.g., clinical decision support, CPOE, EHR adoption). CPOE-coded articles were retrieved as a subset from the larger search results. Search terms were

> online order entry OR computer-based physician workstation OR practitioner order entry OR physician order entry OR electronic health record OR computerized physician documentation OR computer medical records OR medication order entry OR computer based order entry OR CPOE OR POE

The CPOE search yielded 178 potentially eligible articles.

CPOE articles were rated for eligibility with empirical studies of any design and systematic reviews being considered relevant. The relevant studies examined implemented solutions with a concentration on any practice implications of CPOE. Letters, opinions, and editorials were excluded, as were articles dealing with models or theoretical discussions about systems. Further, studies were excluded if they (a) provided only verbal summaries of CPOE impacts or satisfaction with CPOE; (b) focused solely on CPOE costs or ordering volumes; (c) primarily focused on imaging, dentistry, simulations, psychiatry, data mining, or genetics; or (d) focused solely on CPOE or EHR adoption methods. The authors separated studies with a major focus on guidelines and order-related decision support into a separate section of this chapter. This first section targets clinical impacts of paper-based ordering compared to CPOE.

BCMA Search Strategy

A review of studies published in peer-reviewed journals and meeting abstracts was undertaken. The search criteria used for PubMed® was as follows:

> barcode point-of-care technology OR bar code medication administration OR BCMA OR medication bar coding OR barcode medication administration OR barcode point-of-care technology OR eMAR OR electronic medication record

The search was limited to studies with abstracts that were published in the English language and spanning the years 1976 to 2005. This search retrieved 205 abstracts, out of which 29 were relevant. A second search was conducted to look for studies that focused on the nursing domain by combining the above search strategy with "AND nursing." The same limits were applied to this search as well. A total of 33 abstracts were retrieved, out of which 10 were considered relevant for this review. In all, 39 abstracts were considered relevant in our first evaluation.

A second evaluation was conducted by retrieving and reading the full text articles. The inclusion criteria used to determine whether a study was relevant or not were the same as those used for CPOE, as described above. Eight studies provided evidence of actual implementation of a BCMA system and its evaluation; the remaining 31 articles were discarded. Further, quality assessment of the studies was conducted using the QUASII instrument. Table 5 presents a summary of the key findings and variables measured in the nine studies that were finally evaluated.

Decision Support Search Strategy and Methods

The broader search strategy used for this review is described at the beginning of the chapter. The results retrieved from this larger search were further analyzed for relevance to DSS interventions for nursing. To be included in the final round, a study had to be reporting an actual

evaluation or research study conducted with real patients cared for with the intervention in place. Although the focus was on those studies associated with CPOE and an EHR, few have been conducted (especially for nursing). Therefore, studies were included where the intervention could easily be implemented *in the context* of CPOE with an EHR. Studies whose main focus was on nursing interventions designed to improve documentation, care planning, or administration were *not* included. Simulations, early reports of development findings, or validation of DSS software were also not included, nor were studies that were simply descriptive or had a "lessons learned" perspective. However, studies that used methods close to a traditional qualitative methodology or formal human factors analysis were included when appropriate, for example, the focus was on a system implemented in real time.

Inclusionary terms:

Online order entry OR computer-based physician workstation OR practitioner order entry OR computer-based medical record OR electronic health record OR computerized physician documentation OR computer medical records OR decision support computer program OR health maintenance reminder OR CDSS OR computer-aided OR computerized decision making support OR clinical decision support system OR computerized feedback OR computer-assisted dosing OR computer feedback OR predictive instrument OR computer-aided quality assurance OR computer alert OR clinician order entry OR provider order entry OR computerized reminder OR computer reminder OR computer-based monitoring system OR expert system OR computer-based medical decision support OR decision support system OR computer based order entry OR event reporting system OR electronic healthcare record OR electronic monitoring OR electronic health record OR electronic medical record OR electronic incident reporting OR electronic record OR electronic patient record OR electronic record keeping OR medical information system OR computer-predicted OR computer-based monitoring OR computer-based prompt system OR CPOE OR POE OR electronic journal OR medical reminders OR electronic reminders OR medical record alert.

Inclusionary Mesh® terms (for PubMed® only):

"Decision Support Systems, Clinical"[MeSH] OR "Hospital Information Systems"[MeSH] OR "Medical Records Systems, Computerized"[MeSH]

Exclusionary terms:

NOT (X-ray OR biochemistry OR DNA OR RNA OR genome OR tomography OR dentistry OR dental OR simulation OR molecular OR animal OR psychiatric OR biofeedback OR HIPAA OR in-home OR data mining OR algorithm)

Exclusionary Mesh® terms (for PubMed® only):

NOT ("Validation Studies"[Publication Type] OR "Editorial"[Publication Type] OR "Letter"[Publication Type] OR "News"[Publication Type] OR "Comment"[Publication Type] OR "legislation and jurisprudence"[Subheading] OR "Libraries, Medical"[MeSH])

Limits

Articles considered were those published in English during the time period January 1, 1976 to August 1, 2004.

Acknowledgments

Chapter 48. Patient Safety, Telenursing, and Telehealth

Loretta Schlachta-Fairchild, Victoria Elfrink, Andrea Deickman

Background

Tele is a prefix meaning "at a distance," and it is used in terms such as telescope, or telemetry. The prefix *tele,* when combined with the term *scope,* has the single clear following meaning: an instrument to view phenomena at a distance.[1] However, in health care, as in other arenas, the prefix *tele* often takes on several meanings. For example, the term *telemetry* is described as a process,[2] data,[3] and an electronic device[4] related to the task of remote measuring and reporting of information of interest. There is inconsistent and emerging nomenclature related to *tele* in health care.

The inconsistent use of language associated with the delivery and management of health care at a distance has made it even more difficult to distinguish the ontology of terms and describe their related safety and quality issues. Specifically, previous literature has used the terms *telehealth, telemedicine,* and *telenursing* somewhat interchangeably, and the few articles reporting safety concerns were difficult to cluster for further analysis.

Telenursing is the use of "technology to deliver nursing care and conduct nursing practice"[5] (p.558). Although the use of technology changes the delivery medium of nursing care and may necessitate competencies related to its use to deliver nursing care, the nursing process and scope of practice does not differ with telenursing. Nurses engaged in telenursing practice continue to assess, plan, intervene, and evaluate the outcomes of nursing care, but they do so using technologies such as the Internet, computers, telephones, digital assessment tools, and telemonitoring equipment. Bearing in mind that health services now provided via teletechnologies have expanded, the term telehealth is used to capture the breadth of services. For the purposes of this review, the Health Resources and Services Administration defines telehealth as "the use of electronic information and telecommunications technologies to support long-distance clinical health care, patient and professional health-related education, public health and health administration."[6] Telemedicine, the original term, is defined as the practice of health care delivery, diagnosis, consultation, treatment, transfer of medical data, and education using interactive audio, visual, and data communications.[7] The American Nurses Association has defined telenursing as a subset of telehealth in which the focus is on the specific profession's practice (i.e., nursing).[8]

The delivery of telehealth care is not limited to physicians and nurses; it includes other health disciplines such as radiology, pharmacy, and psychology. These disciplines also deliver care using electronic information and telecommunications technologies and are accordingly called *teleradiology, telepharmacy, telepsychology,* and so forth. Although they are not the focus of this review, these disciplines are selectively included here for two reasons: (1) the safety issues associated with care delivered using electronic and telecommunications technologies are more similar than they are different among the various health disciplines, and (2) the dearth of research on safety and quality in the telenursing literature led the authors to include important research in other health disciplines. By including the research findings on safety and quality from varied health disciplines, the body of telenursing knowledge is expected to expand.

Research Evidence

Although the summary for the AHRQ evidence report, *Telemedicine for the Medicare Population*,[9] specifically mentions safety related to telemedicine and how evidence could be presented and researched, it is ironic to note that in all the evidence tables of all the AHRQ reports there are no studies that mention safety or specifically research patient safety in telehealth. Indirect evidence such as monitoring, prevention of acute care events or complications, testing the technology for comparison with in-person care, and outcomes research all allude to safety but do not address it specifically. It is clear that there is a gap in the literature and research evidence for telehealth specifically related to safety. However, telenurses and other health care professionals are continually struggling to increase the safety of their patients, increase the quality of health care, and decrease adverse events, although the evidence of the impact of these concepts is not apparent in the research.

The four themes that emerged upon review of the literature offer insight into the field of telehealth and the practice of telenursing. Although not noted or researched specifically, patient safety is an important part of the diagnosis, monitoring, outcomes, and technical tools used in telehealth practice.

Diagnosis and Teleconsultation

A great deal of research has been done on the use of telehealth for diagnosing disease. It has been shown that diagnosis of disease using telehealth is successful (Evidence Table 1). For example, Schwabb and colleagues[10] found that the remote interpretation and diagnosis with electrocardiogram results was just as good as interpretation in person. Additionally, telehealth has successfully been used as a tool for diagnosing acute leukemia.[11]

In addition to diagnosis, educational sessions for providers, as well as patient education and psychosocial counseling, have been researched. Telehealth has been shown to be a successful endeavor for education and counseling through two-way audio and video technology.[12–14] Providers of care also have seen great benefits from consultations through telehealth equipment. Similar to education and counseling, two-way audio and video technology has been researched and shown to be beneficial for consults between providers.[15] For instance, home health nurses may use telehealth equipment to consult with specialists, or physicians may consult with each other regarding a particular patient.

Monitoring and Surveillance

Compliance and adherence problems are among the many issues that are important to achieving patient safety. After a patient leaves a provider's office or a hospital, the patient is responsible for his or her own health care at home. Patients often do not follow a treatment plan as directed by a physician or provider due to several factors, including: miscommunication or faulty understanding of the treatment plan, lack of access to facilities needed for the treatment plan, and a complex treatment regimen that the patient cannot comprehend without additional guidance.[16] This can cause negative outcomes and creates safety issues for the patient. Therefore, inventive and efficient telehealth-based methods of caring for patients are increasingly being used to improve compliance or adherence to the prescribed regimen of care, as well as for symptom management. Telehealth is one strategy for monitoring and communicating with

patients beyond the acute care setting. It has also had an impact upon health care utilization rates for acute care services (such as decreasing visits to the Emergency Department) in studies with limited sample sizes, although large randomized trials have not yet been reported (Evidence Table 2).

Adding to the problem of adherence in patients is a lack of access to quality health care, specialists, or nurses. With the current trend in outpatient care management, monitoring, and surveillance of patients, additional nurses are needed for the increasing number of home care patients and the increasing acuity of illnesses in these patients.[17] Further, patients who live in rural areas or in medically underserved areas may not be receiving the expert care that is needed.[18, 19] Traveling far distances to a treatment facility, time lost from work for treatment, and other responsibilities also contribute to the compliance issue.

To meet the patients' needs, and with the additional burden on nursing because of the current nursing shortage, many home care agencies are looking for innovative ways to care for a large number of patients. Telehealth technology offers increased productivity for nurses by decreasing travel time to remote areas, thereby increasing the average daily census.[20] Especially in rural areas, where driving time to patients' homes can take up the majority of a nurse's day, new time-saving and patient safety initiatives are imperative, leading to further adoption of telehealth in home care. Audio and video technology can facilitate remote home health monitoring between patients and caregivers.[17, 20] Often, peripheral devices placed in patients' homes—such as thermometers, sphygmomanometers, and stethoscopes—are connected to the telehealth equipment so telenurses can monitor clinical signs remotely. Nurses are able to spend more time on direct patient care rather than indirect care, resulting in better use of their time and education. Hence, telehealth and telenursing address barriers to quality health care that are created by geographic location and costs associated with lost time.

Clinical and Health Services Outcomes

The majority of research completed on outcomes after implementing telehealth has been related to chronic conditions such as diabetes, congestive heart failure (CHF), and chronic obstructive pulmonary disease (COPD). Often, morbidity and mortality are measured outcomes for these patients, and telehealth use shows better outcomes in these areas (Evidence Table 3).

More specifically, telehealth technology has been shown to be a successful method of telehealth intervention, inducing communication that has helped patients' HbA1c levels to decrease, as well as offering assistance to traumatic brain injury patients in transitioning from the hospital to the community.[16, 21]

In addition to the more widely used telehealth technologies, there are a number of devices and applications with specific functionalities that are making a difference in patient health care and safety as related to health outcomes. Glucoboy and Digiscope are two examples of these new technologies. The former is a diabetic tool in a video game cartridge format. The cartridge is inserted into Nintendo's Game Boy and has been shown to help children with the management of type 1 diabetes mellitus.[22] The Digiscope is a telehealth technology that allows for screening of diabetic retinopathy in a primary care physician's office rather than under the specialized care of an ophthalmologist.[23] These telehealth technologies have been shown to be practical alternatives to traditional care.

Technical Issues

Telehealth technology differs in every situation and can range from telephone calls postoperatively to preventing diabetic complications in children by using a popular video game system, to live, interactive voice and video patient education, to downloadable data devices used by patients with data interpreted by telenurses. Studies report various technology approaches used by various types of providers in different settings with diverse disease entities (Evidence Table 4).

For instance, telephone technology has traditionally been used as a telehealth mechanism. While using a technology that is already in place in many patients' homes, this technology can be used to deliver important aspects of health care, including education,[21] psychosocial therapy,[16] and emotional support.

One of the most common technology configurations for telehealth applications uses two-way audio and video, or teleconferencing equipment. This technology allows patients and caregivers to communicate effectively, while allowing caregivers the benefit of seeing the patient. Other technologies can be incorporated into the main audio and video equipment to transmit specific health care data such as blood pressure and heart rate. These technologies makes telenursing possible because data to support patient safety in home care can be retrieved from home telehealth devices if proper terminology and data standards are employed.[24]

One innovative technology that has recently begun to be studied would allow patients to be monitored remotely with even less of a time burden placed on the nurse and the patient. Infrared technology offers perhaps the most continuous method of telehealth monitoring equipment. Infrared scanners have been shown to be effective in reporting deviations from a daily routine.[25] With this technology, the monitoring of elderly or dependent patients is done from a remote location; patients can be monitored at home, in a nursing home, or in the hospital. Safety of the patient can be assessed without the patient purposely getting in front of a camera or logging on to speak to a nurse.

Evidence-Based Practice Implications

The research related to telehealth and telenursing practice has shown great benefits related to diagnosis and consultations, monitoring and surveillance of patients, clinical and health services outcomes, and technology advancement. Each of these areas have important patient safety concerns, and while not studied as a unique entity, patient safety themes have emerged throughout the literature. Telehealth is a unique field that uses innovative technologies to improve patient care and thereby improve safety. These technologies range from the telephone to ubiquitous computing and only promise more in the future. Special concerns related to patient safety emerge with each of these methods of health care delivery.

Technologies have evolved to offer more and broader capability for telehealth/telenursing practice. With telehealth technologies, patient adherence to care increases, access to care is improved, providers can network with each other, and the safety of patients can be monitored more closely in homes and alternative living facilities.

With telephone-based telehealth, there is relatively no cost to the patient and no technical setup required for a telehealth interaction. Most patients already have a phone in the home that can be used for sessions. However, telephone discussions are usually limited to education and counseling because there are no visual cues for the provider/telenurse.

Two-way audio and video increases the functionality of telehealth by allowing the telenurse/health care provider to see the patient. In addition, peripheral monitoring devices can be used by the patient to transmit clinical information to the remote provider. More patient education is required initially for the use of the equipment with this type of technology, and the initial investment costs for the telehealth equipment can be large. Further, the patient must have Internet access or transmission lines to accommodate the video equipment.

Products such as the Glucoboy are innovative technologies that have been researched and shown to be effective in helping diabetic children maintain a healthy lifestyle.[22] The new product has taken a monotonous, sometimes painful task and made it into a game for children. However, the cost of this technology and who bears the cost remain to be seen.

Finally, infrared technology and sensor technology promise to deliver remote monitoring capabilities into the hands of providers. This has implications for caregivers and even family members of a person who lives at a distance. Falls, injuries, or illness will be easy to detect using such a system, offering immediate care to patients. However, the continuous monitoring nature of these devices may prove to be an infringement of patients' rights to privacy, and therefore an ethical issue for health care providers to consider.

With telehealth, confidentiality also remains a concern and must always be considered. While technology is becoming more sophisticated, telehealth sessions remain as a confidential interaction between a provider and a patient. Enclosed rooms without traffic or others present are imperative to maintain privacy. Health care providers need to be conscious of who is in attendance for the session and respect privacy and confidentiality of the patient. Further, as the numbers of new and innovative technologies emerge, researchers and developers must remember the security of patient information, regardless of how it is transmitted. In the researched technologies, data are transmitted over secure lines. However, new wireless technologies, increased use of e-mail by providers, and the continual threat of computer viruses increase the need for security and confidentiality of patient data to remain in the forefront of telehealth.

The different platforms for telehealth are diverse, yet all increase the ability of telenurses to communicate with and receive data about their patients. Regardless of the specific telehealth technology utilized, the reliability and validity of data transmission is essential to the safety of patients. Further, accepted and proven nursing practice must not be compromised. It is imperative for nurses to see the telehealth technology as a medium for care, and not a tool to replace high-quality nursing practice. Patient safety will be maintained with telenurses who are able to focus on patient care and not the technology itself.

Research Implications

The possibilities for telehealth technology abound, although pitfalls are also a potential. Telehealth has evolved throughout the years, from the first telephone interventions to the present-day use of sensors and remote monitoring devices. Much research has been completed on telehealth technology; however, it can be expanded upon exponentially—and should be expanded to include safety as a variable in all studies.

New wireless technologies have introduced new options for telehealth, which include nanotechnology and artificial intelligence.[26] Both of these offer great possibilities for diagnosis and treatment. However, researchers have only begun studying the potential of these technologies that offer promises for future health care.

In the shorter term, increasingly sensitive and accurate peripheral devices are needed for clinical monitoring. While the technologies currently exist, many can be improved upon to ensure valid clinical results. Peripheral device use can also be expanded. Ubiquitous computing is an option that will allow for clinical monitoring at home or in the community without being intrusive to the patient.[26] There is a greater chance of adherence in patients with this type of technology; however, research will need to be conducted to confirm the expectations.

Telehealth technologies will continue to evolve, as technology has in other business sectors. Health care needs to commit to this progress in order to provide up-to-date technology and safe devices for patients. The majority of studies that were reviewed compared telehealth care vs. in-person care and involved patient monitoring. Overall there were some positive outcomes indicating the benefits of telehealth. However, patient safety issues were not the main focus of these studies. Only one article was found that directly focused on safety issues: That article provided important information on the safety of wireless technologies; however, it was not a research article. Further, in a recent conference funded by the Agency for Healthcare Research and Quality, telehealth nursing experts were brought together to create a national agenda for telenursing research.[27] Themes for future research included cost effectiveness, clearly identified populations, standard outcomes, and standard methodologies to support telenursing. Specific research agenda topics identified were chronic disease management, patient empowerment, and enhanced self-care. While patient safety is a faction of all of these topics, it was not included specifically as a research agenda topic for telenursing. Therefore, the review of the current literature as well as decisions for future research goals indicate a gap of information and future direction regarding patient safety issues related to the use of telehealth in clinical practice.

Conclusion

The scarcity of research evidence focused primarily on patient safety in telehealth may in part be due to a lack of understanding about the emerging safety issues associated with telehealth and telenursing. The safety issues identified for telehealth and telenursing extend beyond the limited view of the precision of the information.[28] Telehealth encompasses a wide range of applications, including teleconsultations, telediagnosis, telepharmacy, e-health via the Web, telephone triage/telephone advice, tele-emergency support, disease management, and telehomecare. The safety issues associated with telehealth are, in turn, more complex and include not only apprehension about malfunctioning equipment, but also concerns regarding potential adverse effects on patient management decisions through delayed or missing information, misunderstood advice, or inaccurate findings due to patient or caregiver error.[29] Further research is clearly needed in the arena of patient safety as it is directly related to telehealth practice.

Search Strategy

The majority of research studies to date have focused upon teleradiology, telepathology, telepsychiatry, and other medical uses of telemedicine technology for medical care and diagnosis. These studies were purposely not included in this review. The purpose of this literature review was to focus upon the safety issues associated with care delivered by and relating to telenursing. The search strategy and distillation process of the literature consisted of three primary activities: (1) identification of meaningful MeSH® search terms and searching in

PubMed®, (2) an alternative process for locating articles, and (3) identification and validation of safety and quality related themes.

Identification of Meaningful MeSH® Search Terms and Searching in PubMed®

The U.S. National Library of Medicine developed MeSH®, a controlled vocabulary for indexing articles, which is located in the MEDLINE®/PubMed® databases. It took several iterations of MeSH® terminology to produce references that reflect the scope of safety and quality issues inherent in telehealth. For example, a search using the MeSH® terms "safety" and "telehealth" produced 12 articles, only 5 of which dealt specifically with monitoring equipment safety issues related to telehealth. Furthermore, the details of the MeSH search indicated that it could not find the term "telehealth" or "telemedicine" and instead suggested terms like "equipment safety" and "health care technology." A further search of the PubMed® database yielded zero results for "telehealth" and seven journal titles for the term "telemedicine."

Alternative Process for Locating Articles

Two of the seven journals identified through PubMed were *Journal of Telemedicine and Telecare* and *Telemedicine and e-Health.* Volumes of these journals were hand culled to locate any articles related to telehealth and its related safety concerns. As these articles were located, the reference list of each was also reviewed and relevant articles flagged for further searching. Additionally, professional organization sites such as the American Telemedicine Association and the Telehealth Information Exchange were searched to locate references to telehealth and safety.

Identification and Validation of Safety/Quality Themes

One author conducted the search and located all of the articles included in this review. A total of 41 articles were found to have some relevance to telehealth and safety. After an initial appraisal of the articles, they were examined for semantic similarities and differences. Four themes emerged among the 41 articles: (1) diagnosis and teleconsultations, (2) monitoring and surveillance, (3) clinical and health services outcomes, and (4) technical/ethical issues. The articles were then distributed among the authors, and the themes were validated. Where appropriate, articles were redistributed from their initial category to a more appropriate category. The included safety and quality topics are described in Table 1, below.

Table 1. Safety and Quality Topics as Related to Telehealth

Number of Articles	Category	Included Topics
2	Diagnosis and teleconsultation	The use of EKG leads in diagnosis and Web-based decision support in the care of leukemia patients.
11	Monitoring and surveillance	Adherence issues among patients using telehealth technologies to manage asthma, medication regimen, and CHF.
19	Clinical and health services outcomes	The use of telehealth applications and telenursing for managing CHF and diabetes at home. The use of telehealth technologies for consults such as dermatology, cardiology, intensive care, and emergency care/trauma.
19	Technical and ethical issues	Questions surrounding interoperability of equipment, algorithms for applying telehealth development, and issues in developing various technologies.

It became clear to the authors that issues such as measuring return on investment are often tied to clinical outcomes; thus these studies were included in the review. Additionally, articles that addressed disparities to access in health care and the potential benefits of telehealth are included, as these articles address the prevention of safety problems.

Evidence Tables

Evidence Table 1. Diagnosis and Consultations Using Telehealth

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)	Category of Telehealth Article O = Outcomes M = Monitoring D = Diagnosis/ Consultation T = Technical/ Ethical
Belachel 2005[11]	Web-based clinical decision support tool	Changing practice projects/ research	Observational study with controls (Level 3) Other measurable variables with an indirect or unestablished connection to the target safety outcome (Level 3)	191 Acute leukemia cases from the database of Cliniques Universitaires Saint-Luc Brussels, Belgium	Web-based clinical decision support tool to virtually diagnose and support secure and timely electronic data exchange regarding acute leukemia.	The percentage of correct classification in this experimental testing was consistent with the proposed prototype. 96.4% of acute leukemia cases were correctly classified, proving that Web integration can be a promising tool for dissemination of computerized decision support system tools. The system is robust and capable of deployment for referring physicians.	D

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)	Category of Telehealth Article O = Outcomes M = Monitoring D = Diagnosis/ Consultation T = Technical/ Ethical
Schwaab 2005[10]	The study compared the accuracy of a 12-lead electrocardiogram (ECG) recorded by patients and transmitted to a cardiology call center via telephone (tele-ECG) with standard 12-lead ECGs.	Non-randomized trials	Nonrandomized control trials (Level 2) Surrogate outcomes (Level 2)	158 post myocardial infarction cardiac patients living at home with the capacity to communicate the tele-ECG via telephone.	Tele-ECGs were compared with standard ECGs by two cardiologists and one internist, independently and blindly.	In 155 of 158 patients (98%), the quality of the tele-electrocardiogram (tele-ECG) was adequate for diagnosis. Reliability coefficients ® for PQ, QRS, and QT intervals between tele- and standard ECG. Additionally, negative T-waves and ST segment detection was very good. Residual signs of myocardial infarction could be detected by tele-ECG, with very good agreement for anterior as well as for posterior localizations. The tele-ECG technique seems a promising approach to reducing pre- and in-hospital time delays to the initiation of thrombolytic therapy.	D

Evidence Table 2. Monitoring and Surveillance Related to Telehealth and Telenursing Practice

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)	Category of Telehealth Article O = Outcomes M = Monitoring D = Diagnosis/ Consultation T = Technical/ Ethical
Chan 2003[30]	Test the use of an Internet-based store-and-forward video home telehealth system to manage asthma in children	Prospective cohort study	Observational studies with controls (Level 3) Surrogate outcomes (Level 2)	Pediatric patients ages 6–17 years with persistent asthma were recruited from among the population of patients with asthma in pediatric clinic at Tripler Army Base, Honolulu.	The use of an Internet-based store-and-forward video monitoring system for patients with asthma, and followup with virtual visits via the Internet in comparison to in-person office visits.	No overall change in quality of life reported by patients. However, the caregivers in the virtual followup group reported an increase in the patients' quality-of-life survey scores. Emergency department visits and hospital admissions for asthma were avoided. Rescue therapy was infrequent. A high rate of satisfaction with home telemonitoring was reported. Internet-based, store-and-forward video assessment of children's use of asthma medications and monitoring tools in their homes appeared effective and well accepted.	M

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)	Category of Telehealth Article O = Outcomes M = Monitoring D = Diagnosis/ Consultation T = Technical/ Ethical
Fragou 2005[31]	Adherence to medication regimen	Randomized controlled trial	Randomized controlled trial (Level 1) Clinical outcomes (Level 3)	108 diagnosed schizophrenic outpatients, part of the South London and Maudsley NHS.	Telementoring using a new platform called @HOME, which offered clinicians early warnings about impending nonadherence as well as information about the pattern of medication taking.	In comparison to the other two groups, patients using @HOME showed improvement in the Global Clinical Impression Scale and a significant reduction in emergency visits and medical appointments.	M
Gilbert and Sutton 2006[32]	N/A	Randomized controlled trial (Level 1)	No outcome relevant to decreasing medical errors/ adverse events.	1,457 callers to Quitline (smoking cessation program) were randomly allocated to a control group to receive usual care or to a repeated contact group to be offered abstinence 6 & 12 months after recruitment, quit attempts and 24 hours of periods of abstinence in nonquitters.		Proactive telephone counseling did not significantly decrease abstinence from smoking rate.	M

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)	Category of Telehealth Article O = Outcomes M = Monitoring D = Diagnosis/ Consultation T = Technical/ Ethical
Lamothe 2006[17]	Increased need for home care services	Non-comparative studies	Observational studies without controls (Level 4) No outcomes relevant to decreasing medical errors and/or adverse events (Level 4)	Patient homes in Quebec and Manitoba, Canada; patients with chronic illness.	Telehomecare monitoring, including disease measurements.	Positive impacts on patients and health crisis prevention.	M
Manfredi 2005[33]	N/A	Observations	No outcome relevant to decreasing medical errors/ adverse events	15 inmates were assess & treated in 37 consultations. Subjects were young white males.	Interactive two-way audio-video communication between the psychiatrists & inmates.	Services were readily accepted by inmates and staff. Telepsychiatric examinations & treatment appear to be a feasible method to increase access to mental health care in rural jails.	M
Marinella 2006[34]	Use of telemedicine to monitor patients and deliver care.	Observation, convenience sample	No outcome relevant to decreasing medical errors/ adverse events.	14 Spinal cord injury (SCI**)** patients at home after discharge from James Peteres VA Medical Center.	Monitoring patients for safety, home accessibility, exercise by messaging device or videophone on weekly basis.	Office visits increased, hospitalization and length of stay decreased. Poor reliability of monitoring device was identified as an obstacle.	M

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)	Category of Telehealth Article O = Outcomes M = Monitoring D = Diagnosis/ Consultation T = Technical/ Ethical
Prince 2005[35]	Seniors will be able to safely age in place with use of telehealth	Literature reviews/ narrative	Design (Level 4) Outcomes: telehealth technology and services (Level 4)	Review of previous research and reports of safer and longer aging in place for seniors when using telehealth technology and services.	Telehealth can delay nursing home care, support aging in place at home, and provide in-home monitoring and health care services.	Telehealth has been successfully used in hospital specialty areas to provide health care services. Research points to benefit of seniors use of telehealth in a systematic fashion to acquire services and information so they may age in place in their homes safely and with a good quality of life.	M
Rogers 2001[36]		Randomized controlled trial (Level 1)		121 adults with essential hypertension.	A home service consisting of automatic transmission of blood pressure data over telephone lines, computerized conversion of the info into report forms, & weekly transmission of the report forms to physicians and patients.	Telecommunication service was efficacious in reducing the mean arterial pressure of patients with established essential hypertension.	M

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)	Category of Telehealth Article O = Outcomes M = Monitoring D = Diagnosis/ Consultation T = Technical/ Ethical
Rotondi 2005[37]	Descriptive study of provision of Web -based support services/ information to families of patients with traumatic brain injury (TBI) to improve their patient outcomes, to include safety	Nonrandomized trial	Observational study without controls (Level 4) Self-reports of satisfaction and Web utilization (Level 3)	17 female caregivers of patients with TBI were provided access to Web site for support/services from home.	Study evaluated use of WeCare Web site for information, answers to questions, and support group with other caregivers for those with TBI.	Caregivers used support group as the most frequent function on the Web site. There is strong correlation between caregiver capability and patient outcomes for TBI patients, to include safety outcomes of TBI patients who may have gait or motion dysfunction as a result of their injury.	M
Savard 2003[38]	No outcome relevant to decreasing errors/ adverse events	Case observations, two rehabilitation centers, convenience sample	No outcome relevant to decreasing medical errors/ adverse events.	117 teleconferences with 75 patients ages 9m–-86 yrs. (38 of the visit were with neurological diagnoses.)	High-speed video conferencing with real-time audio-video communication.	Care of individuals with neurological issues can be supported.	M
Smith 2006[14]	Adherence with sleep apnea treatment—Continuous Positive Airway Pressure (CPAP)	Randomized controlled trial	Randomized controlled trial (Level 1) Surrogate outcomes (Level 2)	In-home patients with nonadherence to CPAP regimen.	Telehealth educational sessions.	Increased use of CPAP in the group with the telehealth education sessions regarding CPAP.	M

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)	Category of Telehealth Article O = Outcomes M = Monitoring D = Diagnosis/ Consultation T = Technical/ Ethical
Wang 2005[39]	A feasibility study on an Internet-based compliance system to provide personalized care for patients suffering from chronic diseases.	Changing practice project/research	Observational studies with controls (Level 3) Other measurable variables with an indirect or unestablished connection to the target.	The study monitored the chronic disease management of oral anticoagulation treatment in Spain, asthma care in the United Kingdom, and morbid obesity care in Greece in 25 patients residing at home with access to a personal computer and an Internet connection.	The C-Monitor System consisting of an integrated service aimed at monitoring patients' adherence to therapy at home via the Internet.	Health care providers credited the C-Monitor in helping with the adherence in disease management as determined by the system's ability to create personalized therapeutic schemes, provide an efficient communication channel between providers and patients, and offer satisfactory monitoring of patients' adherence with treatment and their physical status. The performance of the system was assessed by all participants. Most of the patients and physicians agreed that C-Monitor system provided a more valuable service than the traditional ambulatory system and would like to use the C-Monitor service in the future for disease management. Suggestions for improvement of the system were offered by both types of participants.	M

Evidence Table 3. Outcomes Related to Telehealth and Telenursing Practice

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)	Category of Telehealth Article O = Outcomes M = Monitoring D = Diagnosis/ Consultation T = Technical/ Ethical
Adkins 2006[16]	Type 1 diabetes adherence	Pre- and post-test	Observational studies without controls (Level 4) Surrogate outcomes (Level 2)	In patients' home: patients ages 7–18, elevated HbA1c levels and/ or DKA within the last year.	Telephone therapist intervention.	HbA1c levels decreased for patients when they received the telephone intervention.	O
Bunn 2005[40]	The effects of telephone consultation and triage on safety, service use, and patient satisfaction was examined.	Systematic literature review	Randomized controlled trials (Level 1A) Clinical outcomes: morbidity, mortality, adverse events (Level 1)	The researchers reviewed randomized controlled trials, controlled studies, controlled before/after studies, and interrupted time series of telephone consultation or triage in a general health care setting; however, the majority of studies were in primary care.	The researchers searched registers such as the National Research Register, Cochrane Central Register of Controlled Trials and searched databases like PubMed, EMBASE, CINAHL, SIGLE. A list of identified studies and review articles was produced and verified by two independent reviewers.	The findings are mixed. There was inconclusive evidence about the frequency of return visits to general practitioners (GPs) and in the reporting of accident and emergency department (ED) visits. Although telephone consultation appears to have the potential to reduce unnecessary visits to the GP or ED, questions remain about its effect on service use. Further rigorous evaluation is needed with emphasis on service use, safety, cost, and patient satisfaction.	O

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)	Category of Telehealth Article O = Outcomes M = Monitoring D = Diagnosis/ Consultation T = Technical/ Ethical
Dale 2004[41]	The safety of nurses and paramedics offering telephone assessment, triage, and advice as an alternative to immediate ambulance dispatch for emergency ambulance service callers with "nonserious" problems was examined.	Randomized controlled trial	Randomized controlled trial (Level 1) Clinical outcomes (Level 1)	635 patients treated by ambulance services in London and the West Midlands, UK, were the subjects. A multidisciplinary expert clinical panel reviewed data from various ambulance and ED records and call transcripts for patients triaged by nurses and paramedics. Calls were placed into categories that indicated if the dispatch of an ambulance was necessary or not. All cases for which one or more members of the panel rated that an emergency ambulance should have been dispatched were further re-reviewed for an assessment of the "life risk" that might have resulted.	The intervention comprised nurse or paramedic telephone consultation using a computerized decision support system to assess, triage, and advise patients whose calls to the emergency ambulance service had been classified as "nonserious."	From the 239 usable cases, in 237 cases the majority of the panel concurred with the nurses' or paramedics' triage decision. Telephone advice may be a safe method of managing nonemergency (category C) calls. Further study is needed to exclude the possibility of rare adverse events.	O

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)	Category of Telehealth Article O = Outcomes M = Monitoring D = Diagnosis/ Consultation T = Technical/ Ethical
Dang 2006[42]	Care coordination using telehealth reduces hospitalizations, thereby reducing exposure to medical errors	Pre- and poststudy	Design (Level 2) Outcomes (Level 3)	59 chronically ill VA patients. Outcomes were hospital admissions, bed days of care, number of emergency room visits, number of outpatient visits.	Telecare management via an Internet-based home messaging device and whether it can impact health care utilization rates.	Significant reduction in hospital admission and number of emergency room visits occurred pre- to post-6 months with use of telehealth care management. Significant reductions in acute care utilization rates among chronically ill patients imply a reduction in medical error rates since exposure to acute care is less.	O

Finkelstein 2006[43]	A study that examined patient outcomes and cost when home health care was delivered by telemedicine or by traditional means for patients receiving skilled nursing care at home.	Randomized clinical trial	Randomized controlled trial (Level 1) Clinical outcomes (Level 1)	53 rural Minnesotans participated. Candidates for TeleHomeCare had to be (1) eligible to receive skilled home nursing care for either congestive heart failure (CHF), chronic obstructive pulmonary disorder (COPD), or chronic wound care; (2) able to use the equipment or have a supportive care partner who could do so; (3) live in a technically functional home environment.	There were two separate interventions with two intervention groups. In group a, video intervention and traditional skilled nursing care at home was used, and the second group received traditional skilled nursing care at home, virtual visits using video-conferencing technology, and physiologic monitoring.	There was no difference in mortality between the groups. Morbidity, as evaluated by changes in the knowledge, behavior, and status scales of the Omaha Assessment Tool, showed no differences between groups except for increased scores for activities of daily living at study discharge among the intervention groups. The average visit costs were $48.27 for face-to-face home visits, $22.11 for average virtual visits (video group) and $32.06 and $38.62 for average monitoring group visits for CHF and COPD subjects, respectively. The findings showed that virtual visits between a skilled home health care nurse and chronically ill patients at home can improve patient outcome at lower cost than traditional skilled face-to-face home health care visits.	O

Grady and Melcer 2005[44]	N/A	Retrospective record review. Non-randomized trials	No outcome relevant to decreasing medical errors/ adverse events	Service members & their adult family members of National Naval Medical Center.	Telemental health care via video-conferencing vs. care provided in person.	Telemental health care improved adherence, & shorter times to next followup appointment.	O
Grigsby 2005[45]	A meta-analysis of the home telehealth literature using a systematic application of a health services research (HSR) method for assessing the impact of telemedicine on access, quality, and cost of care.	Meta-analysis	Randomized controlled trial (Level 1A)	The criteria for inclusion included the use of telemedicine as a substitute for home visits by nurses and the use of information technology in the management of chronic conditions in the home environment.	A comprehensive model for the evaluation of telemedicine based on an applied research matrix consisting of: cost of care, quality of care, and access to care as used in HSR.	Despite its limited use in telemedicine, the scope of HSR is broader than that of clinical trials, with a focus on the system of care; its acceptance by the users; and outcomes, costs, and access. The methods of HSR provide a valuable analytical framework for the assessment of telemedicine and to discern the real merit of telemedicine.	O

Heizelman 2005[46]	Comprehensive review and synthesis of the literature concerning clinical outcomes associated with various telemedicine applications.	Systematic literature review	Randomized controlled trials (Level 1A)	Inclusion criteria were based on Donabedian's Medical Care process as defined by clinical care processes (diagnosis, clinical management, and clinical outcomes) and user satisfaction.	Key terms were used in searching the PubMed Web site to identify published studies in peer-reviewed journals that focused on the care process and outcome in telemedicine. Inclusion criteria included (1) published between 1996 and February 2004, (2) contained an abstract, (3) had a control group, and (4) not limited to voice communication only.	There were 356 articles analyzed. 160 studies related to diagnosis, 61 studies related to clinical management and clinical outcomes, and 168 studies dealt with user satisfaction. Most clinical outcomes studies to date have focused on diagnosis and patient satisfaction. A few studies investigated telemedicine's effects on clinical management or patient-oriented clinical outcomes. Diagnostic accuracy seems to be well documented in radiology, dermatology, pathology, and ECG interpretation. Psychiatric diagnosis is promising, but study sizes have been small, and ophthalmology diagnostics require further study. The most evidence for outcome and management appears to be with home/institution-based applications for CHF, diabetes, and blood pressure monitoring. Among clinic- or hospital-based applications, the fields of dermatology, cardiology (i.e., echocardiography), and intensive care and emergency care/trauma have stronger evidence for their benefit. Overall user satisfaction is well demonstrated, especially in the areas of psychiatry, dermatology, and other multispecialty applications.	O

Henault 2002[47]	Communication between care-givers for long-term diabetes management	Case control studies	Nonrandomized controlled trial (Level 2) Surrogate outcomes (Level 2)	VA Boston Healthcare System, male diabetic patients with elevated HbA1c levels.	Using e-mail for communication of recommendations from pharmacist to primary care provider.	Intervention and control groups both had a decrease in HbA1c levels.	O
Hilty 2004[48]	Telepsychiatry clinical and educational videoconferencing applications are equal to or better than in-person and also reduce health care utilization	Meta-analysis	Design (Levels 1 thru 4) Outcomes (Level 3)	Review of telepsychiatry studies from January 1, 1965, to July 31, 2003, containing the terms videoconferencing, telepsychiatry, telemedicine, effectiveness, efficacy, access, outcomes, satisfaction, quality of care, education, empowerment, costs.	All 110 telepsychiatry studies that mentioned videoconferencing were reviewed.	Telepsychiatry is effective and has been successfully used to increase access to care, provide patient and provider satisfaction in general, improve outcomes of care, and empower those using it. Further research on impact on patient outcomes is needed. Reduced hospitalizations and decreased use of acute services are two key findings that point to impact on hospital-based medical errors.	O
Hopp 2006[49]	Clinical outcomes with telehealth use; research for evidence-based practice	Randomized controlled trial	Randomized controlled trials (Level 1) No outcomes relevant to decreasing medical errors and/or adverse events (Level 4)	Veterans Affairs Center home care patients.	Interactive telehealth with voice and video and some peripheral attachments for home care patients.	High level of patient satisfaction and health-related quality of life (HRQOL) scores; trend toward decreased outpatient health visits with the intervention group.	O

Joseph 2006[50]	The Veterans Health Administration (VHA) evaluated a care coordination program for diabetic, CHF, COPD, and mental health chronically ill patients using technology to promote self-management.	Changing practice projects/ research	Observational studies with controls (Level 3) Surrogate outcomes (Level 2)	Enrollment in the program began by identifying patients with frequent ED visits or frequent admissions. Additionally, patients with hemoglobin A1c greater than 10 were identified. Following identification, collaboration from the primary care provider was obtained and the patient contacted to request their involvement in the program. Patient had to have a standard plain old telephone system (POTS), electrical service to the house, and be agreeable to monitor and transmit data daily.	Patients were asked to answer a series of questions about their health status and habits using a digital messaging unit placed on their phone line. In some instances ancillary monitoring devices (i.e., glucometers) were directly connected to the messaging device or the patient entered the results information. This information was transmitted to the care coordinator, who would note abnormalities and contact the physician and monitor the patient closely for followup care.	Defined clinical and utilization outcomes were defined and compared to the findings for ED visits and bed days (utilization) and hemoglobin A1c measurement for all diabetic patients, low density lipoproteins (LDL) levels on patients followed for hypertension, diabetes, and CHF (clinical). There were no statistically significant findings; however, care coordination efforts have demonstrated improved glycemic control for diabetic patients, improved lipid management, and decreased use of costly resources, such as ED visits and hospitalizations. The authors concluded that substantial gains in both clinical and resource outcomes have been shown.	O

LaFraboise 2003[51]	A pilot study to determine the feasibility of providing a heart failure disease management program through an in-home communication device, Health Buddy.	Randomized clinical trial	Randomized controlled trials (Level 1) Clinical outcomes (Level 1)	90 home care patients capable of living independently who had been discharged from the hospital within 6 months with a primary diagnosis of heart failure.	The intervention, a telecommunication device named Health Buddy, was compared with traditional methods for home management of heart failure, including in-person visits and telephonic case management.	Confidence in managing disease, quality of life index, functional status, and depression were measured in each of the clinical trial groups. Patients who received telephonic case management experienced decreased confidence in managing their disease; all other groups experienced increased confidence. Functional status, depression, and quality of life did not differ among the groups. The findings suggest that using telehealth to manage home care for heart failure is feasible; however, further study is needed to determine differences that might exist between various treatment methods.	O

McCue and Palsbo 2006[52]	A demonstration of the business case for telemedicine in nonrural areas was shown. The study differed from earlier investigations in that return on investment did not include the variables of provider or patient travel time.	Changing practice project/ research	Observational studies with controls (Level 3) Other measurable variables with an indirect or unestablished connection to the target safety outcome (Level 3)	The case study of poststroke rehabilitation in urban settings in Oklahoma.	Interactive spreadsheet was used to conduct multiple financial analyses under different capital investment, revenue, and expenses for poststroke rehabilitation services to urban patients, including five speech-language pathology (SLP) provided to poststroke patients over videophones or videoconferencing equipment and two physical therapy (PT) codes (individual activities and physical therapy evaluation).	The outcome measures were financial breakeven points and internal rate of return. It was found that a Total of 340 telemedicine visits has the potential to generate a positive net cash flow each year. By the fourth year, this type of service can produce a positive present value return of more than $2,000, and earn rate of return of 20%, which exceeds the hospital's cost of capital. Thus business case was demonstrated. Urban telemedicine programs can be financially self-sustaining without accounting for reductions in travel time by providers or patients.	O

Reardon 2005[53]	A comprehensive review of telemedicine cost research and major issues affecting the yield from this research.	Systematic literature review	Randomized controlled trials (Level 1A)	The criteria for inclusion included studies with major analytic components of health care services cost evaluations, cost analysis decision framework, and methods of inference that affect the quality and productivity of telemedicine cost research.	Keywords evolved from first considering previous studies and then using keyword and database selection strategies to augment the literature. This approach is referred to as iterative triangulation. These terms were used to create a database of keywords, which resulted in overlapping sets of literature. The database of resulting articles consisted of 1,430 telemedicine articles. Sources for the studies were varied and included the NLM Database, CINAHL, Journal of Economic Literature, and AHRQ.	This review supports previous conclusions on the potential net savings to society through specific uses of telemedicine. Most specifically populations in remote areas, in prisons, or on ships may have reduced total cost of care by accessing it through telemedicine. However, these specific reported gains in the cost effectiveness of telemedicine depend on the reduced cost of access to care. Specifically, the greatest potential for cost savings from telemedicine seems to be the production of health or wellness. When study outcomes are measured as health maintenance or wellness, as is usually done in home care, potential savings, especially for high-risk chronically ill patients, are seemingly greater. The review also concludes that the productivity of telemedicine cost studies suffers from an underutilization of appropriate program evaluation and economic methods. Better consensus guidelines and best practices on costs can provide common benefits to cost research and are needed to accurately	O

Slater 2005[22]	Type 1 diabetes noncompliance	Pre- and post-test	Observational studies without controls (Level 4) Surrogate outcomes (Level 2)	In the community, children with type 1 diabetes and their parents.	Use of Glucoboy device for monitoring blood sugar levels.	Testing adherence increased by 200%; HbA1c levels were lowered.	O
Wu 2005[54]	This pilot study evaluated the feasibility and patients' acceptability of using the Internet to communicate with patients with symptomatic heart failure.	Changing practice projects/ research	Observational study with controls (Level 3) Surrogate outcomes: observed error, intermediate outcomes (e.g., laboratory results) (Level 2)	62 home care patients with symptomatic heart failure were enrolled into the program and instructed how to use the Internet communication tool.	The study measured the proportion of patients who used the system regularly for at least 3 months and the safety and maintainability of the tool. Additionally, researchers conducted a content analysis of patient and clinician messages.	The majority of the patients quit using the system; however, 45% of the patients used the system and continued to use it on average for 1.5 years. In a 3-month time period there were over 5,000 entries made by patients. The content analysis of a subset of the patient comments revealed the following major categories of communication: patient information, patient symptoms, patient questions regarding their condition, patient coordinating own care, social responses. The study concluded that an Internet tool is a feasible and safe method of communication in a substantial proportion of patients with heart failure.	O

Diabetic patients who are not receiving recommended eye examinations.	Use of DigiScope imaging.	DigiScope implementation is shown to be a practical alternative for patients not receiving routine eye examinations	T

Chapter 49. Documentation and the Nurse Care Planning Process

Gail M. Keenan, Elizabeth Yakel, Dana Tschannen, Mary Mandeville

Background

Tools are needed to support the continuous and efficient shared understanding of a patient's care history that simultaneously aids sound intra- and interdisciplinary communication and decisionmaking about the patient's future care. Such tools are vital to ensure that the continuity, safety, and quality of care endure across the multiple handovers made by the many clinicians involved in a patient's care. A primary purpose of documentation and recordkeeping systems is to facilitate information flow that supports the continuity, quality, and safety of care. Since recordkeeping systems serve multiple purposes (e.g., legal requirements, accreditation, accountability, financial billing, and others), a tension has arisen and is undermining the primary purpose of the record and instead fueling discontinuity of care, near-misses, and errors. Among the more specialized types of documentation is the plan of care, a requirement of the Joint Commission.[1, 2] Though planning and plans should facilitate information flow across clinician providers there is little generalizable evidence about their effectiveness.

In the first part of this chapter, evidence from studies on nursing documentation, care plans, and interdisciplinary plans of care is presented and synthesized into a framework for the Hands-on Automated Nursing Data System (HANDS) method. The method is an intervention that addresses the need for broad-based standardization of key aspects of documentation and communication to facilitate patient-centric information flow. HANDS standardizes the plan of care documentation and processes by replacing the current widely variable forms. It supports interdisciplinary decisionmaking that is based on the shared knowledge from clinicians. Finally, a case study presenting the history and future plans for the ongoing refinement of the HANDS method is presented.

Research Evidence

Recordkeeping Practices of Nurses and Nursing Documentation

Information work is a critical part of the medical endeavor. Strauss and Corbin[3] note that trajectory work, as they view medical care, requires information flow before and after each task or task sequence to maintain continuity of care. Tasks are not isolated but are intertwined and build on one another to achieve patient goals. Nurses bear a large burden in both managing and implementing the interdisciplinary team's plan for the patient, as well as documenting the care and progress toward goals. As a result, nurses spend considerable amounts of time doing information work. There are several genres of nursing documentation studies: those that examine recordkeeping practices as a whole, those that examine issues relating to the documentation (time, content, completeness), and comparative evaluations of different types of changes in the documentation regime including automation versus paper. Taken together, these provide both

detailed and broad knowledge of nurses' recordkeeping practices and highlight the reasons why any change (manual or computerized) is so difficult to integrate into nursing practice.

General Recordkeeping Practices of Nurses

Nursing documentation covers a wide variety of issues, topics, and systems. Researchers, practitioners, and hospital administrators view recordkeeping as an important element leading to continuity of care, safety, quality care, and compliance.[4–7] Studies, however, reveal surprisingly little evidence of the linkage between recordkeeping and these outcomes. The literature features multiple exhortations and case studies aimed at improving nurses' recordkeeping in general[8–10] or for specific diagnoses.[11, 12]

The literature also reveals the tensions surrounding nursing documentation. These include: the amount of time spent documenting;[13–15] the number of errors in the records;[9,16,17] the need for legal accountability;[18–20] the desire to make nursing work visible;[21] and the necessity of making nursing notes understandable to the other disciplines.[22, 23] For the purposes of this review, we confine ourselves to discussions of either manual or automated nursing systems of documenting patient care, primarily in hospitals. As we have found, while there are good and well-designed individual studies, the different methodologies, populations studied, and variables analyzed have led to little generalizability across the research, making comparisons between them impossible.

There are several literature reviews of nursing documentation systems. Urquhart and Currell[24] completed the most systematic and comprehensive review, examining the literature through 2004. They focus on nursing record systems as variations in the systems effect nursing practice and patient outcomes. Currell and Urquhart conclude that nurses experience tensions between patient care needs and hospital management-promoted documentation rules. They also found that the studies show both mixed responses to new systems and inconclusive links between the nursing documentation system used and its impact on patient care. Also noted was the lack of standardization among systems.[25]

In a more targeted literature review, Langowski[26] examined the relationship between quality health care, particularly safety, and point-of-care online nursing documentation systems. Unlike Currell and Urquhart,[25] Langowski found that overall documentation quality improved with an online electronic health record (EHR). The measures used, however, varied between the studies, and documentation impact on quality was assessed through evaluating the presence of certain types of information and the frequency of data entry. The accuracy of the information was not evaluated. Nurses' satisfaction with documentation systems has also been used as a measure of quality though the relationship between satisfaction and documentation is never clearly delineated. The variation in the definition and measures used for evaluating quality is characteristic of this literature.

The final review was carried out by Karkkainen, Bondas, and Eriksson.[27] They conducted a metasynthesis of 14 qualitative research reports to determine how well individualized patient care was represented in nursing documentation. Karkkainen and coworkers identified three themes in the literature reflecting the tensions in the record: demands of the organization, nurses' attitudes and duties, and the patient's involvement in care. This mirrors the findings of Currell and Urquhart. In conclusion, Karkkainen, Bondas, and Eriksson argue that individualized patient care is not visible in nursing documentation, and that current methods used to standardize communication in the records (forms with check-off lists) contribute to this gap. In another work, Karkkainen and Eriksson[28] note that, although standardized forms of documentation can enhance concise and directed information, poorly designed forms may enhance document content but do

little to support patient-centric care. The challenge is to design systems that are patient focused but also reap the benefits of standardization in terms of more accurate, precise, and up-to-date information transfer among all members of the interdisciplinary team.

Several single studies provide additional insight into nursing recordkeeping practices. Allen[29] examined nurses' views of the nursing record and its routine usage in practice. Using observations and interviews, Allen found that nurses were ambivalent towards the records, both seeing them as a symbol of the place of nurses in the clinical arena, but also reporting that the records are too heavily structured by management, a finding echoed throughout the literature (e.g. Lee and colleagues[30]). As a consequence, Allen points to the practice of nurses developing shadow documentation systems (informal nursing records and ward diaries) that help nurses maintain a high-level overview of the patient's care on one's shift.

In another qualitative study, Hardey and colleagues[31] observed nurses in five acute elderly care wards at a district general hospital in the south of England. They argue that "scraps," individualized information systems, contained a unique combination of personal and professional knowledge and changed dynamically in response to patient care on a shift. The main source of information in the scraps was information conveyed during the nurse handover. This finding suggests that scraps provide information not found in the patient record. Instead the scraps contain the summarized or synthesized version of the patient's story that includes only the information the nurse feels is needed to carry out care effectively on one's shift.

Ngin[32] picks up on the idea of information work as discussed by Strauss and Corbin[3] and provides an in-depth analysis of nurses' retrieval, interpretation, documentation, and passing of information. She, too, found that nurses relied less on the formal forms of documentation in the medical record and the care plan than on informal sources; her subjects preferred getting information directly from other nurses who had first-hand, observational knowledge of patients or from summary documentation, such as in Kardexes or personal notes. Ngin quoted nurses as saying, "The Kardex is a 'living document' which nurses have dubbed the Bible of nursing care. On the other hand, nurses tend to regard care plans as 'just a requirement'"[32] (p. 81). Ngin also differentiates between coordination of care (which she saw as the role of the Kardex, various worksheets, and more personalized information systems) and continuity of care (which she viewed as sustained by handovers).

In combination, these reviews and studies indicate that nursing documentation in the medical record does not meet the espoused purpose of being a communication tool that supports the continuity, quality, and safety of care. The evidence presented in this section also points to several conditions that perpetuate misunderstanding of nursing work and the means to track it. First, there is wide variation in recordkeeping practices between units and between health care organizations. Second, nurses heavily utilize shadow recordkeeping systems to aid in immediate patient care activities and decisions. Finally, there is an overwhelmingly negative attitude toward formal recordkeeping—either outright hostility or the view that documentation is "just a requirement."

Representativeness and Completeness of the Content

In several more targeted studies, the central issues of concern were how well the records reflected the care given and accuracy of the patient's condition. Tornvall and colleagues[33] audited EHR records and found that reports of medical status and interventions were more prevalent than nursing status. The authors concluded that nursing documentation was limited and inadequate for evaluating the actual care given. Ehrenberg and Ehnfors'[34] triangulation between

data from a chart review and interviews of nurses revealed little agreement between the records and the care nurses reported as having given. The researchers went so far as to state in their findings (p. 303) that "there are serious limitations in using the patient records as a data source for care delivery or for quality assessment and evaluation of care."[34]

Another set of studies examined the completeness of nursing documentation; these typically utilized chart review and audit as a methodology. The issue of completeness is important; Croke[35] cites failure to document as one of the six top reasons that nurses face malpractice suits. In terms of overall completeness, Stokke and Kalfoss[36] found many gaps in nursing documentation in Norway. Care plans, goals, diagnoses, planned interventions, and projected outcomes were absent between 18 percent and 45 percent of the time. Taylor[37] found that many of the care plans reviewed did not convey the specific information necessary to carry out the required procedure. One third of the nurses in this study mentioned accessing written documentation but did not express any preference for care plans.[37]

Other completeness studies have evaluated the impact of the form type and content required. In a controlled clinical trial utilizing a chart review method, Sterling[38] analyzed wound assessment documents from three different units. While more of the important details of wound assessment were recorded when using a wound assessment chart, missing information was found for both charting methods (conditions) in the study. In another controlled clinical trial with home care nurses, Tornkvist and colleagues[39] administered an educational intervention focusing on pain management. Their findings indicated that several statistically significant improvements in care were achieved after the introduction of the pain-advisers in the study units. Most pertinent to this chapter, the nurses' satisfaction with their written documentation on pain increased with the addition of several new types of assessments used for charting pain.[39]

While computerization has been referred to as a cure for incomplete records, the evidence on this is also mixed. Larrabee and colleagues[40] found that completeness increases over time after system implementation, with expected gains not being realized until 1 year after implementation. Care planning systems are also not immune from problems with the completeness of documentation. While Bjorvell and colleagues[41] reported increased completeness of documentation, particularly in the proportion of discharge planning notes, Griffiths and Hutchings'[42] audit of records from home health care nurses found initial nursing assessments poorly documented, affecting later care.

The studies in this section indicate two things. Completeness of a record may have an impact on the quality of care, but only if it reflects completeness of the right content. Echoed again here is that document focus, rather than the patient-centric nature of the medical record, does little to support shared understanding by clinicians of care and the communication needed to ensure the continuity, quality, and safety of care. The typical content and format of documentation—and its lack of accessibility—have also resulted in document-centric rather than patient-centric records.

Time Spent Documenting

Time spent documenting patient care is generally not regarded by nurses as being patient care, even though there is a Nursing Intervention Classification (NIC) term for it. Studies focused on time indicate that nurses spend a significant amount of time recordkeeping. In the most comprehensive literature review on time, Poissant and colleagues[14] reviewed 11 studies examining documentation time before and after moving from a manual to an online system. Of these studies, six reported a time savings when using a computer. There was up to a 25 percent savings by nurses charting with bedside systems. Three studies reported increased time,

particularly in the one study that employed handheld computers. However, of the three studies that assessed nurses' efficiency by using the patient as the sampling unit, the results were negative—more time was spent on documentation per patient after system implementation, with increases ranging from 7.7 percent to 128 percent. The authors propose that time efficiencies are gained by standardized forms in systems, although some systems require more information to be documented.[14]

Other studies have exposed the overall documentation burden carried by nurses. Hardey and colleagues[31] found that recordkeeping was given lower status and priority than was direct patient care. It was also viewed as excessively time consuming. Nurses regularly copied data from the medical record and other documents to create personal records that guided their activities. Korst and colleagues[13] conducted a work-sampling study over a 14-day period. Out of 2,160 observations, the average percent of time nurses spent on documentation was 15.8 percent; 10.6 percent for entry on paper records and 5.2 percent on the computer. The percentage of time spent on documentation was independently associated with day versus night shifts (19.2 percent vs. 12.4 percent, respectively). Time of day is also a factor in retrieving information.

The series of studies in this section indirectly expose the cost implications of maintaining medical records that offer little assistance to clinicians in the provision of patient-centric care. Moreover, maintaining medical records that bring little clinical value not only wastes nurses' time but also limits the time available to engage in value-added care activities. The cost implications alone justify a call-to-action to redesign documentation systems so that they are patient-centric and aligned with intended purposes.

Studies That Focus on Improving Documentation

Deficiencies in the nursing record, such as problems with accurately representing the patient, the time-consuming nature of recording, and the completeness of the record, have led to a series of interventions aimed at improving nursing documentation. The impetus for changing nursing documentation has come from several sources: hospital management, the nurses themselves, and nursing researchers. Compliance with legal mandates, paperwork reduction campaigns, and meeting professional standards are also common reasons for changing recordkeeping regimes.

The changes made to the documentation process to reach these goals vary broadly. Much of this literature is characterized by contradictory case studies. Scharf[43] reported a case study of one hospital that simplified a set of complex forms to enable nurses to spend more time caring for patients while still meeting the Joint Commission's documentation requirements. Another case study[44] involved a change from a preprinted form to a free-text, handwritten care plan for each patient. The studies reviewed include examples of those focused on understanding users' needs (through assessing attitudes and opinions) and those focused on implementing and evaluating interventions designed to improve documentation.

Dillon and colleagues[45] conducted a survey to assess nurses' readiness to adopt a new EHR. Their findings indicated that nurses had a positive overall attitude, although nurse age was a significant factor in determining nurses' attitudes regarding the EHR. Nurses were concerned, though, about the impact of the new EHR on quality health care delivery. In closing Dillon and coworkers noted that "these results clearly show that the nurses have real concerns about the new impending computer system and that the new system may be risky and might remove the human component of what they do"[45] (p. 144). For example, a comment made by one nurse reflected the concerns of many, "I just don't want the system problems to interfere with patient care." One of

her colleagues also commented, "I'm nervous about it [the impending system implementation]—hoping that it will not slow down my productivity—or be too time-consuming"[45] (p.144).

Other studies have used educational interventions designed to improve documentation alone or documentation and care. Karkkainen and Eriksson[46] completed a pre- and postintervention study, which involved an educational intervention to have nurses apply a theory of caring science to the care plans, to promote a more patient-focused documentation. Chart audit was done pre- and postintervention, and questionnaires assessed nurses' attitudes about this theory-based recording method. The major change observed was more attention by nurses to patient views and increased recording of these in the plan.[46]

Studies of computerized charting and care planning systems usually provide some measure for nurses' satisfaction. Two surveys of nurses' attitudes toward computerization are important to note. Axford and Carter's[47] study on how nurses believed computer technology impacted their practice is important in this regard. Their survey asked about resource consumption, nursing work practices, and professional and patient outcomes. Their findings indicated that nurses did not think technology would have a negative impact on practice. This was true for both those knowledgeable about computers and those less familiar with them— although the strength of this belief did vary, with experts feeling more strongly.

Other researchers have examined the effects of computers on nursing documentation directly. Nahm and Poston[48] did a quasi-experimental, modified time series study that measured the effects of the nursing module of a point-of-care clinical information system on nursing documentation and patient satisfaction. Data were collected before implementation, and after implementation at 6-, 12-, and 18-month intervals. Compliance with items applicable to nursing documentation in the JCAHO Closed Medical Review Tool was used to assess the quality of nursing documentation. Nahm and Poston found a statistically significant increase in the quality of nursing documentation after system implementation and a reduction in the variability of charting. Most importantly, charting compliance increased and continued at the 12- and 18-month time points after initiation of the new system. This indicates that change is incremental, and that longitudinal studies are critical to assess the impact of computer systems.

The body of the literature reviewed in this section provides evidence indicating that well-constructed interventions, such as education and revising formats (automation and forms), can enhance documentation and improve patient care. The evidence also suggests that there is a time-related pattern to user satisfaction, perceptions of value, and achievement of desired documentation outcomes following the implementation of new computer information systems. Nonetheless, the findings must be interpreted with caution due to wide variation of the settings examined, interventions applied, and methods of evaluation. As with all of the literature in this area, the main limitation is lack of generalizability, due primarily to the wide variation of documentation practices within and across organizations.

Nurse Care Planning and Plans

In health care organizations, the EHR, oral reports, handoffs, conferences, and health information technologies (HIT) are intended to facilitate information flow. In particular, the JCAHO specifically conceptualizes the care planning process as the structuring framework for coordinating communication that will result in safe and effective care.[2] The *Essentials of Baccalaureate Education for Professional Nursing Practice*,[49] drafted by the accrediting body the American Association of Colleges of Nursing, lists several core competencies that directly relate to the nurse's care planning process including the ability to "…diagnose, plan, deliver, and

evaluate quality care" (p. 11), "use appropriate technologies in the process of assessing and monitoring patients" (p. 14), "apply health care technologies to maximize optimal outcomes for patients" (p. 16), and "develop a comprehensive plan of care…" (p.16). Although there appears to be clear value to effective care planning and the process of communicating the plan, evidence of this in the literature lacks specificity.

The patient care planning literature encompasses a wide variety of concepts, studies, and interventions. The main subdivisions of patient care planning in the literature are advance care planning (care at the end of life), case management (working with the entire medical team and associated professionals), and critical pathways or protocols for treating specific diseases. As defined, these categories are all potential conceptual matches and should encompass nurse-related care planning and plans. The majority of the care planning literature, however, is disease-oriented or medically focused, with little attention to the actual judgments and actions nurses take in carrying out the interdisciplinary plan at the point of care. Nor does this literature evaluate the impact of nursing care on patient outcomes. We believe the following illustrates the content of literature related to nurse care planning and plans.

Several studies have been done focusing on the introduction of the Scandinavian VIPS (well being, integrity, prevention, safety) model into care planning. Ehrenberg and Enfors[34] performed a stratified, randomized controlled trial using chart audit and interviews. They reported that their study group that received a new form and educational intervention exhibited increased completeness and correctness of documented information, although there were still some areas in which the control group documented better than the study group.

Care plan findings from Mason's[50] qualitative study indicated that care plans were not thought to adequately represent the patient, and consequently were not used in the planning or evaluation of care. Observations conducted as part of this study confirmed that the major guides to practice were report, direct observation of the patient, and bedside charts. In these clinical units, the care plan was viewed as actually discouraging thinking, because the standardized formats hindered individualized care by operating as check-off lists that discouraged nurses from engaging in mindful care planning. In one unit, however, the care plans were successfully integrated with practice.[50] Nurses' attitudes toward care plans in this unit were generally positive and the plans were used to aid in explanation and communication, and to guide practice. In this unit, care plans were kept at the bedside. The success of nurses' adoption of the care plans was attributed to the fact that they were perceived as clinically driven, more representative of the patient's condition, and there was a sense of local ownership.

Smith and colleagues[51] studied the implementation of a computerized care planning and documentation system, using the NIC and nursing outcomes classification (NOC) framework. Data were collected through questionnaires, observations, and chart audits both before and after computer implementation. Post implementation data revealed that the nurses' attitudes toward computers were more negative and charting time was unchanged; however, chart audits revealed improvement in the completeness of the nursing record.

In research where the intervention has focused on changing the care planning process, findings have shown that patient outcomes can be improved. Implementation of a care pathway for post surgical patients, to streamline nursing care of postoperative colon resection patients, resulted in a statistically significant shorter length of stay.[52] In another controlled study, From and colleagues[53] found that new care planning forms, as opposed to a narrative written in the medical record, could be associated with earlier recognition of patient problems, a shorter length of stay, and a higher accuracy in planning the discharge time.

Other studies have reported finding previously noted problems in the care planning practices. Research on the effects of the NANDA International, Nursing Interventions Classification (NIC), and Nursing Outcomes Classification (NOC) terminologies in the care planning process has also shown mixed results. Scherb[53] found that nursing care did make a difference in patient outcomes. However, because the method of data capture, it was impossible to identify the nursing diagnoses and interventions that contributed to the positive patient outcomes.[54]

In a related study, Lillibridge[55] found that when nurses were asked to list the type of data they would normally collect using specific examination techniques, 23 percent provided nursing assessment details. It can be argued that if nurses were provided with an explicit nursing framework (and language) to document and communicate about their care that nurses and the interdisciplinary team members would more readily understand the importance and impact of nursing care and patient outcomes. Others have also found that the care plans typically do not reflect actual nursing practice.[56, 57]

Even when care planning interventions are similar, as in the case of the introduction of the Scandinavian VIPS method for nursing documentation, results vary among studies. Studies by Darmer and colleagues[58] show both more methodological rigor and more positive results. This controlled, longitudinal study introduced the VIPS care planning model to nurses on eight units (four study and control units, respectively). The intervention consisted of different educational interventions prior to utilizing the VIPS care planning model. Data included surveys of nurses' attitudes towards documentation and their knowledge of the new regime. Nurses in the study group had more confidence in their ability to create good care plans and did better than the control group on the knowledge tests. Overall, the nurses in the study by Darmer and coworkers were more positively predisposed towards documentation than those in another VIPS study, by Björvell and colleagues.[41]

The Björvell and colleagues[41] study also featured a VIPS intervention and results overall were positive. There was a statistically significant score increase in quantity (*P* values for the quantity variables ranged from $P < 0.0001 – 0.0003$) as well as quality of the nursing documentation (*P* values of the quality variables ranged from $P < 0.0001 – 0.0002$). In a followup study, Darmer and colleagues[59] reviewed 600 charts utilizing the VIPS model at four sites using a standardized audit tool. They found that nursing documentation significantly improved during the course of the study ($P = .00001$). After the second year, the participants used the keywords appropriately and correctly according to the VIPS model. Overall, this structured implementation program significantly improved nursing documentation.

Implementing a new care planning system without sufficient cultural, educational, and organizational support has been identified as leading to problems. Educational interventions, in particular, are a major focus in the literature. Hansebo and colleagues[60] found that although care planning documentation increased after an educational intervention, the level of assessment was low. The authors concluded that educational interventions were needed to improve clinical judgment.

Lee[61] also identified major educational issues associated with the implementation of computerized documentation systems. He argues that launching a care planning system alone, without knowledge of the diagnoses or how to use the care plans in clinical decisionmaking, limits their utility. For Lee and colleagues,[30] the new system also increased nursing workload, primarily due to a lack of computers, and competition for terminals with other professionals and students. In the end, the nurses found the care plan lacking in three aspects: (1) content, primarily the inability to individualize patient care; (2) poor system function; and (3) lack of system

integration with the other information technology systems. In another article, Lee and Chang[62] report on an interview-based evaluation of this system. In this latter study, the nurses interviewed saw the new system as paperwork and not patient-oriented.

The quality of and implementation strategy for care planning systems has impeded adoption as much as the actual care plan within the system. Ammenwerth and colleagues[63] found that planning and documentation of tasks ($P = .004$) and report writing ($P = .019$) required significantly more time with the computer based system than with the paper based system. For the care planning module, no statistically significant difference between the study and control groups was seen due to the limited number of items. At the conclusion of Ammenwerth and colleagues' study, seven nurses (58 percent) agreed that the PIK software application saved time for care planning, but only three agreed that PIK saved time for documentation of tasks or for report writing. The majority of nurses agreed that with PIK, nursing documentation is more complete (10 nurses), legibility is better (9 nurses), and that the quality of documentation is better (8 nurses).[63] However, Ammenwerth and colleagues did not tie these findings to patient outcomes or changes in nursing practice. The conclusion that the introduction of a care planning system alone, without supporting organizational change, will not work is also supported by Spranzo's[64] work.

In summary, the nurse care planning literature indicates several things. First, when thought goes into the care planning process, better patient outcomes are possible. Second, altering the care planning process has thus far been done in an ad hoc manner and most of the evidence is from case studies. Individualized approaches have been implemented in specific settings. Their replicability across patient care settings, even from acute care to stepdown units within one hospital, has not been tested. While supporting the continuity of care on an individual unit is good, the larger issue of increasing continuity of care across time and space (across units and health care settings) needs to be addressed if patients are to receive truly holistic care. Third, current approaches to care planning have focused primarily on the care planning document itself. While some studies[52, 53] have changed the care planning process, the focus has been the actual plan. Finally, when the care planning process has been computerized, there appear to be substantial system problems resulting from a lack of nursing input into the module's design and functionality.[30] Lack of nursing input has contributed to the failure of the nurses in these studies to embrace care planning and, at times, even to be able to judge whether a different care planning approach would result in better patient outcomes.

Towards an Interdisciplinary Plan of Care

Given the problems in developing a care planning system that works well for just nurses, it is clear why creating comprehensive systems that support interdisciplinary plans is that much more complicated. This is particularly true if Gage's[65] conception of interdisciplinary teams is utilized. He defines multidisciplinary teams as those in which consultation is a series of individual consultations, where interpretation is made independently by members of the medical team. On the other hand, interdisciplinary care planning occurs when the team collaboratively synthesizes the information and reaches consensus around treatment and goals for the patient. Much of the literature falls short of Gage's ideal and what is categorized as interdisciplinary care planning should more appropriately be viewed as case management.

The majority of articles on interdisciplinary care planning focus either on case management or clinical pathways. These emanate from specialties and areas that traditionally have had closer ties among a variety of professionals (doctors, nurses, social workers) to manage a patient's

condition. Typical among the case management genre are case studies of interdisciplinary care planning in nursing homes[66] or for the elderly.[67] The clinical pathways articles focus on a specialty or specific unit, such as acute care.[68] In one qualitative study of an interdisciplinary discharge planning process, Atwal[69] found that many parts of the discharge process were regularly ignored and assessments were not done collaboratively. Nurses mentioned lack of time as the biggest barrier to interdisciplinary collaboration. Interdisciplinary care planning and the resulting plan can bring value to patients and enrich all disciplines; however, in its current iteration the vision proposed by Gage has not yet become a reality.

Practice Implications

Though the literature in this area lacks generalizability, there are a number of important implications that can be drawn. First, the enormous variability in the documentation and care planning practices exposed in this literature is a serious problem in and of itself. Given patients typically receive care from a variety of points across the health care system, moving from place to place where record content and format is variable, renders current medical records virtually useless in supporting patient-centric care in day-to-day practice. Moreover, information about a patient, once recorded, is either not accessible or—if available—is often in an unstandardized format (e.g., clinicians' own words), resulting in countless errors of omission, misinterpretation, and redundancies in care. So too, most care planning methods are considered to bring little value and suffer from the same problems of poor design, poor accessibility, and no standardization. The lack of utility of the medical record in day-to-day practice begs the moral issue of whether the cost of maintaining the record in its current form (approximately 15 percent of a nurse's time) is justified. The dollars spent on maintaining the "broken medical record" would bring more value if shifted to fund developing and refining industrywide solutions to repair the broken record. Further, the literature suggests that to compensate for poor record keeping systems, clinicians develop individualized shadow methods (scraps, also not standardized) to assist with organizing what each believes to be key information needed to carry out patient care. Since these information practices are nurse-centric and therefore variable, shadow methods further impede the flow and easy accessibility of patient information that promotes care continuity, quality, and safety.

Finally, there are valid instances of successful education interventions that improve aspects of documentation and care. The examples, however, are all locally focused and consequently also do little to fix the broken medical record. We see the broken record as a serious and costly problem to the health care industry and one that deserves a patient-centric industrywide solution. There were no studies of industrywide solutions noted in the literature. Until there is a true commitment to developing and refining industry-wide solutions that ensure accurate and comprehensive documentation, facilitating patient-centric care, the improvements that are possible in the areas of safety, cost, quality, and continuity will not be fully realized.

Research Implications

The research imperative for further study of this problem is manifested by the current state of the medical record and the high cost being incurred to maintain it. One approach to improve medical records is a patient-centric approach, which redesigns the recordkeeping system, and

that will automatically ensure that the continuity, quality, and safety of care are a primary focus. From this review, there are several key questions that need methodologically rigorous research:

1. How does variability in documentation impact patient outcomes?
2. What are the key components of an effective documentation process that is patient centered and improves the transfer of information among clinicians and across settings of care?
3. What aspects of documentation are shared among an interdisciplinary team, and what contributions to the patient record can each team member effectively provide?
4. Should documentation vary across settings of care?

Conclusion

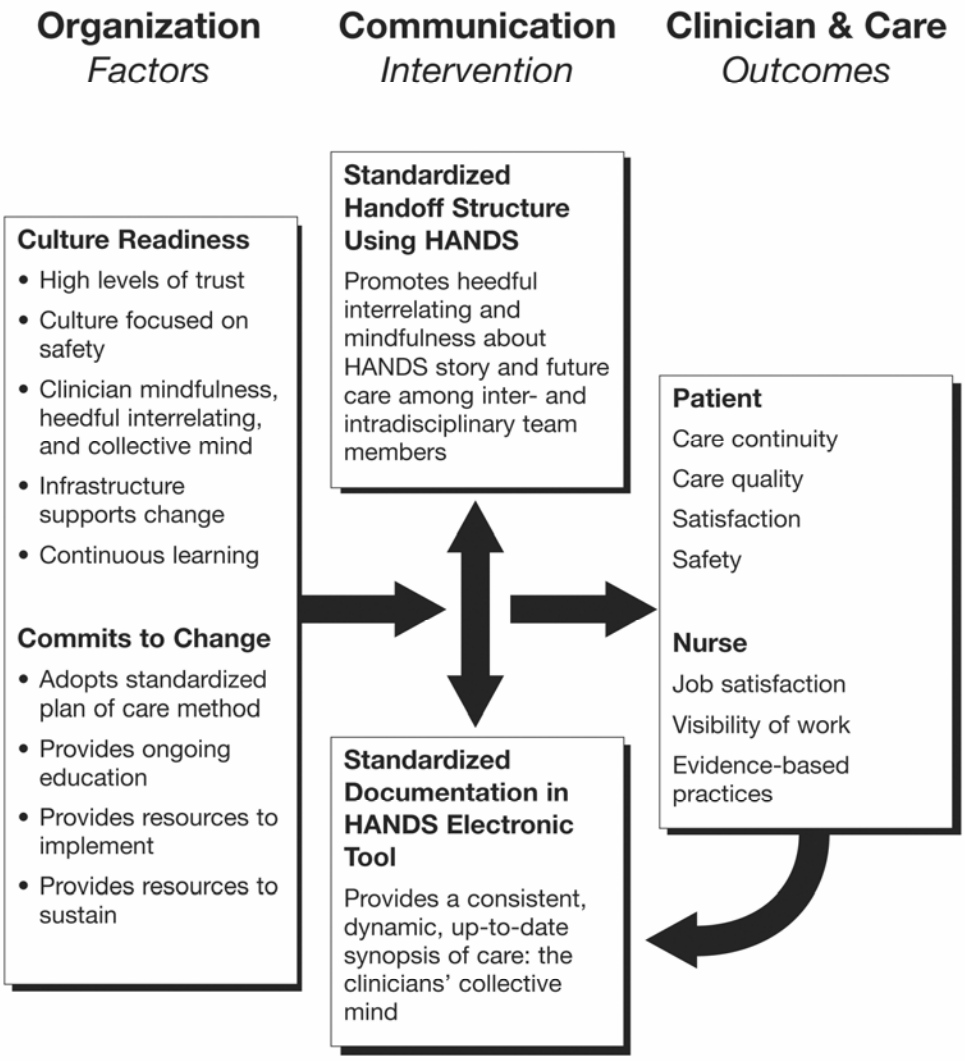
The evidence reviewed in this chapter suggests that formal recordkeeping practices (documentation into the medical record) are failing to fulfill their primary purpose, of supporting information flow that ensures the continuity, quality and safety of care. Moreover, disproportionate attention to secondary purposes (e.g., accreditation and legal standards) has produced a medical record that is document centered rather than patient focused. Cumbersome and variable formats, useless content, poor accessibility, and shadow records are all evidence of the extraordinary failure of the medical record. Given the exorbitant cost of the record and urgent need for tools that facilitate the flow of patient-centric information within and across systems, it is imperative to develop broad-based solutions.

Case Study: The HANDS Initiative and Plan-of-Care Method

The HANDS method is an intervention currently being refined to bring a strong patient focus to the medical record by replacing current forms of care plans with a single, standardized plan and related plan of care processes. The method addresses the needs, uncovered in this chapter, for summary patient care information that is standardized, meaningful, accurate, and readily available to all clinicians involved in a patient's care across time and space. The HANDS method embodies the concepts and characteristics of high reliability organizations and as such is fixated on ensuring the continuity, quality, and safety of patient care (See Figure 1: HANDS Method Framework, following this page).

As depicted in the framework, the central thrust of the HANDS plan-of-care method is to facilitate clinician behaviors (mindfulness) and communication (heedful interrelating) that form the basis of a collective mind among the clinicians (interdisciplinary team) involved in a patient's care. Organizations and systems factors must be aligned to support the mindfulness, heedful interrelating, and collective mind. The precursors to implementation of HANDS include culture readiness and a commitment to adopt and sustain the HANDS method (i.e., a commitment to change). Culture readiness is defined as an organization or system with an infrastructure that supports change and continuous learning, and is characterized by high levels of trust among its members and expectations that clinicians will engage in activities promoting mindfulness, heedful interrelating, and collective mind. Organization or system commitment to change is manifested by an organization or system formally adopting the HANDS standardized method for systemwide use, and by providing the necessary resources to educate, implement, and sustain the method across time. Finally, as is noted in the model, the patient care outcomes to be

Figure 1. HANDS Framework



HANDS = Hands-on Automated Nursing Data System

achieved by using HANDS and enabling mindfulness, heedful interrelating, and collective mind are safety, continuity, quality, and evidence based.

Earlier in this chapter, evidence from studies on nursing documentation and care plans as well as on interdisciplinary plans of care is presented and synthesized into a framework for the HANDS method. The method is an intervention that addresses the need for broadly based standardization of key aspects of documentation and communication, to facilitate patient-centric information flow. HANDS standardizes the plan-of-care documentation and processes, replacing the current widely variable forms, to support interdisciplinary decisionmaking that is based on shared knowledge among the clinicians. In this section, the history and future plans for the ongoing refinement of the HANDS method are presented.

This second part of the chapter focuses on the history of the HANDS Initiative and ongoing testing and refinement of the standardized plan-of-care method to date and future directions. The initiative addresses the gap previously identified in indicating the need for clinically relevant and patient-centric documentation and communication tools that support the collective mind (shared understanding) of the many clinicians involved in a patient's care across time and space. The project formally began in 1998[70] with the main purpose of bringing visibility, utility, consistency, and accessibility to the nursing portion of the interdisciplinary plan. As was previously noted, nursing care plans generally have brought little value in day to day practice due to the wide range of formats, lack of individualization and accessibility, and the infeasibility of keeping them current. During the initiative's early years the primary focus was on "perfecting" the format of the plan-of-care document through enabling technology and standardization. Through iterative refinement under real world conditions, we have learned that care plans, regardless of the quality of the document, bring little value unless they are an integral part of clinician-to-clinician (intra- and interdisciplinary) communication, serving as the basis upon which a collective mind among clinicians about a patient's care is formed. Our ultimate vision is to standardize the documentation and communication of a useful and dynamic interdisciplinary plan of care that is patient-centric, available, and used everywhere. In the following section, pertinent background information is presented, followed by a summary of the HANDS project accomplishments to date, future plans, and conclusions.

History of HANDS

The project began when our team of researchers attempted to use existing vendor software products to collect a nursing dataset coded with standardized terminologies, for a study of the Nursing Outcomes Classification in the mid-1990s.[71,72] The terminologies had been developed for the main purposes of representing nursing in health care databases and generating comparable nursing data for evaluating nursing practice. At the time, however, it became very apparent that, because of the wide variation in the practices used by vendors to integrate the terminologies into their systems, data was not comparable and frequently not retrievable. The HANDS initiative was thus born to remedy this situation and a prototype automated plan-of-care system with a database architecture that supported the generation of comparable nursing data was developed. It was clear to us, then and now, that the use of standardized terminologies alone is insufficient to produce comparable data. Instead, comparable data is generated when the same types of information are gathered at the same time intervals, using the same standardized response sets (standardized terminologies), same database architecture, and the same rules of data entry.

Standardized Nursing Terminologies

Since the late 1970s, efforts have been underway to identify nursing content and develop a means of representing it in computerized national health databases and clinical documentation systems. Werley and Zorn[73] first described a minimum set of elements needed in Nursing Minimum Data Sets, and they noted that content (terminologies) would need to be developed to represent the nursing-specific items of diagnosis, intervention, and outcome. It was projected that collection of the elements represented by standardized terminologies would provide comparable data that allowed multiple uses (e.g., describe, evaluate, trend, and benchmark nursing practice).[73] Subsequently, a number of terminologies have been developed to serve as response sets for nursing diagnosis, outcomes, and interventions. It is currently the purview of the American Nurses Association (ANA) Committee on Nursing Practice Information Infrastructure to set recognition criteria and formally recognize those terminologies meeting the established criteria. Over the years, the recognition criteria have been expanded and revised to align with the improvements in methods and tools for generating computable concept representations.[74] Unfortunately the Committee's actions have inadvertently confused the nursing constituency and thwarted progress toward achieving the vision of collecting comparable nursing data.

Since the early 1990s, the Committee on Nursing Practice Information Infrastructure has recognized more than one terminology (response set) for each of the data elements (diagnosis, intervention, and outcome), thus causing potential adopters to ask the question, "How are we going to get standardized data if nurses use different standardized languages?" The more recent recognition of entities (e.g., Systematized Nomenclature of Medicine Clinical Terms [SNOMED CT], and ABC Codes) that encompass content from the originally recognized nursing terminologies (NANDA, NOC, NIC, Omaha System, Perioperative Nursing Data Set, Clinical Care Classification, International Classification on Nursing Practice) has begged the question of how we are to use these recognized entities to achieve our professional goal of generating comparable nursing data. In truth, it is not clear how the 12 ANA recognized terminology entities can be used to generate comparable nursing data.[75]

The Terminology Solution in HANDS

From the beginning the HANDS project team grappled with how to create a long-term strategy that would generate professionwide, comparable nursing data when there was no professionwide commitment to a single terminology system. Given the circumstances of the time, we realized that professional consensus around a single terminology system was unlikely to occur in the absence of real time testing that demonstrated the value. We thus selected the terminology system with the broadest applicability—and that possessed characteristics indicative of its potential to grow and evolve over the long term—to be included in the HANDS method. The terminology system includes what is now called NANDA Classification,[76] NIC,[77] and NOC[78] to represent the diagnosis, intervention, and outcome data elements respectively gathered in HANDS. All three of the terminologies have infrastructures in place to maintain and evolve the terminologies across time. The NANDA, NOC, and NIC (N3) terminologies provide comprehensiveness of terms, in that each includes terms to describe care in all types of settings. Additionally, all have been developed through research involving literature review and the extensive input of large numbers of nurses.

The rate of diffusion of a new language can be accelerated by defining a clear direction and taking action. For example, usage of N3 in the 43 nursing programs in Michigan substantially

increased from1997 to 2001 following a resolution by Michigan Nurses Association to support N3 use in the State. NANDA usage remained high in 2001, with 92 percent of the schools of nursing (community college and university programs) indicating use. NIC usage rose from 22 percent to 58 percent and NOC usage rose from 0 percent to 58 percent between 1997 and 2001.[79]

Finally, there are several other points of evidence worth mentioning that indicate the long-term viability of the N3 terminologies within the nursing community at large. First, the N3 terminologies form a subset of SNOMED CT, the comprehensive clinical terminology. The SNOMED CT terminology is recognized by the National Centers for Vital and Health Statistics and the Consolidated Health Informatics Initiative as an acceptable standard for the Federal Patient Medical Record Information effort[80] and is an ANA recognized terminology.[75] Though nursing-specific terminology content is available in SNOMED CT, it is not the purview of SNOMED CT to keep the content current. Rather, the responsibility falls to nursing entities (terminology developers) to ensure that the quality and comprehensiveness of the terminologies is sustained and improved across time.

The N3 terminology developers are already taking responsibility for ensuring that the content is updated regularly, and that the terminology structures evolve in alignment with accepted standards for computable concept representations. As was previously noted, all three have strong internal structures for maintenance and updating of these terminologies, which have been in place for over a decade. The ongoing maintenance and support for NIC and NOC are provided through the University of Iowa-based Center for Nursing Classification and Clinical Effectiveness. To date, NIC has been translated into eight foreign languages and NOC into seven, indicating a growing international acceptance of these terminologies.[81] The ongoing maintenance and development of NANDA are provided by the NANDA International office at info@nanda.org. Every 2 years a joint N3 international conference is held at a central location in the United States to promote crosspollination of ideas that support continuous diffusion of these terminologies both nationally and internationally.

Another indicator of the long term viability of N3 is its growing and extensive presence in the literature. The technique for measuring such presence, bibliometrics, has been used in health care to evaluate the extent and rate of diffusion of an innovation.[82] For purposes of this chapter, a systematic search was conducted (with the help of CINAHL® personnel) to identify numbers of journal articles, complete books, and proceedings in which some aspect of the ANA-recognized, "nursing developed" terminologies (nursing content only) were a "major focus" between 1996 and 2006. The results appear in Table 3, and are organized by the nursing terminology system defined as providing terms for the data elements of nursing diagnosis, intervention, and outcome. Using this definition, there are five currently recognized ANA nursing terminology systems in addition to N3: the International Classification on Nursing Practice, the Omaha System, the Perioperative Nursing Data Set, the Clinical Care Classification, and (formerly) the Home Health Care Classification. Though the results must be interpreted with caution, it is readily apparent that there are major and substantial differences in the number of literature entries and trends between the N3 system and the others. Moreover, the number of entries for N3 appears to be growing rather than diminishing. Further analysis and interpretation of the findings will be presented in a forthcoming manuscript. Also of note is that the HANDS research conducted to date is providing evidence that N3 can be successfully integrated into a standardized, technology-supported care planning method, and generate comparable data to evaluate nursing practice.

The HANDS Initiative: Phase 1

Phase 1 of the HANDS project emerged in response to the absence of a path that would lead to the collection and generation of comparable nursing data. In this phase, our team focused on creating a standardized prototype of a dynamic, technology-supported plan that would generate comparable data. Our vision, then and now, is to evolve a useful care planning method that standardizes both the plan and the planning processes, is used widely, and generates standardized and comparable data for identifying and disseminating best practices. For a more specific account of the prototype development, see Keenan and colleagues[70]

In creating the original HANDS prototype, the team made a deliberate choice to incorporate the N3 terminology system to represent the data elements of clinical (nursing relevant) diagnosis, interventions, and outcomes for the reason described above. The initial HANDS work thus focused on perfecting a tool that could be used to document the plan and generate comparable data. The teams' efforts focused on the plan format, database, and rules of data entry. The approach matched the assumed need for such a tool with the availability of the means, including the technology and terminologies.[83] It was believed that the tool would help meet the vision of the HANDS.

Version 1 of HANDS (single user application) was initially implemented and tested in one intensive care unit. A sociocultural approach, putting our users front and center, was used to gain an understanding of the impact of the HANDS technology on nurses' work practices.[84] Many qualitative and simple quantitative methods were employed and repeated across time in our evaluations, and the results were added to improve the HANDS tool and processes through iterations of the design, test, and refine cycle. Our methods included observations, surveys, focus groups, "think-alouds," analysis of individual use patterns available in transaction logs, and routine checks of term meaning reliabilities and NOC outcome ratings.

The findings[85] gathered from the multiple methods in the pilot study helped uncover a number of issues with the technology that were not always apparent to our nurse subjects and permitted us to implement remedies. Most importantly we learned that our initial approach was document-centric. And although our method improved compliance and satisfaction with the care planning documentation, it did little to promote the collective mind of the clinicians involved in care. In fact, we found that many of the individual nurses religiously and mindfully updated plans of care in isolation. Rarely did nurses use the plans to guide clinician-to-clinician transfer of information. In retrospect, this finding was understandable and echoed the evidence reviewed in this chapter, that the plans have typically brought little value in day-to-day practice. Expecting nurses to use plans in more patient-centric, rather than document-centric, ways without educating them about how this might be done is unlikely to bring about the desired change. These results were used to refine the software and revise the rules and training for Phase 2 of the HANDS research initiative.

The HANDS Initiative: Phase 2

In preparation for this phase, the HANDS tool was converted to a Web-based application. WEBHANDS allows the clinician to easily enter and update a patient's plan from any terminal on the unit. Since the plan-of-care histories are stored on a central server, clinicians involved in a patient's care also have ready access to the history of the patient's plan from previous episodes. This information provides the clinician an "at-a-glance summary" of the issues that have been

addressed through the care provided by the health care team, and progress toward outcomes across time. The improvements in the software accessibility were expected to streamline the documentation of the plan of care and make it easier to integrate the plan into handover communication (intradisciplinary heedful interrelating)

Phase 2 research built on lessons learned in Phase 1, as well as the integration of evidence on communication, handovers, and behaviors characteristic of high reliability organizations. There are two major aims of this 3-year, multisite study of the HANDS method, *HIT Support for Safe Nursing Care*, funded by the Agency for Healthcare Research and Quality.[86] The aims include demonstrating that standardization of the HANDS method can be maintained across multiple diverse sites and that that the method fosters mindfulness, heedful interrelating, and collective mind as described in our framework presented earlier in the chapter. As can be seen, our emphasis moved from a document-centered to a patient-focused plan-of-care method that encompasses both the plan and the planning processes.

In the study, the HANDS method is implemented and fully evaluated on the participating units. Nurse champions are first identified and educated (40 hours: combination of in class, and independent study). The champions, in turn educate the remaining nurses employed on the unit (6 hours: 2 hours of classroom, 4 hours of independent study). A greater emphasis was placed on educating nurses to engage in heedful interrelating during handovers in this phase of our research. At this writing, we have just entered year 3 of the study and all units are fully live with the HANDS plan-of-care method. Nurses are required to enter admission or update care plans on all patients and to use the plans to structure communication at every handover.

Similar to our pilot phase, we are using multiple and repeated methods of evaluation and have already analyzed and integrated early findings into the tool and method.[87, 88] Thus far, we have demonstrated that standardization of care plan entry, storage, and retrieval can be maintained across the eight participating diverse units with the HANDS software tool. As in the pilot unit, nurses have reported high levels of satisfaction with the tool and are nearly 100 percent compliant in entering admission and update plans on all patients at every handover. Still needing improvement is the use of the plan at handovers (heedful interrelating). From interviews with nurses from our four first-year study units, we learned that there was wide variation in how nurses used the plans in the handover, and this was thought to add little value.[88] So, too, nurses complained that the most current plan was not always readily accessible for the handover. To remedy the situation, the nurses recommended developing a consistent format for handovers and creating easy access to the most current plan via the computer. The feedback was used to improve the software and plans of care were made readily available to the nurse via the patient list screen. In addition the SHARE (S-ketch, H-ANDS, A-ims, R-ationale, and E-xchange) structure was devised to help nurses uniformly integrate the plan of care into the handover process and both were added to the training of nurses in our year-2 study units.[88]

At this writing the four year-2 sites have been live with the revised HANDS method for nearly 4 months and, as with the year-1 sites, indicate satisfaction with the tool and almost 100 percent compliance with entering plans as directed. Nonetheless, even with the new enhancements, issues are surfacing that indicate that the revamped handover process is not yet fully working as expected. Further study of this issue is planned to determine how the handover communication can be improved. Intervention will then be devised and tested in an effort to improve heedful interrelating through our continuous learning model. In addition, we will complete our planned data collection, which will allow us to more thoroughly evaluate mindfulness and the impact of the HANDS method on the safety culture and error rates.

Future Plans for HANDS

Even without completing the full evaluation of the HANDS method in the current study, findings to date suggest several next steps. First and foremost, the study has provided evidence that the HANDS method is valuable and stable and should be considered for fuller adoption. This is because most of the benefits of the method can only be realized through widespread adoption and use, which motivates commitment that cannot be achieved when only one or two units in a system have adopted the method. For example, plan-of-care histories are not readily available unless all units in the system are using HANDS. Nurses also are reluctant to change comfortable (though variable) handover routines to embrace standardization before there is a full organizational commitment to the standardization. So, too, without widespread adoption and use of the method, it is difficult to identify best practices and disseminate these to the practitioners at the point of care through HANDS infrastructure. As is noted in our framework, depicted in Figure 1, the level of success of HANDS is integrally connected to the level of commitment to the change by the overall organization. For this reason we are encouraging organizations who express interest and readiness to adopt HANDS, to commit to full organization and adoption of the HANDS method.

We also see the need to formally position the HANDS method as an interdisciplinary initiative. As was noted in the previous sections' conclusions, there is a pressing need for tools that support the collective mind of the entire interdisciplinary team around a patient's care. The HANDS method already includes a number of features that can be easily adapted to accommodate the needs of the interdisciplinary team members. At this time a future study is planned to collaborate with physicians on refining the method for interdisciplinary use.

Finally, the method has been designed to work in and across all types of settings where patients seek care. To bring the intended value the method must work regardless of the Clinical Information System (CIS) adopted within the institution. We have begun planning the development of a universal connector that will allow HANDS to seamlessly connect to an organization's CIS regardless of the vendor types. In addition, other studies are underway to determine how to make HANDS available for immediate and widespread use. Of deepest concern and the direction of the team's passion and efforts is achieving our longstanding vision for health care.

Even without completing the full evaluation of the HANDS method in the current study, findings to date suggest several next steps. First and foremost, the current study has provided some evidence that the HANDS method is valuable and stable and should be considered for wide scale adoption. This is because most of the benefits of the method can only be realized through wide scale adoption and use that motivates commitment that cannot be achieved when only one or two units in a system have adopted the method. For example, plan of care histories are not readily available unless all units in the system are using HANDS. Nurses also are reluctant to change comfortable (though variable) handover routines to embrace standardization before full organization commitment to the standardization has been established. So too, without widespread adoption and use of the method it is difficult to identify best practices and disseminate these to the practitioners at the point of care through HANDS infrastructure. As is noted in our framework, depicted in Figure 1, the level of success of HANDS is integrally connected to the level of commitment to the change by the overall organization. For this reason we are encouraging organizations who express interest and readiness to adopt HANDS, to commit to full organizational adoption of the HANDS method.

It could be important to formally position the HANDS method as an interdisciplinary initiative. As was noted in the previous section, there is a pressing need for tools that support the collective mind of the entire interdisciplinary team around a patient's care. The HANDS method already includes a number of features that can be easily adapted to accommodate the needs of the interdisciplinary team members. Finally, the method has been designed to work in and across all types of settings where patients seek care. As such, to realize the intended value, the method would need to be effectively integrated in all clinical information systems across institutions.

Search Strategy

The areas covered in this literature review were nursing documentation and care planning. The literature cited in this chapter was identified in several ways. The medical and nursing literature on care planning, standardized terminologies, documentation, and quality indicators has been reviewed, selecting and retaining only those references that pertain to this work in some way regardless of the quality of the evidence. Additionally, a comprehensive search of the health care and organizational behavior literature was conducted, from 1996 to 2006 in MEDLINE® (using the OVID interface), CINAHL®, Cochrane Library, PubMed®, Dissertation Abstracts International, and Business Source Complete (EBSCO) to find high quality evidence available on nurse care planning and documentation. The main MeSH® subject search terms included continuity of patient care, documentation, medical errors, nursing records, patient care planning, and quality indicators–health care. A successive fractions search strategy was employed—a large selection of articles was made and then this was pared down to create a subset of the most applicable articles. To generate a large collection of potentially appropriate articles, each subject term was searched with minimal parameters from the subject heading; generally methods, standards, trends, and utilization were selected generating 9,422 matches. The additional limits of clinical, controlled, and randomized controlled trials (English) were set, producing a total of 118 matches.

Review of the 118 studies revealed that a number were not pertinent. For example, none of the 22 patient care planning articles pertained to nurse care planning. Only 3 of the 31 documentation articles were relevant. Many of those in the overall category of documentation were general and did not pertain to nursing. Also documentation often referred to research data collection or some other intervention, and not to patient care documentation. Consequently the results of the three searches (patient care planning AND nursing records, patient care planning AND documentation, and nursing records AND documentation) were reviewed to identify other pertinent studies, largely evaluative in nature. In these secondary searches, articles by anonymous authors, foreign language materials, commentaries, letters, 1-2 page articles, and those that were out of scope were eliminated. The resulting summaries of these articles appear in two evidence-based tables. Table 1 includes 17 studies representing the literature associated with recordkeeping quality, including studies evaluating completeness, accuracy, and timeframe of documentation. In Table 2, 22 articles are included describing research aimed at improving documentation and care planning practices.

Table 1. References Associated with Recordkeeping Quality (Completeness, Time)

Source	Issue	Design	Sample	Methods/Measures	Selected Findings
Allen 1998[29]	Examines nurses' views of the nursing record and its usage in practice	Qualitative study, United Kingdom	1 Hospital 2 Units 29 Registered nurses 8 Doctors 5 Auxiliaries 11 Clinical managers	Observations Interviews	-Written form of the nursing process comprises three main components: (1) pro forma, where biographical information is recorded; (2) a nursing care plan (patient's problems are identified and the appropriate nursing response is agreed upon); and (3) the nursing kardex (record of patient's progress). -Perceptions of care planning: (1) pressured to included 'problems' to satisfy quality assurance initiatives; (2) completed for fear of repercussion by senior staff; (3) mechanistic script to alleviate legality concerns; (4) devalued, as it is destroyed after patient's discharge; (5) rarely reviewed during patient stay.
Bjorvell 2002[41]	Evaluate effects of intervention on the quantity and quality of nursing documentation	Quasi-experimental longitudinal study	1 Hospital 3 Wards 269 Patients records	Intervention = organizational changes and education regarding nursing documentation, with the VIPS model using the Chart Audits (Cat-ch-Ing Instrument)	-Statistically significant score increase in quantity (*P* values for the quantity variables ranged from $P < 0.0001 – 0.0003$) as well as quality of the nursing documentation (*P* values of the quality variables ranged from $P < 0.0001 – 0.0002$), in the intervention wards, directly after the intervention.
Currell 2003[25]	Assess the effects of registered nurses' record systems on nursing practice & patient outcomes	Cochrane systematic review	8 Clinical Trials 1,497 people	Systematic Review	-No conclusive evidence was found of effects on practice attributable to changes in record systems. -RNs experience tensions between PT needs and hospital management documentation rules
Ehrenberg 2001[34]	Analyzes the concordance between nursing documentation & descriptions of practice	Case comparison study random sampling	17 Nursing homes wards 85 Patients 128 interviews	Audits of records; Interviews of patients and RN	-Problems more frequently reported than recorded in the patient records—between 11% and 59% of the patients' problems identified by the nurses were recorded. -Concordance between nurses' statements and recorded data was significantly better in the study groups on mental condition ($P < .001$), and mobility ($P < .005$)

Source	Issue	Design	Sample	Methods/Measures	Selected Findings
Griffiths 1999[42]	Determine adequacy of nursing documentation in describing patient care	Retrospective, criteria based audit Random sampling	1 Trust 103 care plans	Audit of Charts	-Room for improvement in the documentation of evaluation within the nursing care plans.
Hardey 2000[31]	Explore the role of RN interaction and documentation on patient care	Qualitative, nonexperi-mental ethnographic study	1 Hospital 5 Wards 34 Registered nurses 23 Handovers	Observations Interviews	-Nurses argued repeatedly that their scraps (personal notes) were more up to date, convenient, and therefore were a better source of information than was conventional paperwork. -Care plans were not used to inform care
Karkkainen 2005[27]	Synthesis of literature surrounding patient care & nursing documentation	Meta-synthesis evaluation study	14 Qualitative research reports	Literature Review and Synthesis (1996 – 2003)	-Individualized care not clearly visible in nurses' documentation; tasks described more frequently than patients' experiences of their care. -Documentation did not reflect the care being provided to the patient. The structure of nursing documentation, which is presupposed by the organization, may prevent individual recording of patient care.
Korst 2003[13]	Determine time spent on documentation	Work sampling study	1 Hospital 1 Unit 120 Observations	Observations (of documentation in the EHR and paper format)	-Percentage of time spent by nurses on each activity: 15.79% spent on all documentation: paper charting used 10.55% of nursing time, computer charting used 5.24% of time; 11.39% of time charting at the bedside, compared with 4.4% at other unit work areas.
Langowski 2005[26]	Determine electronic documentation systems link with improved quality	Literature review	5 Studies	Literature Review	-Overall, online nursing documentation systems would be beneficial in improving documentation requirements, end-user satisfaction, and influence how nursing is practiced
Larrabee 2001[40]	Evaluates differences in documentation after implementation of nursing information system	Time series evaluation study	1 Hospital 3 Units	Intervention = implementation of care planning feature in a NIS (Nursing Information System)	-Mean nurse assessments of patient outcomes (NASSESS) scores were statistically significant at the $p<0.000$ among nurses during each of the three study time points. No consistent pattern for which unit had the highest/lowest score, although Unit 3 did have the lowest score at Times 1 and 2. -Six months of using a nursing information system is not sufficient time for registered nurses to acquire documentation mastery (as evident by decrease in scores from Time 1 to 2 and increase from Time 2 to 3 for many of the variables).

Source	Issue	Design	Sample	Methods/Measures	Selected Findings
Ngin 1993[32]	Explores user acceptance of health information technology	Non-experimental, descriptive study	547 Registered nurses	Focus Groups Observations Surveys	-Health information technology required greater coordination so that information is entered and Registered nurse tasks are carried out in a timely manner. -Hospital membership, position occupied, and unit norms significant predictors of computer use. -Organizational variables were better predictors of actual computer use, and individual variables were better predictors of attitudinal user acceptance.
Poissant 2005[14]	Identify factors associated with differences in effectiveness among electronic health records	Systematic review	23 Studies	Literature Review	-Use of bedside terminal and central desktops respectively saved registered nurses 24.5% and 23.5% of time spent documenting during shift. -Desktop for computerized prescription order entry was found to be inefficient, increasing work time 98% to 328% (Medical doctor time per shift)
Sterling 1996[38]	Determine change in documentation of wound assessment	Nonexperi-mental, comparative independent groups study	2 Hospitals 3 Wards 46 Patient charts	Chart Audits	-Relevant parameters of wound assessment were documented more frequently when a wound assessment chart was used -Many of the delaying factors suggested as important in the literature for wound care were not documented.
Stokke 1999[36]	Evaluate quality and completeness of documentation	Nonexperi-mental, descriptive study	2 Hospitals 5 Wards 55 Patient Records	Chart Audits	-Nursing care plan was present in 62% of the records. Nursing goals were lacking in the remaining 38%, diagnosis and planned interventions were absent in 18%, and 45% of the diagnoses lacked information concerning patient progress or outcome. -The nursing care plans were updated in only 40% of the records and discharge notes were present in 35% (NBH recommendations not met).
Taylor 2002[37]	Identify problem-solving studies used while providing patient. care	Qualitative, nonexperi-mental study	1 Hospital 33 Registered nurse students/Registered nurses	Observations Interviews	-Nurses accessed four main data sources when preparing to carry out a procedure: nursing handover, patient documentation, previous knowledge of the patient, and a selection of other sources grouped as “miscellaneous.” -Patient documentation (history and care plan are two most significant sets of documents): Many of the nursing care plans reviewed in this study did not convey the specific information necessary to carry out the required procedures; 1/3 mentioned accessing written documentation, but did not express a preference for source.

Source	Issue	Design	Sample	Methods/Measures	Selected Findings
Tornkvist 2003[39]	Determine effects of an implementation of pain-advisers on satisfaction & documentation	Controlled clinical trial	5PHCCs 53 Registered nurses	Intervention = implementation of 'pain advisers' Survey	-Several statistically significant improvements were achieved after the introduction of 'pain-advisers' in the study units -Increased registered nurse satisfaction with documentation in study units
Tornvall 2004[33]	Determine what documented in the health record	Nonexperimental, descriptive study; stratified random selection	27 Primary health care centers 154 District nurses 41 Nursing records	Survey Chart Audit (using Catch-Ing,)	-Keywords "nursing intervention," "nursing outcome," and "nursing status" received the highest score, whereas keywords "nursing goal" and "nursing diagnosis" received the lowest score. -Patient status found in 30% of the notes under keyword "nursing intervention." All notes contained medical details and medically based treatments. -Predominance of documentation of medical/objective status rather than nursing status.
Urquhart 2005[24]	Update of Currell and Urquhart (2003) Cochrane Review assessing the effects of registered nurse record systems on nursing practice & Patients outcomes	Systematic review	26 Qualitative studies	Systematic Review	Qualitative research on nursing records systems, documentation of verbal exchanges concerning nursing care, and organization of nursing records are inconclusive concerning how well the records represent nursing practice and which systems (analog or computerized) improve patient outcomes.

Table 2. References associated with Improving Documentation and Care Planning Practices

Source	Issue	Design	Sample	Methods/Measures	Selected Findings
Ammenwerth 2001[63]	Investigate influence of information technology on time and quality of documentation	Randomized control trial	1 Hospital 5 Medical doctors 12 Registered nurses 60 Patients	Intervention = implementation of a nursing information system. Documentation Analysis; Survey	-Documentation of tasks (*P* = .004) & report writing (*P* = .019) required more time with the computer-based versus the paper system; time for preparing care plans was not significantly different between groups -Survey—7 registered nurses (58%) agreed that PIK saved time for care planning; only 3 (25%) agreed that PIK saved time for documentation of tasks or for report writing; 10 registered nurses (83%) agreed nursing documentation was more complete, 9 (75%) agreed that legibility was better & 8 (66%) agreed that quality of documentation was better.
Atwal 2002[69]	Understanding of RNs' perception of the discharge process	Case study	1 Trust 19 RNs	Interviews Observations	-Communication dependent on the relationship between members of the team. RNs noted difficulty in communicating with others on the team (i.e., time-consuming task) -RNs concerned that nurses did not question info that they did not comprehend at handover. Handover was the key area where information was miscommunicated.
Axford 1996[47]	Determine impact of CIS on nursing practice	Non-experimental, descriptive study	33 Registered nurses (interviews) 291 Registered nurses (survey)	Interviews Surveys	-Nurses (whether computer naive or knowledgeable) do not expect the technology to have negative impact on practice. -The two groups differed mostly in the strength of their beliefs. One startling outcome, that slow computer response time delayed care, was identified within the computer-user group and direct action was taken as a result.
Bjorvell 2002[41]	Evaluate effects of intervention on the quantity and quality of nursing documentation	Quasi-experimental longitudinal study	1 Hospital 3 Wards 269 Patient records	Intervention = organizational changes and education regarding nursing documentation with the VIPS model Chart Audits (Cat-ch-Ing Instrument)	-Statistically significant score increase in quantity (*P* values for the quantity variables ranged from $P < 0.0001 – 0.0003$) as well as quality of the nursing documentation (*P* values of the quality variables ranged from $P < 0.0001 – 0.0002$), in the intervention wards, directly after the intervention.

Source	Issue	Design	Sample	Methods/Measures	Selected Findings
Darmer 2006[59]	Evaluate the quality of nursing assessment and quantity of care plans using the VIPS model	Evaluation study	4 sites 600 Patient charts	Intervention = implementation program introducing the VIPS model Chart Audits (Cat-ch-Ing Instrument)	-Nursing documentation significantly improved during the course of the study (*P* = .00001). -The structured implementation program significantly improved nursing documentation and the simultaneous training of the entire nursing staff.
Darmer 2004[58]	Explores registered nurses' knowledge and attitudes towards documentation	Controlled clinical trial	1 Hospital	Intervention = implementation program introducing the VIPS Model Survey & Test	-Experimental group were significantly stronger in their convictions that they had the knowledge to make care plans (*P* = 0.03) and that they routinely made them (*P* = 0.01). -Experimental group showed less motivation than the control group, although both did consistently better on the knowledge tests
Dillon 2005[45]	Predict registered nurses intention to adopt Electronic Health Records	Nonexperi-mental, descriptive study	1 Hospital 140 Registered nurses	Survey	-Age was a significant factor in determining nurses' attitudes towards the electronic patient record system (*P* < .05). -Age had a direct (*P* = .02) and indirect (via Image, *P* = .02) effect on nursing attitudes towards the electronic patient record system. -Image had a direct effect (*P* = .000) on attitudes of nurses towards the electronic patient record system. -Nurses presented concern with the new electronic patient record system, thinking it may be risky and remove the human component of what nurses do.
Ehrenberg 2001[34]	Analyzes the concordance between nursing documentation & descriptions of practice	Case comparison study, random sampling	17 Nursing homes wards 85 Patients 128 Interviews	Audits of records Interviews of patients and registered nurses	-Problems more frequently reported than recorded in the patient records—between 11% and 59% of patient problems identified by the nurses were recorded. -Concordance between nurses' statements and recorded data was significantly better in the study group on mental condition (*P* < .001), and mobility (*P* < .005)

Source	Issue	Design	Sample	Methods/Measures	Selected Findings
From 2003[53]	Evaluates care planning in 2 different ways, and its effectiveness on improving outcome	Randomized controlled prospective	Study 1 (S1): 1 Hospital 4 Units 222 Patients Study 2 (S2): 1 Hospital 4 Units 304 Patients	S1 Intervention = Registered nurses & Medical doctors collaboratively developed care plans S2 Intervention = care plan randomly removed from record Interview Chart Audits	(S1) -Problems identified earlier with intervention *P* = .01 (1 vs. 3 days) - Solutions initiated earlier with intervention (Not statistically significant); LOS same between both groups (Not statistically significant) (S2) -Patients with planning form still on record had lower length of stay (*P* = .02) and greater accuracy of expected length of stay (*P* = .02) -Accomplishment of plan of action and readmission unchanged.
Hansebo 1999[60]	Comparison of nursing documentation before and after a supervised intervention	Pre-/post-intervention study Sweden	3 Wards 58 Patients	Intervention = implementation of individualized and documented care using the RAI/MDS Chart Review	-Daily notes increased both in total (42% increase after intervention) and within parts of the nursing process (patient situations increased 63%, implementation by 61%, and evaluations by 100%). -52% of the Resident Assessment Protocol items not documented in care plans.
Karkkanien 2005[46]	Extent to which theory-based documentation reveals actual patient's experience with care	Pre-/post-intervention study	6 Hospitals 7 Wards 137 Registered nurses	Intervention = educational component to apply theory of caring science to care plans Audits Surveys	-Post-intervention, more attention was noted to patient views and increase in recording of patient care plans -RNs need strong support from managers to successfully implement a theory-based documentation system
Lee 2005[30]	Identify factors influencing effectiveness of information technology	Cross-sectional, non-experimental study	120 Units 738 Surveys	Surveys	-Major issues identified by users of computerized documentation systems**:** hardware insufficiency, content design, poor system function, policy requirement, privacy/legal violations, and other perspectives -Nurses were dissatisfied with the care plan content, inability to individualize, poor system function, and no system integration

Source	Issue	Design	Sample	Methods/Measures	Selected Findings
Lee 2005[61]	Explore factors affecting nurses' use of nursing diagnoses in charting standardized nursing care plans	Qualitative Taiwan	1 Hospital 12 Registered nurses	Interviews	-Themes described by nurses when using nursing diagnoses in standardized nursing care plans: (1) choosing familiar patient problems—fitting diagnoses to existing paper form; (2) Inapplicable related factors—turn to SOAP notes (some of the factors on the standardized forms were not applicable); (3) Unavailable subjective data—replaced with objective data; (4) Unrealistic expected goals—skip or ignore (expected goals largely ignored); (5) General intervention—selected or added to the chart as needed (listed activities comprehensive, but not realistic); (6) requirement for consistent evaluation created meaningless tasks (most labor-intensive aspect of documentation).
Lee 2004[62]	Explore nurses' experiences using a standardized care plan	Qualitative Taiwan	1 Hospital 19 Registered nurses	Interviews	-Themes describing impact of standardized care plan: (1) being reminded of care procedures; (2) time saved in making care plans (with standardized format); (3) Making shift reports very timely (too much paper); (4) Undesirable content design (inflexible & hard to apply to individual patients); (5) paperwork-oriented/not patient-centered (time consuming, double charting). -Some patient problems ignored to lighten the paperwork load
Lillibridge 1999[55]	Investigate health assessment and documentation practices	Nonexperi-mental, descriptive study	1 Hospital 2 Domiciles 65 Registered nurses	Survey	-Only 23% of nurses mentioned nursing assessment details when asked to list the type of data they would collect for specific examination techniques - Findings generally indicated that nurses appear to maintain a medical- versus-nursing perspective of their actions—perpetuates view that nursing practice is medically driven
Mason 1999[50]	Investigate current care planning and effects on practice	Qualitative United Kingdom	5 Trusts 5 Units	Observations Focus groups Subject Diaries	-In the 4 comparable units, the primary issues identified with care planning included lack of time, pressure, not seen as valuable, & lack of specificity. -Observation confirmed the main guides to practice were verbal report, direct observation of the patient, and bedside charts. -In the specialty unit, the care plans were integrated well with practice, were viewed positively, guided communication & practice, and were kept at bedside.

Source	Issue	Design	Sample	Methods/Measures	Selected Findings
Nahm 2003[48]	Determine effects of a clinical information system on documentation & patient satisfaction	Quasi-experimental study	1 Hospital 11 Units 288 Patient charts	Chart Audits Survey	-13% increase in compliance to JCAHO standards (85% vs. 98% at 18 months) (*P* = .0003) after intervention of a clinical information system -After intervention, each of the three time periods showed a statistically significant improvement in quality of documentation (*P* < .01)
Scharf 1997[43]	Examine the association between time associated with documentation practices and patient outcomes	Pre- and post-controlled pilot study	2 Units 100 Patients	Intervention = revised flow sheets replaced previous documents. Included standard nursing interventions for the most commonly identified nursing diagnoses.	-A decrease of 20 minutes in charting per shift (143 minutes vs. 123 minutes) after intervention, while patient outcomes (length of stay, nosocomial infection, medication errors, and falls) remained the same on both units. -Slight improvement in patient's satisfaction and knowledge rates on the experimental units, with decreases in satisfaction and knowledge rates in the comparison unit.
Scherb 2002[54]	Identify effects of nursing interventions noted in the EHR on patient outcomes	Longitudinal study	2 Facilities 669 Patients	Chart Review (care plan and NOC outcomes on admission and discharge)	-Nursing care did make a difference in patient outcomes, although it was not possible to identify which interventions contributed to achievement of outcomes -3 outcomes with the largest sample size for each patient population were significantly improved at discharge compared to the admission rating (*P* < .008).
Smith 2005[51]	Identify association between a computerized documentation system with satisfaction, completeness, and timeliness	Quasi-experimental, evaluation study	3 Units 46 Registered nurses 141 Patient Records	Intervention = implementation of electronic care planning system Survey Observations Audits	-Statistically significant decreases in scores from pre- to post-intervention: (1) computers make registered nurses ' jobs easier (*P* < .001); (2) computers save steps and allow registered nurses to become more efficient (*P* = .002); (3) increased computer usage will allow RNs more time for patient care (*P* = .002); and (4) computer increases costs by increasing the registered nurses' workload (*P* = .002). -Completeness of documentation post-intervention: 28 (34%) documentation elements (of 8 NIC categories) were significantly more complete post computerization; 49 (60%) of the data elements remained unchanged, and five data elements (5%) were less complete post-intervention. -Time spent with the patient directly reduced from pre- to postintervention (40.4 minutes to 35.5 minutes, not statistically significant) although documentation time remained unchanged

Source	Issue	Design	Sample	Methods/Measures	Selected Findings
Spranzo 1993[64]	Effects of computerized care planning on select outcomes	Pre-/post-intervention study with qualitative component	1 Hospital 4 Units 88 RNs 153 Patients	Intervention = implementation of a computerized care planning system Survey & Patient interviews	-Introduction of care plans had little effect on patient outcomes. -Quality of nursing care remained constant despite the difference in documented care planning.
Stephen 2003[52]	Identify link between implementa-tion of critical path and patients length of stay	Pre-/post-intervention Study	1 Hospital 138 Patients	Intervention = implementation of the critical pathway for Patients undergoing colon resections	-Mean total length of stay was less in post clinical pathway patients compared to preclinical pathway patients ($P < .001$) -Average cost per patient, with readmission costs added, was higher in the pre-pathway group compared to post-pathway group ($P = .002$).

Table 3. Number of CINAHL "Major Focus" Entries for the 5 ANA Recognized Nursing Interface Terminology Systems 1996-2006*

Terminology systems**	1996-2000	2001-2005	2006 – 10/27/06	Total
1. N3				
NANDA	115	189	45	349
NIC	38	126	23	187
NOC	26	114	25	165
Total/***duplicates	179/19	429/145	93/26	701/190
Total minus duplicates	160	284	67	511
2. ICNP	5	44	4	53
3. OMAHA	25	19	3	47
4. PNDS	5	8	1	14
5. CCC****	2	6	-	8

* Includes journal articles, books, and conference proceedings in which a terminology system or component of it was considered a "major focus."

** Includes terms for nursing diagnoses, interventions, and outcomes. NANDA diagnosis, NIC interventions, and NOC outcomes, though recognized singularly by ANA as interface terminologies, are used in combination (N3) as a terminology system. Thus there are currently "5" nursing interface terminology systems recognized by ANA.

*** Duplicates include entries where two or more of the N3 terminologies are considered a "major focus."

**** Formerly the Home Healthcare Classification.

Chapter 50. Patient Care Technology and Safety

Gail Powell-Cope, Audrey L. Nelson, Emily S. Patterson

Background

The general public believes that technology will improve health care efficiency, quality, safety, and cost. However, few people consider that these same technologies may also introduce errors and adverse events.[1] Given that nearly 5,000 types of medical devices are used by millions of health care providers around the world, device-related problems are inevitable.[2] While technology holds much promise, the benefits of a specific technology may not be realized due to four common pitfalls: (1) poor technology design that does not adhere to human factors and ergonomic principles,[3] (2) poor technology interface with the patient or environment,[3] (3) inadequate plan for implementing a new technology into practice, and (4) inadequate maintenance plan.[4]

Patient care technology has become increasingly complex, transforming the way nursing care is conceptualized and delivered. Before extensive application of technology, nurses relied heavily on their senses of sight, touch, smell, and hearing to monitor patient status and to detect changes. Over time, the nurses' unaided senses were replaced with technology designed to detect physical changes in patient conditions.[5] Consider the case of pulse oxymetry. Before its widespread use, nurses relied on subtle changes in mental status and skin color to detect early changes in oxygen saturation, and they used arterial blood gasses to confirm their suspicions. Now pulse oxymetry allows nurses to identify decreased oxygenation before clinical symptoms appear, and thus more promptly diagnose and treat underlying causes.

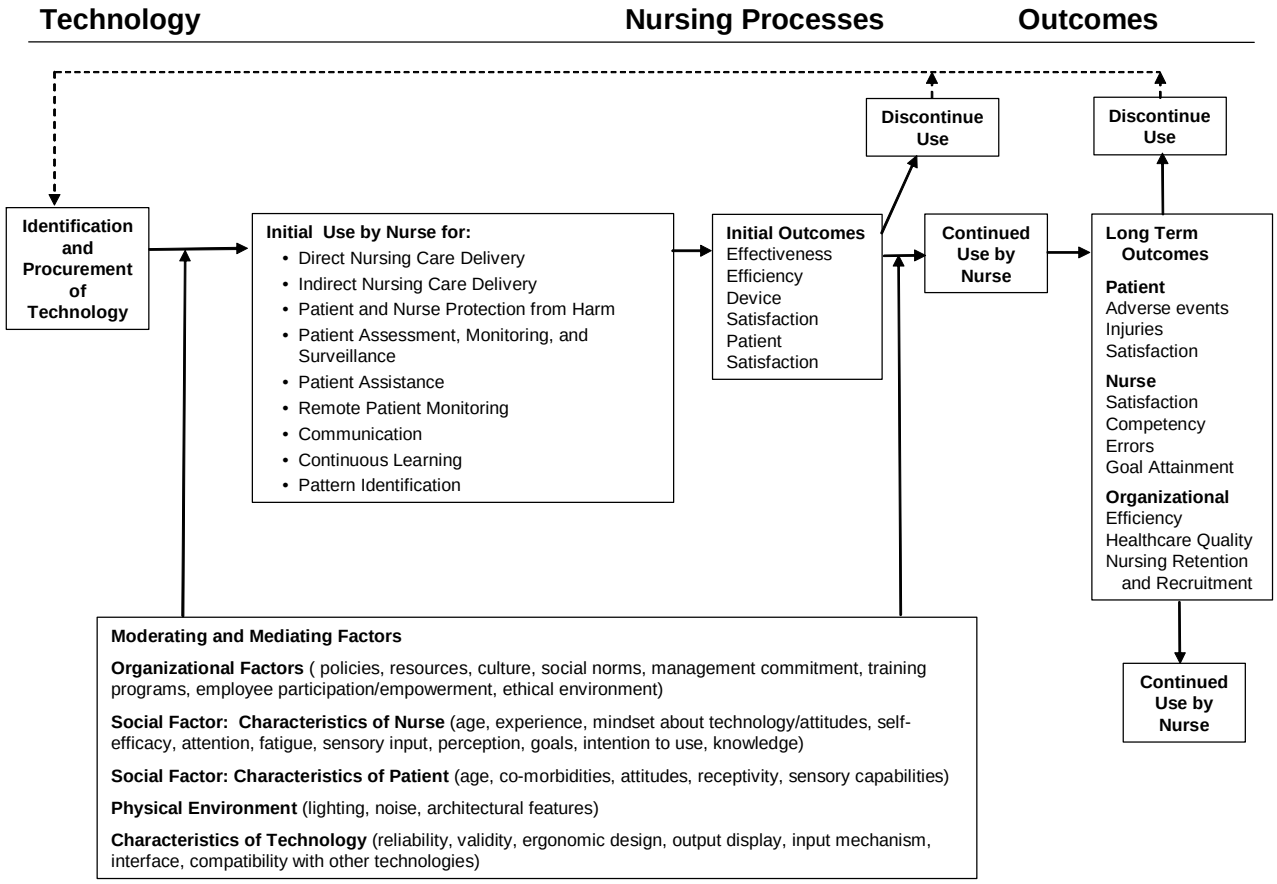
While technology has the potential to improve care, it is not without risks. Technology has been described as both part of the problem and part of the solution for safer health care, and some observers warned of the introduction of yet-to-be errors after the adoption of new technologies.[6] For example, nurses and other health care providers can be so focused on data from monitors that they fail to detect potentially important subtle changes in clinical status. Problems may emerge based on the sheer volume of new devices, the complexity of the devices, the poor interface between multiple technologies at the bedside, and the haphazard introduction of new devices at the bedside. Despite the billions of dollars spent each year on an ever-increasing array of medical devices and equipment, the nursing profession has paid little attention to the implementation of technology and its integration with other aspects of the health care environment.

Patient care technologies of interest to nurses range from relatively simple devices, such as catheters and syringes, to highly complex devices, such as barcode medication administration systems and electronic health records.[7] Technology can be broadly defined to include clinical protocols and other "paper" based tools, but for the purpose of this chapter, we will focus more on equipment and devices that nurses are likely to encounter in delivering direct care to patients. The purpose of this chapter is to provide a conceptual model for technologies that nurses are likely to encounter and to delineate strategies for promoting their effective and safe use.

Conceptual Framework

Based on a review of the literature, a conceptual framework was developed that depicts the relationship among the nurses' use of technologies; moderating and mediating factors that affect use; and the potential nurse, patient, and organizational outcomes (Figure 1). This model was developed independently, but is similar to the work of Fuhrer and colleagues,[8] whose framework of assistive technology device outcomes is patient-centric. We included key nursing processes and outcomes for which technology plays an important role in care delivery and in preventing adverse events.

Figure 1. Conceptual Model for Technology, Nursing, and Patient Safety



This conceptual model places the use of technology in the context of nursing practice and offers a framework for examining both the short- and long-term outcomes of technology use on the patient, the nurse, and the organization. Fuhrer's model focused on assistive technologies, that is, a spectrum of interventions—including structural and nonpermanent alterations of the physical environment, equipment attached to the physical environment, devices used by individuals, and behavioral modification—for promoting independence and function with a disability. This model is extended to include a full range of technologies used by nurses in the delivery of nursing care (Table 1). Patient care technologies can be classified in many ways. These technologies are categorized by commonly understood nursing activities: direct nursing

care delivery technology, indirect nursing care delivery technology, communication technology, patient and nurse protective devices, nurse protective devices, patient assessment, monitoring and surveillance, patient assistive devices, remote monitoring, continued learning, and pattern identification. Well-designed technology allows nurses to focus on caregiving functions and promoting the health of patients.

Table 1. Technology Commonly Used by Nurses

<table>
<tr>

According to Stone and Wiener,[9] workplaces have four dimensions: (1) organizational arrangements, for example, goals, structure, policies, and rewards; (2) social factors, for example, organizational philosophy and values, management style, and interactions with employees and patients; (3) the physical setting/environment, for example, character, physical design, and ergonomics; and (4) technology. In our proposed model, these workplace dimensions affect the nurses’ initial and continued use of technology.

Technology

Technologies used by nurses offer the means for preventing errors and adverse events (e.g., medication errors, miscommunications, delays in treatment, and adverse events—such as failure to rescue, nosocomial infections, pressure ulcers, falls, and complications of immobility). Yet technology also introduces unintended side effects and opportunities for failures.[6] In a chart review, Samore and colleagues[10] found that devices most commonly associated with adverse events were foley catheters (57 percent of adverse events involving devices), arterial catheters (17 percent of such events), central venous catheters (17 percent of such events), and peripherally inserted central catheters (7 percent of such events)—all devices used by nurses in the direct care of patients. At one pediatric hospital, implementation of a computerized provider order entry system intended to reduce handwriting and transcription errors was unexpectedly associated with increased mortality, presumably due to a reduced ability by nursing personnel to anticipate the needs of patients prior to arrival of the patient.[11] Other research showed that although barcoding medication administration was believed by most nursing personnel to decrease medication errors, it was also believed to reduce the ability for physicians to review the accuracy of medication administration and decrease the ability to deviate from routine medication administration sequences.[12] In another example, a few years ago, in an effort to prevent hip fractures from falls from bed, some nursing homes used non-height-adjustable low beds. This solution for preventing hip fractures among residents, however, forced nursing staff to provide care on their knees or bent over, thus increasing staff risk for back and knee injuries. Green[13] noted that all injuries and unintended consequences of technology are impossible to know beforehand, and that they are an unavoidable aspect of technology development. In other words, without technology failures there cannot be progress in technology development.

Nurses may respond to unintended consequences of technology with "work-arounds," or temporary fixes to technology problems or malfunctions. While work-arounds fix an immediate problem at hand, work-arounds can be dangerous, not solving the underlying problem in a system,[14] and thereby increasing opportunities for error over time. For example, in early implementation of barcode administration, scanning devices that were attached to the medication cart with a cord often made it difficult for nurses to scan the patients' identification arm due to infection control restrictions. In response, nurses made duplicate arm bands that they kept at the medication cart. The duplicate bands allowed for ease in scanning, yet doing so bypassed the safety feature that required a positive patient identification (by scanning the band on the arm) before administering a medication and increased the likelihood of "wrong patient" errors. When this work-around was discovered by an independent evaluator, nursing worked with the vendor and infection control experts to use disposable plastic covers to scan infectious patients.[15, 16]

Organizational Factors

Organizational factors that influence the use of technology include policies, resources, culture, social norms, management commitment, training programs, and employee empowerment. It has been noted that the effects of implementing technology—for example, information technology—can vary widely depending on the setting,[17] presumably due to differences in the social-organizational environment such as workflow, work tasks and processes, and the people in the environment. Policy is often looked at as an effective means for implementing change. For example, when implementing safe patient movement and handling

programs, it is helpful to have firmly established leadership and management support, equipment, training, and coordination with other departments before mandating mechanical lifting through policy.[18] Policy hastily implemented before consideration of the impact of technology can result in staff averting the policy and risking the consequences or staff appearing to be in compliance with the policy when they are not. Both of these situations can adversely affect staff morale and satisfaction.

Social Factors

Sandelowski[19] noted the complex and often troubled relationship between technology and nursing since the establishment of nursing as a profession in the latter part of the 19th century. Nurses have been both users of technology and facilitators for gaining patient acceptance of technology, but it has sometimes been a struggle for nurses to define the role of technology in their profession. Technology has played out in the debates of caring versus curing and high-touch versus high-tech in explaining the role of nursing in health care. In the 1970s, the mastery of technology often took second place after the mastery of psychosocial skills such as communication and development of a therapeutic relationship. This relatively recent culture of nursing and the culture of health care have in many instances served to work against the systematic incorporation of technology into nursing practice to improve patient outcomes. Using a Heideggerian analysis of technology, Zitzelsberger[20] proposed that the usual ways in which we perceive technology in terms of function, utility, and positive outcomes overshadow other "modes of revealing," so that nurses and other health care personnel are likely to accept technology and incorporate it into practice without critical evaluation of its benefits and problems. For example, why is it that nursing that requires higher levels of technology, as in critical care, is valued more (e.g., paid more) than nursing that requires little technology, as in the personal care of residents in a nursing home?

Certainly, characteristics of nurses will affect the adoption of technology, although little empirical evidence was found to document this phenomenon. Nurses have been found to be willing to embrace safe patient handling and other technologies if they are convenient; easy to use; target a high-risk, high-cost, and high-prevalence problem (such as falls); are consistent with unit and/or organizational goals; and are either compatible with existing work patterns or have the potential for improving efficiency and time spent with patients. It is likely that nurse characteristics that influence the use of technology are specific to the technology in question. For example, in a study of implementation of a nursing documentation information technology system, the investigators found that adoption was influenced by a number of attributes of the nurses, including commitment to nursing care planning and written documentation, acceptance of computers in nursing, computer and typing skills, professional experience, level of motivation, and climate of trust and support within the nursing team.[17]

Physical Environment

The physical environment, particularly in older buildings that were never designed to accommodate newer technologies, is often a constraining factor in the use of many types of equipment used by nurses. For example, research has shown that an ergonomic approach that relies on equipment to promote safe patient handling decreases musculoskeletal injuries in nurses.[21] The environment is critical in the nurses' use of this equipment because if the

equipment is not readily accessible, the nurse will be less likely to use it. If the patient handling equipment is located at the end of a hallway in a room behind other equipment, the nurse is less likely to use it than if it is stored in an open alcove in the hallway where it can easily be retrieved.[22]

Mediating and Moderating Factors

Ergonomics and human factors engineering offer useful frameworks for examining many of the mediating and moderating factors (e.g., the user/technology interface) that will affect use of the equipment and outcomes of its use. According to the International Ergonomics Association,[23]

> Ergonomics (or human factors) is the scientific discipline concerned with the understanding of interactions among humans and other elements of a system, and the profession that applies theory, principles, data and methods to design in order to optimize human well-being and overall system performance.
>
> Ergonomists contribute to the design and evaluation of tasks, jobs, products, environments and systems in order to make them compatible with the needs, abilities and limitations of people.

According to Gosbee[24] (p. 3), "Human factors engineering is the discipline concerned with understanding human characteristics and how humans interact with the world around them and the application of the knowledge to the design of systems that are safe, efficient and comfortable." Without a complete understanding of human factors, the tendency is to focus on human failures as the major source of error, and to focus attention on automation of tasks to prevent errors. Several problems with this approach are evident: [4]

- By taking away the easy parts of the job, automation can make the difficult aspects of the job more difficult.
- While humans are known to be fallible, we leave staff to cope with tasks the designers could not figure out how to automate, most important, the job of restoring the system to a safe state after a failure.
- Humans are expected to "monitor" the automated processes, even though we know vigilance is not likely when abnormal events are relatively rare.
- Skills need to be practiced continuously to preserve them, yet the occasional system failure denies the staff the opportunity to practice the skills needed in such an emergency.
- Nurses are generally not exposed during educational programs and on the job to engineers, biomedical engineers, industrial designers, and ergonomists, the designers of the equipment they use in providing care.

Because nurses work at the front lines of health care—where nurses, patients, and technologies intersect and where actions are highly visible—there is a tendency to blame these frontline workers for human error associated with technology failures. Reason[4] called these "human operator problems," which can be classified at the individual or systems level. Examples of individual-focused problems include deficient procedures or documentation, lack of knowledge or training, failure to follow procedures, and deficient planning or scheduling. Systems-oriented problems include miscommunication, deficient supervision, and policy problems. Technology failure should be viewed in the broader context of the complex health care system, rather than inappropriately blaming the individual nurse.

Outcomes of Technology Use

As Fuhrer and colleagues[8] noted, a paucity of outcome measures is a significant barrier to the conduct of outcomes research related to technology. The lack of conceptualization of outcomes in the context of the type of technology and its context of use is added. The key initial outcomes of technology are effectiveness, efficiency, and user (i.e., nurse) and patient satisfaction with the device. Verza and colleagues[25] specifically examined "equipment abandonment," that is, the disuse of a previously obtained device, in the context of assistive devices for persons with multiple sclerosis. They found that abandonment could be reduced by an interdisciplinary prescribing approach.

Longer-term objectives reach beyond these immediate ones and include adverse events, injuries, satisfaction, competency, errors, goal attainment, and organizational outcomes such as efficiency, cost (including cost avoidance, return on investment, margins, and working capital),[26] health care quality, and nursing retention and recruitment. Karwowski,[27] in building a model of ergonomics, differentiated positive outcomes (e.g., improved work productivity, shorter performance times, improved product quality, and desirable psychological and behavioral outcomes) from negative outcomes (e.g., loss of productivity, low quality, accidents, injuries, and undesirable physiological and psychological outcomes).

Optimally, technology is designed to minimize errors and buffer the consequences of errors[1] by (1) eliminating errors and adverse events; (2) reducing occurrence of errors/adverse events; (3) detecting errors early, before injury occurs; and (4) mitigating the effects of errors after they occur to minimize injury.[3] In this "ideal" scenario, patient care technology would yield positive nurse, patient, and organizational outcomes. Consider all of the alarms and warning systems used in the delivery of nursing care to detect errors before injury. A partial list includes bed exit alarms, warnings on IV pumps that signal occlusions, patient-initiated call bells, staff-initiated code alarms, wandering and elopement alarms, cardiac monitor alarms, and ventilator alarms. All of these warning systems depend on the ability of the nurse to notice the warning, process the alarm and comprehend what is happening, and finally take the appropriate action to decrease risk to the patient.[28] In one recent study, medical/surgical nurses wanted "smart monitoring devices" that interfaced with the electronic medical record as well as with wireless communication devices.[29] However, this strategy of using automated alarms is challenged by "alarm fatigue" stemming from the sheer number of alarms. Further, alarm fatigue is exacerbated by the well-intentioned, yet misguided decision to deliberately set alarms with a high false alarm rate; the effectiveness of an alerting signal drops precipitously with just a small number of false alarms.[30]

A significant difference in the model presented here from Fuher's[8] is that both nurse and patient outcomes are included. In addition to the potential physical harm from technology, Monk and colleagues[31] proposed that for older adults living with disabilities in their homes, psychological harms are as important as the physical ones. These researchers argued for including three types of physical harm (injury, untreated medical condition, and physical deterioration), four types of psychological and social harm (dependency, loneliness, fear, and debt or poverty), and four generic consequences (distress, loss of confidence in ability to live independently, costly medical treatment, and death) for systematically evaluating technology used to promote independent living.

While patient care technology offers many opportunities to improve nurse productivity and satisfaction, operational efficiency, patient satisfaction, safety, and quality, there is little research evaluating the outcomes of specific patient care technologies. Barcoding, scanning, and robotics

have been shown to improve efficiency and decrease costs.[32] The Veterans Health Administration (VHA) has successfully implemented barcode medication administration software. This innovative automated system uses a wireless, point-of-care technology with an integrated barcode scanner. The system can dramatically reduce medication administration errors by letting clinicians verify a patient's identity and validate medications against active orders. After implementation at the Kansas VA hospital, the VHA estimated that the software prevented 549,000 errors while dispensing 8 million doses.[32] In a quality improvement project, Bahlman and colleagues[33] found that implementation of an integrated communication system in an operating room had a positive effect by reducing staff time for phone calls to relay messages; reducing time nurses had to spend hunting pieces of equipment; enabling more timely administration of antibiotics for total joint procedures; improving communication with family members about progress of the patient through preoperative, operative, and postoperative care; and providing a quieter environment due to less overhead paging and the use of vibration modes for wireless telephones.

Moderate evidence is available supporting use of electronic medical records and automated drug-dispensing machines, with reports of increases in nurse satisfaction, retention, and productivity, as well as decreases in errors.[32] Despite the limited research available to support the benefits of technology, a recent Institute of Medicine report identified use of information technologies to automate clinical information as one of the keys to safer, quality health care systems.[34]

Practice Implications

Being informed consumers and users of technology in health care means that nurses be involved in the selection of new equipment, receive the proper training for its use, and monitor equipment safety and the effect of technology on patients and families on an ongoing basis.

Selecting the wrong equipment and technology can be costly and expose the patient to errors.[35] Even when optional equipment/technology is selected, if it is not well integrated into the current delivery system, or it is implemented in a chaotic way, this can result in unexpected costs and increased errors.[35] In choosing the best equipment for the task at hand, we found ergonomic-based and social-marketing approaches extremely beneficial. An ergonomic assessment, focusing on the user/equipment interface, involves asking nurses to test equipment and provide feedback on usability, safety, and patient acceptance. Equipment fairs are one strategy to allow staff the opportunity to evaluate which brand or model of technology would work best in their setting. Manufacturers are usually willing to loan equipment to promote onsite clinical testing. From a social-marketing perspective, all stakeholders potentially affected by a device should be invited to participate in equipment trials.[36] Different user groups will have different perspectives and requirements of the equipment. For example, in evaluating a hospital bed, a patient may focus on comfort, a biomedical engineer may focus on compatibility with other technologies and the ease of maintaining the bed in good working order, and a nurse might focus on the usability of special features such as built-in scales and bed exit alarms. Once a purchasing decision is made, including input from staff nurses, training is critical and may require ongoing competency assessments over time.[35]

The World Health Organization Medical Devices and Equipment team described a life-cycle approach that systematically includes maintenance, training, monitoring, and vigilance reporting on medical devices in use.[37] Through surveillance, nurses play an important role in early

identification and correction of latent errors related to technology. Staff who operate equipment and are trained in its use can recognize maintenance problems and request timely maintenance.[38] Similar to the notion of patient surveillance to detect errors early and prevent adverse events[3] (p. 91), equipment surveillance means that nurses conduct purposeful and ongoing data collection to identify malfunctioning and broken equipment, interpret data that indicate equipment problems to determine the source of error, and act based on the interpretation by quickly and directly responding or appropriately reporting and following up.

The Safe Medical Devices Act of 1990, which became effective in 1991, *requires* (italics added) health care facilities to report to the manufacturer and/or the Food and Drug Administration (FDA) all incidents that reasonably suggest that the medical device might have contributed to a death or serious injury or illness. Nurses should be familiar with internal systems of reporting, as well as the FDA medical device reporting (MDR) system (available at http://www.fda.gov/medwatch/how.htm). MDR is the mechanism by which the FDA receives information about medical device adverse events from manufacturers, importers, and user facilities, so any problems with the device can be detected and corrected. ECRI Institute encourages the reporting of device-related incidents and deficiencies to determine whether a report reflects a random failure or one that is likely to recur and cause harm. (Reports can be submitted to ECRI's Web site at http://www.ecri.org/PatientSafety/ReportAProblem/Pages/default.aspx.) Health care failure mode effect analysis[39] and sociotechnical proactive risk modeling[40] offer methods for identifying equipment failures before they happen and strategies for preventing them. Both of the methods have been used in engineering, and both are prospective in that they can be used to identify and prevent product and technology-related problems before they occur. Proponents of proactive risk modeling methods, relatively new to health care,[40] suggest that nurses could play an active role in preventing equipment and technology failures and in responding appropriately to them should they occur.

Risk modeling, an established analytic method in high-risk industries such as aerospace and engineering, is a structured process of determining all the ways a failure can happen to identify likely prevention strategies. Proactive risk modeling has been described as a hybrid between traditional decision support models and process analysis techniques (e.g., root-cause analysis, failure modes, and effects analysis),[41] designed to address rare adverse events associated with high mortality and high costs. For example, after installation of mobile patient lifts into a facility, nurses may anticipate that they would be forced to perform manual lifts, putting themselves at high risk for a lifting injury, if all of the backup battery packs were not fully charged, rendering the electric lifts useless. In naming all of the ways this could happen, a group of nurses would identify processes that, if in place, would avoid the failure of charging batteries, for example, buying extra battery packs or plugging in equipment after each use. Competency checklists could be used to reinforce this process and ensure that everyone is performing it in the same way. Alternatively, the nurses may opt for an alarm system that notifies them when a battery's charge is running low and does not stop alarming until it is plugged into the electrical outlet to charge. Nurses could be proactive in equipment use by discussing "what if" scenarios to determine useful responses in the event of equipment failures. For example, a group of nurses could be asked to discuss what they would do if a patient became stranded in a ceiling lift that would not lower back down to the bed. After such a discussion, nurses would be in a better position to respond if that event were to occur than if they had not anticipated this possibility.

Nurse educators could advance the role of nurses in the use of technology by providing human factors content into nursing curricula and including human factors engineers into newer

interdisciplinary approaches to professional education. An engineering perspective views safety as a feature that needs to be "engineered" into technology and that human errors emerge from the human/machine interface. Equipment misuse is viewed as a failure of the designer to tailor the system appropriately to the cognitive strengths and weaknesses of human users.[4] Human factors engineering and good design can help trap failures so the end result is not a bad outcome,[42] and good design can be facilitated by more informed and sophisticated users. Nurses need to operate as though just because a technology is commercially available does not mean it is good. In our experience, manufacturers welcome feedback from nurses because it allows them to make design changes that not only improve patient safety, but also make products more marketable to nurses. Gosbee[42] suggested that nurses can be trained to more easily detect human factor design issues instead of dismissing them as human error or "somebody else's job."

Implementation of new technologies offers nurses yet another avenue for ensuring safe and efficient use of technology (Table 2). In our experience, we have found that staged implementation is often desirable, because it allows for formative evaluation that can be used to improve the implementation process. Staging also minimizes overload associated with training and behavioral changes. From the literature on research translation and our own experiences, clinical champions, local opinion leaders,[43] or "super users" of equipment may greatly facilitate smooth implementation of new equipment. These clinical leaders are most effective when they are respected by coworkers and perceived by coworkers as knowledgeable, clinically competent, and accessible. Clinical leaders can offer on-the-spot training, encouragement, advice, and troubleshooting expertise to other staff as workers are learning to use new equipment.

Table 2. Tips for Nurses To Influence Technology at the Bedside

- Organize equipment fairs to gain input from key users and stakeholders before purchases.
- Examine performance of technology on challenging scenarios in a simulated setting with a small number (three to five) of untrained, representative users.[44]
- Mentor and oversee temporary (agency) nurses and other personnel (e.g., resident physicians) during first-time use of sophisticated technology.
- Develop cogent arguments to administration to justify purchase of new equipment and technologies, balancing the cost of equipment (costs of purchase, training, and maintenance) against costs saved if equipment was not purchased.
- Become critical users of technology by identifying problems early and communicating them to vendors and in-house biomedical engineering staff.
- Report adverse events associated with medical devices to the Food and Drug Administration MAUDE reporting system and/or ECRI's Problem Reporting System.[45]
- Serve as a resource person on your unit for new technologies by getting training early, communicating with vendors, training others on your unit, and offering to field questions as new technology is implemented.

Research Implications

As previously described, there are a number of moderating and mediating factors for how useful technology is in practice. Appropriately addressing these factors will require collaboration across a number of disciplines. Clinical experts are needed to provide critical input into the design and application of technologies in health care. Direct patient care nurses need to be actively involved in the design and testing of technology. Human factors experts aid in integrating technology into existing workflow and in making interfaces easy to learn and use under stressful conditions.

It has been suggested that some of the mismatches between device design and health care settings might stem from a more fundamental disagreement about the nature of work.[46] An area for further study is whether the implicit theories of work by designers and managers are oversimplified in relation to the actual work setting, and whether these oversimplifications doom technologies to fail regardless of how usable the interface is or how many clinical experts have provided input during the design, procurement, implementation, and maintenance phases.

A major barrier to widespread use of technology is cost. Further research is needed to build a business case for use of technology, including return on investment and cost-benefit analyses.[35] Proactive assessment of key stakeholder perceptions of the technology is also essential, including end-users (nurses and others directly involved) as well as patients and their families.[35]

Chaotic implementation of new technologies appears to be the norm in health care. More research is needed to more effectively introduce new technologies, minimizing risk to the patient, and reducing stress on nursing staff. Likewise, once technology is integrated into nursing care delivery systems, adequate maintenance programs are needed.

Specific research priorities include the following:

1. There is a paucity of research evaluating the outcomes of specific patient care technologies. Further research is needed to evaluate the immediate and long-term outcomes associated with specific technologies used in nursing practice. Research should include nursing, patient, and organizational outcomes.
2. Nursing practices and care delivery systems vary across sites. Further research is needed to evaluate the effects of various nurse processes and environmental conditions on the use, effectiveness, and efficiency of specific technologies used in nursing practice.
3. There are a number of moderating and mediating factors affecting technology use in health care (e.g., organizational factors, social factors, physical environment, and characteristics of technology). Further research is needed to examine these mediating and moderating factors and how they affect both the use of technology and outcomes.
4. Variations in how technologies are implemented exist across organizations and practice settings. Research is needed to improve the processes for introducing technology into the workplace to optimize outcomes.
5. Given that a major barrier to widespread use of technology is cost, further research is needed to build a business case for use of specific technologies, including return on investment and cost-benefit analyses.
6. Because learning from errors and near misses is critical for building an effective culture of safety, research should be conducted to identify effective ways to learn from equipment-related adverse events across practice sites.
7. Research and development needs to focus on how to best integrate multiple technologies into patient care to maximize outcomes and decrease burdens on nurses.
8. Recognizing the inordinate amount of time nurses spend in performing indirect or nonnursing care, research is needed to evaluate the effect of technologies designed to reduce the time spent on nonnursing tasks (such as hunting and gathering supplies) and in indirect nursing care activities (such as documentation) to maximize the time nurses can spend in providing direct patient care.

Other considerations are:

1. What are the most critical challenges to successfully implementing new technologies into health care environments and nursing practice?

2. How do nurses serve as the last line of defense in protecting the patient from harm associated with technology?
3. What are the opportunities for nurses at the bedside to become involved in technology design and testing?

Conclusions

Research on the quality of care reveals a health care system that frequently falls short in its ability to apply new technology safely and appropriately.[34] Workplaces, instruments, and equipment can be developed according to human factors design criteria,[47] but as an end-user, nurses can maximize safety through the selection process, ongoing surveillance of equipment, and proactive risk-assessment methods.

The approach offered for nurses is consistent with the following four-pronged strategy developed by the World Health Organization Medical Devices and Equipment team:[37]

- **Policy:** Nurses providing direct patient care should be involved in setting and evaluating institutional, organizational, and public policy related to technologies.
- **Quality and Safety:** Nurses providing direct patient care can ensure that the technologies they use meet international quality and safety standards and technical specifications needed to perform in the clinical environment in which they are used.
- **Access:** Nurses providing direct patient care can ensure that institutional decisions are made with their input and the input of other critical stakeholders.
- **Use:** Nurses providing direct patient care should be involved in their intuitional policies and processes related to maintenance, training, monitoring, and reporting adverse events related to technology.

Chapter 51. Enhancing Patient Safety in Nursing Education Through Patient Simulation

Carol Fowler Durham, Kathryn R. Alden

Background

The alarming rise in morbidity and mortality among hospitalized patients throughout the United States heightens concerns about professional competency.[1] Nurses and other health care professionals are under increased scrutiny to provide safe, effective care. Likewise, nursing education programs are faced with increased pressure to produce graduates who are capable of providing safe patient care. Toward that end, nursing education programs develop curricula, hire qualified faculty, and select learning experiences for students in an effort to train and graduate competent, effective nurses. The instructional strategies utilized in both didactic and clinical components of nursing education courses are highly influential in determining critical thinking and clinical decisionmaking ability as well as in developing the psychomotor skill performance of new graduates.

Of course, it is unrealistic to think that graduates of nursing education programs have received all the training they need when they depart the doors of academia. Orientation programs for new graduates and continuing education for nurses are essential tools to help practitioners improve their knowledge, skills, and expertise so that quality patient care is provided and outcomes are optimized while errors are minimized. Ongoing evaluation of nursing competence is necessary to promote patient safety.

In the Institute of Medicine (IOM) report, *To Err is Human: Building a Safer Health Care System*, simulation training is recommended as one strategy that can be used to prevent errors in the clinical setting.[1] The report states that "… health care organizations and teaching institutions should participate in the development and use of simulation for training novice practitioners, problem solving, and crisis management, especially when new and potentially hazardous procedures and equipment are introduced"[1] (p. 179).

Nursing education has long utilized simulation in some form to teach principles and skills of nursing care. Models of anatomic parts, whole body mannequins, and various computer-based learning programs have provided educators with training tools for students seeking to become professional nurses. Current interest in simulation as a clinical teaching tool has largely been fueled by development of the human patient simulator.

Human patient simulation is a relatively new teaching strategy that allows learners to develop, refine, and apply knowledge and skills in a realistic clinical situation as they participate in interactive learning experiences designed to meet their educational needs. Learners participate in simulated patient care scenarios within a specific clinical environment, gaining experience, learning and refining skills and developing competencies; all this is accomplished without fear of harm to a live patient. The use of simulation as a teaching strategy can contribute to patient safety and optimize outcomes of care, providing learners with opportunities to experience scenarios and intervene in clinical situations within a safe, supervised setting without posing a risk to a patient.

The focus of this chapter is on the use of patient simulation in nursing education programs. A review of the various types of simulation is presented, followed by detailed information about the human patient simulator and its use as an instructional strategy. Specific information is provided about use of patient simulation in relation to prevention of medication errors, developing critical thinking and clinical decisionmaking skills, use of effective communication skills, and the importance of teamwork. The use of the METI® Human Patient Simulator (HPS) in a university nursing program is described, and an example of a patient care simulation that is used with undergraduate students is given.

Types of Simulation

In general terms, simulation is a technique or device that attempts to create characteristics of the real world. Simulation allows the educator to control the learning environment through scheduling of practice, providing feedback, and minimizing or introducing environmental distractions.[2] In health care, simulation may refer to a *device* representing a simulated patient or part of a patient; such a device can respond to and interact with the actions of the learner.[3] Simulation also refers to *activities* that mimic the reality of a clinical environment and that are designed for use in demonstrating procedures and promoting decisionmaking and critical thinking.[4] In health care education, simulation can take many forms, from relatively simple to highly complex. The various types of simulation are listed in Table 1, along with advantages and disadvantages of each. The types are briefly described in the following paragraphs.

Part Task Trainers

Part task trainers, also known as low-tech or static task trainers, are designed to replicate only a portion of the body or the environment. Many of these represent selected anatomical areas of the human body and are used to teach basic psychomotor skills and procedures. They range in complexity from an item as simple as an orange that is used to teach injection technique to an arm for teaching venipuncture or a mannequin for teaching cardiopulmonary resuscitation (CPR). These simulation tools are relatively inexpensive, and multiple models are often available for use within the same institution, allowing for larger numbers of learners to practice simultaneously.

Simulated Patients

Simulating patients through role play between learners and educators is commonly used in medical and nursing education. Physical assessment skills, history taking, and communication techniques are often taught using student pairs. Trained simulated patients can be used to simulate psychiatric interactions where the learners can try out appropriate interventions. Live female pelvic and male prostate models/teachers provide a dual role of allowing students to refine their exam techniques on the model while receiving real-time feedback about the pelvic or prostate exam. Expense and scheduling are challenges for this type of simulation.

Screen-Based Computer Simulators

Screen-based computer simulators are designed to model various aspects of human physiology or specific tasks or environments. Through a variety of computer programs, learners

use information to make clinical decisions and observe the results in action. There is often feedback during and after the interaction. Computer-assisted instruction programs or Web-based programs are relatively inexpensive and reusable and can be used individually or in groups.

Complex Task Trainers

Complex task trainers involve virtual reality and haptic systems, representing the highest level of computer-based technology. Haptic refers to technology that can sense where touch occurs as well as the amount of pressure being applied. This type of technology is particularly useful in learning environments where the faculty cannot clearly see where the student is assessing the patient. For example, during a pelvic exam, it is difficult for the faculty to determine if the learner is doing a thorough exam. With haptic technology, sensors are placed inside a pelvic model to provide feedback to the learner about areas assessed with touch and the amount of pressure applied. Complex task trainers are often combined with part task trainers so that a physical interaction can occur within the virtual environment. This type of simulation is gaining popularity for training practitioners in surgical techniques such as laparoscopy. While such technology is reusable, it can also be relatively expensive.

Integrated Simulators

Integrated simulators combine computer technology and part- or whole-body mannequins to provide a more realistic learning experience. The degree of sophistication of the mannequin and the computer that drives it determine the degree of engineering fidelity of the system. According to Maran and Glavin,[5] fidelity can be defined as the degree to which the appearance and capabilities of the simulator resemble the appearance and function of the simulated system. Human patient simulators, therefore, are generally categorized as low, intermediate, or high fidelity systems (see Table 2).

Human patient simulators. Human patient simulators are among the most recent technologic advances in instructional methodologies for medical and nursing education. These interactive mannequins are capable of realistic physiologic responses, including respiration, pulses, heart sounds, breath sounds, urinary output, and pupil reaction. Additionally, the more advanced models can communicate with the student, responding to questions posed by the learner in real time during the simulation exercise.

The authors are most familiar with the Human Patient Simulator by Medical Education Technologies Incorporated (METI®) and SimMan™ by Laerdal™. Each company has a variety of portable simulators representing different patient ages to meet the educational needs of the learners at all levels. Both vendors have models with realistic anatomy and clinical functionality.

The METI HPS represents the latest in state-of-the-art simulation technology. Physiological and pharmacological models are used as the operating platform, allowing the simulator to react like a live human. These unique integrated models imitate the human response in a multilayered, real-time manner, providing a realistic clinical presentation.[6] The HPS has a data recorder that records the learner's actions, allowing precise accounts for review and debriefing. Additionally, the HPS interfaces with a patient monitor like those used in most hospitals. Adjustments to the patient scenario can be made "on the fly" as the educator deems necessary.

Laerdal's SimMan operates using personal computer (PC) software. The simulator displays patient physiologic parameters on a PC screen that emulates a patient care monitor. The SimMan software includes the first Integrated Video Debriefing System. The video Web camera records

video and audio that is synchronized with the event log, providing a valuable tool for debriefing. Laerdal's software allows ease of management of patient parameters during scenarios.[7]

Although most simulators owned by schools of nursing are adult males, infant and pediatric models are also available. The simulators have interchangeable genitalia so that the mannequin can present as a male or female. It is possible to adapt the appearance of the mannequin to represent a range of ages from young adulthood to geriatric. Additionally, with the aid of a wig, makeup, and female clothing, the realism can be enhanced as the male mannequin is transformed into a female patient. The mannequin can also be successfully outfitted to present as a pregnant female with the appropriate props.

Promoting Safety Through Education With the Patient Simulator

Patient safety is a multidimensional concept that is central to clinical education. Numerous aspects and principles of patient safety can be easily incorporated into education of nurses and nursing students using the patient simulator. This discussion will focus on four primary areas: preventing medication errors, developing critical thinking and clinical decisionmaking skills, promoting effective communication, and encouraging teamwork.

Preventing Medication Errors

The 2006 IOM report, *Preventing Medication Errors*, concludes that at least 1.5 million preventable medication errors occur each year in the United States. (This number does not take into consideration the errors of omission.) The report indicates that, on average, a hospitalized patient is subjected to more than one medication error each day.[8]

In the National Safety Goals for 2007 of the Joint Commission (formerly the Joint Commission on Accreditation of Healthcare Organizations, JCAHO),[9] improving the safety of medication use is listed as the third goal, preceded only by improving the accuracy of patient identification and improving the effectiveness of communication among caregivers. Goal #8 also relates to medication safety: "Accurately and completely reconcile medications across the continuum of care."

Research has shown that medication errors, otherwise known as adverse drug events (ADEs), are most likely to occur during the prescribing and administration stages and are attributed to a variety of factors. ADEs commonly occur at transition points during hospitalization: admission, transfer between units, and discharge. Errors are often due to confusion caused by similar drug names. Another factor is lack of understanding by patients about their medications, including the risks and side effects of medications and what to do if side effects occur.[8] Medication errors directly related to nursing practice usually involve inappropriate medication dosage, overlooked allergies, giving the wrong drug, and incorrect administration site. All these errors are impacted by environmental distractions, miscommunication, and drug labeling problems.[10]

Medication administration is a vital aspect of nursing practice and a critical component of nursing education curricula. Faculty in schools of nursing are concerned with teaching students about safe medication administration. Educating students about safe administration of medications is multifaceted and involves instruction about actions and uses of medications, safe dosage, side effects, and nursing implications.

A recent analysis of 1,305 medication errors by nursing students over a 5-year period showed that the most common medication errors were those of omission and giving the wrong dose of a drug. Errors were primarily attributed to students' performance deficits with significant contributing factors identified as inexperience and distractions.[11]

Calculation of medication dosages has been identified as a deficit for many nursing students.[11–13] This may be related to weak math skills resulting in computational inaccuracy and to the lack of opportunity to utilize dosage calculation in the clinical setting. The advent of unit-dose packaging has limited the need for calculation of medication dosages.

Safe administration of medications is more than a psychomotor or mathematical skill. It also requires critical thinking and clinical decisionmaking. To safely administer medications, students must be able to assess and manage side effects and educate the patient and family about the prescribed treatment regimen. The patient simulator provides a realistic approach to medication administration in a safe setting where patient risks are eliminated. The computer technology of the METI HPS utilizes a barcode system in which specific medications can be scanned to activate physiologic responses in real or compressed time.

Incorporating medication administration into patient simulation scenarios offers numerous learning opportunities and benefits to students. Understanding of the rationale for medication use is enhanced as students are able to see how medications fit into the treatment of selected conditions. They have an opportunity to identify the appropriate drugs, determine safe dosages, calculate dosages, properly identify the patient, administer medications by a variety of routes, observe for side effects, and evaluate the effectiveness of medications. The simulation presents a realistic simulated clinical setting with inherent distractions that may interfere with safe medication administration. For example, in the midst of activities surrounding a code situation, students are exposed to the reality of medication administration in an emergent situation and to the importance of providing the right patient with the right medication in the right dosage at the right time by the right route. Students can be taught to identify areas of potential error risk during patient transitions and handoffs, including shift report, transfer, and discharge. The importance of effective communication can be emphasized and practiced through accurate reporting of medications and aspects of the treatment plan through simulated handoffs.

Patient and family education related to medications can be incorporated into patient simulations. As part of a simulated scenario or role play, students can ask the patient or family member about current medications in an effort to identify medications, including over-the-counter medications and herbal medications the patient is taking, and to determine if the medications are being used appropriately. As students inquire about side effects of medications that the patient may be experiencing, they can use critical-thinking skills to determine if the medications may be related to the patient's current health problems. As part of a scenario, students may be required to provide patient or family teaching about medications.

Developing Critical-Thinking and Clinical Decisionmaking Skills

Nursing educators are challenged to teach students to think critically, to go beyond simply "knowing," to advance to synthesis and application of knowledge as they assess, plan, implement, and evaluate nursing care. Simulation provides an alternative to the traditional teacher-centered approach to nursing education with emphasis on the learning needs and preferences of contemporary nursing students. Simulated learning experiences with the patient simulator allow faculty to expose students to situations that they may never see in their clinical practicum experiences. Because students are placed in a variety of units for their clinical

experiences, there is a lack of consistency in learning opportunities across and among students. Use of the patient simulator enables faculty to provide structured simulation lab experiences instead of trying to find appropriate and/or rare patient care opportunities in a health care setting.[14]

Promoting Effective Communication

The overwhelming majority of untoward events occurring in health care settings involve miscommunication. The Joint Commission identifies communication as the root cause of approximately 70 percent of all sentinel events.[15] Effective communication and teamwork are fundamental to quality patient care. According to the Joint Commission, patient safety is improved when communication is clear, accurate, complete, and timely. The significance of the quality of communication among team members is emphasized by the Joint Commission in one of its National Patient Safety Goals for 2007: "To improve the effectiveness of communication among caregivers."[9] Because errors often occur during times of patient transition in health care settings, the Joint Commission specifies that facilities must "[i]mplement a standardized approach to handoff communications, including an opportunity to ask and respond to questions."[9]

Communication is an essential component of all health care curricula; however, intradisciplinary communication is typically the focus. Each discipline has its own terminology, expectations, and idiosyncrasies relative to communication, all of which can impact the effectiveness of communication across disciplines. Because health care involves multiple disciplines, a means of standardized interdisciplinary communication is needed to enhance quality of care and promote patient safety.

A recently proposed model of interdisciplinary communication, known as SBAR, is gaining increased attention. This is a shared model for standardized communication designed to facilitate and improve communication between and among health care personnel. SBAR can be applied to both verbal and written communication. The model consists of four components:

Situation—statement of what is happening at the present time that has triggered the SBAR

Background—information that puts the situation into context and explains the circumstances that have lead to the situation

Assessment—statement of the communicator's ideas about the problem

Recommendation—statement of what should be done to correct the problem, by when, and by whom[16]

Patient care scenarios using the human patient simulator provide an opportune way to teach students to effectively use a standardized communication method such as SBAR and to allow them to practice this technique. With minimal effort, SBAR can be added to each simulation, requiring practitioners at all levels to develop and refine their communication techniques to be more effective. Ideally, students representing various health care disciplines can work together in patient care simulations, practicing communication techniques that are representative of the actual health care setting.

Encouraging Teamwork

The 2000 IOM report has heightened awareness about the need for system changes to promote patient safety and quality. The report urges organizations to develop strategies to improve team function, thereby increasing the quality of care for the patient.[1] In an effort to enhance teamwork, many organizations have adopted the principles of Crew Resource Management (CRM), originated by NASA and used in the aviation industry in response to aviation disasters. The CRM training model focuses on leadership, decisionmaking, communication, and team training.[17] It also provides training in ever-changing team structures for members who need to have portable skills to apply to various health care settings such as operating rooms, emergency departments, or intensive care units.[18] Ostergaard, Ostergaard, and Lippert[19] suggest that the individual should develop general team competencies that can be transferred from team to team.

Medical and nursing educational programs train students as individuals; yet, as practitioners they are most often required to work in teams within organizational systems. In the practice setting, nurses and physicians interact on a regular basis with each other and with other personnel in the health care institution. Working together as a team and sharing information among team members can contribute to enhanced quality and safety of patient care. Research findings indicate that the risk of serious events seems to be reduced when team training has been implemented.[17, 20, 21]

Simulation emphasizes the importance of teamwork in providing care for patients. It allows the learner to practice as a team member. Working in small groups with the simulator, students may be assigned specific roles such as primary nurse, secondary nurse, medication nurse, communicator, or recorder. They learn how to delegate tasks appropriately, to follow directions, and to communicate effectively with nurses and other practitioners. The simulation allows learners to assess the patient and the situation, identifying pertinent information that must be communicated to the primary health care provider. Students determine appropriate nursing interventions and implement orders from the health care provider. They evaluate patient responses and the outcomes of their assessments and interventions.

To prepare practitioners to work as effective team members, educational programs for all health care personnel need to increase opportunities to work in interdisciplinary teams.[22] Simulation can be used to train individuals in the context of team activities, creating a more realistic clinical environment. Ostergaard and associates[19] state that simulation is the preferred educational strategy to teach teamwork skills such as leadership, communication, and cooperation. Students from several disciplines such as nursing, medicine, respiratory therapy, pharmacy, and social work can be brought together in a patient simulation scenario. This allows each learner to practice their patient care role and relate in real time to the other professionals with whom they will need to work to effectively provide safe and quality patient care. Johnson[23] states that CRM or team training needs to be introduced early and reinforced often. He further acknowledges that accomplishing quality teamwork requires that practitioners (crews) are trained as a team throughout their educational experiences.

While patient simulation scenarios provide a means of teaching interdisciplinary teamwork and communication, it is important to remember that it is also an excellent strategy for educating students about intradisciplinary teamwork and communication. For instance, as nursing students participate in simulated patient scenarios, they assume a variety of nursing roles, particularly if they are learning in groups. Acting as a team providing nursing care, someone must assume the

leadership role, directing other team members and delegating tasks and responsibilities. A primary nurse is identified as the team leader and is assisted by a secondary nurse. Other students may be assigned specific roles such as recorder, communicator, or resource person. Simulated scenarios allow students to work collaboratively as team members with the additional benefit of having faculty present to facilitate teamwork and observe the effectiveness of teamwork.

Use of Patient Simulation in Nursing Education Programs

Patient simulation is an instructional strategy that can be implemented in a variety of settings. The versatility and adaptability of the technology provide a broad range of uses for the patient simulator.

Nursing Education Programs

University and community college nursing education programs use patient simulators with a variety of learners. Patient simulators are used to teach basic assessment and psychomotor skills with beginning students, evolving to complex clinical scenarios as students advance in the curriculum.[4, 15, 24–30] Graduate nursing programs utilize the patient simulator to teach advanced practice skills and concepts in nurse practitioner and nurse anesthesia programs.[31–34] It is used by clinicians to teach new procedures, to validate competencies, and to transition new graduates into the clinical practice.[35, 36] The patient simulator can be used in research concerning best practice for patient care and education.[37] It has potential for use in master's and doctoral-level education programs to train future faculty members.

Continuing Education

The patient simulator can be incorporated into a variety of continuing education programs, departing from the traditional lecture format to provide a more experiential learning experience for participants. Physical assessment classes, nurse anesthesia updates (e.g., airway management), advanced cardiac life support (ACLS) certification, critical care courses, and nurse refresher programs can be conducted using patient simulators.[30]

Nurse refresher courses typically consist of didactic and clinical components to prepare nurses to return to practice after an extended absence. Using patient simulators, these nurses can practice assessment and psychomotor skills before entering the clinical area. This helps promote self-confidence in the nurse refresher students as they resume hands-on care in a setting that does not endanger a live patient.

Population-specific classes can also be taught using the patient simulator. For example, it can be utilized to teach nurses to recognize and respond to critical situations that may occur in geriatric patients in acute and long-term care situations.

Staff Development

Health care institutions can use simulators in staff development programs such as orientation of new graduates and continuing education programs. Orientation programs for new graduates can utilize the human patient simulator to present specific policies and procedures, to assess clinical competence, and promote communication and collaboration among the nurses. Simulators can be used in continuing education to introduce new equipment, to teach new

procedures, to assess competency of nurses in responding to specific clinical situations, to assess adherence to specific protocols, and to promote teamwork.[28, 35, 36]

Evidence Supporting the Use of Patient Simulation in Nursing Education

Search of the literature on patient simulation reveals that the majority of research related to use of the patient simulator has been conducted in medical and anesthesiology settings. Evidence supporting the use of simulation as an instructional strategy in medical education is clear, although experts have pointed out that such research needs improvement in terms of rigor and quality.[38]

Issenberg and associates[38] conducted an extensive review of the medical literature on simulation, identifying 670 articles, of which 109 were used in their analysis. Based on the available evidence, the researchers concluded that simulation can enhance learning by providing feedback (47 percent of articles), repetitive practice (39 percent of articles), curriculum integration (25 percent of articles), a range of difficulty level (14 percent of articles), multiple learning strategies (10 percent of articles), a capture of clinical variation (10 percent of articles), a controlled environment (9 percent of articles), individualized learning (9 percent of articles), defined outcomes (6 percent of articles), and simulator validity (3 percent of articles).

An integrative review of medical and nursing literature was conducted by Ravert[39] in an attempt to identify quantitative studies related to computer-based simulation in health care education and to determine the effect of simulation on learning. Nine studies out of 513 references met the inclusion criteria; five were conducted in medical schools with medical students and four were done by registered nurses using samples of nurses. Seventy-five percent of the studies indicated positive effects of simulation on knowledge acquisition and/or skills training.

Evidence in the literature related to the use of patient simulation in nursing education and practice is ever increasing, although still sparse in comparison to the medical literature. The majority of articles in the nursing literature are descriptions of how patient simulation is utilized in a particular setting. There is a definite paucity in actual research studies that have been conducted about patient simulation.

The first reports of patient simulation in nursing education describe its use with nurse anesthesia students.[31, 33, 40] Incorporation of the human patient simulator into nurse practitioner and clinical nurse specialist education programs occurred somewhat later and is described in articles by Hravnak, Tuite, and Baldiserri,[32] and Scherer, Bruce, Graves, and Erdley.[34]

Numerous articles have been published describing the use of simulation and how simulation programs have been developed within schools of nursing, primarily with undergraduate students.[4, 14, 24–29] There are limited reports of patient simulator use by hospitals to train registered nurses.[35, 36]

Seropian and associates[41, 42] provided detailed descriptions of simulation technology and guidelines related to development of a simulation program. The articles review the types of simulation and offer rationale for selection of the appropriate technology to fit the educational needs of learners.

Henrichs, Rule, Grady, and Ellis[43] explored perceptions of nurse anesthesia students about the use of a human patient simulator in their first year of clinical training. Analysis of data collected through observations, student journals, and focus groups indicated that students felt the

simulation experience was educational, although they experienced feelings of apprehension, uneasiness, or fear during the sessions.

In another study of nurse anesthesia students, Farnsworth and colleagues[44] examined the efficacy of the human patient simulator in teaching conscious sedation skills. A sample of 20 nurses completed pretests and then experienced a training session consisting of 4 patient simulation scenarios followed by a practical exam. They were asked to complete post-tests and evaluations of the patient simulation training sessions. Overall scores on the post-test were significantly higher than pretest scores. As part of the evaluation, students were asked to rate the training session on a scale of 1 to 4 with 1 = poor and 4 = excellent. The mean rating score was 3.75, indicating that the participants found the training session to be both beneficial and enjoyable.

Nehring and Lashley[30] conducted an international study of human patient simulation in nursing education. They examined the use of the METI HPS by nursing schools and associated simulation centers. The researchers mailed surveys to 66 nursing programs and 150 simulation centers, hospitals, and other institutions of higher education that were located near nursing programs. Thirty-four nursing schools (18 universities and 16 community colleges) and 6 simulation centers throughout the world responded by completing the 37-item closed- and open-ended survey designed by the researchers. Results were categorized and reported as follows:

(1) Curricular use: Greater use of the HPS was reported by community college programs for more hours in all courses with the exception of the maternal newborn course. In university programs, the HPS was most often used in basic skills courses, while community colleges reported the greatest use in advanced medical-surgical nursing courses. Most schools used the HPS as part of required clinical time.

(2) Faculty use: Ninety-three percent of schools indicated that 25 percent or less of their faculty used the simulator; more than half of the sample states that their faculty was generally receptive to HPS use in their courses.

(3) Student views: Twenty-one schools reported collecting information on student perceptions of the HPS. In relation to use of the HPS for competency evaluation of undergraduate students, 42 percent of schools stated that it should be used, 36 percent agreed it should be used in some circumstances, and 22 percent indicated it should not be used.

(4) Other uses of HPS: Only six institutions indicated that they were conducting research about HPS use. Six nursing programs and four simulation centers reported use of the HPS in continuing education programs.

Feingold, Calaluce, and Kallen[45] conducted a study to evaluate nursing student and faculty perceptions about patient simulations using the Laerdal SimMan Universal Patient Simulator. Using a 20-item tool, the researchers surveyed 65 students who had participated in simulations during 2 consecutive semesters. Four faculty members were surveyed using a similar 17-item tool. Findings showed that while the majority of students and faculty felt the simulations were realistic and valuable, only half of the students agreed that skills learned in the simulation were transferable to a real patient care setting. Faculty indicated that simulations reinforced clinical objectives and adequately tested clinical and decisionmaking skills. Concerns of faculty members relative to patient simulator use included extra preparation time and lack of faculty support to use the technology.

Bearnson and Wiker[46] explored the benefits and limitations of using the METI HPS as a substitute for a clinical day in a junior-level nursing course. Each student had a 2-hour session

involving three preprogrammed scenarios. Following the scenarios, the students completed a brief survey instrument (four items) consisting of a Likert-type scale (1 = strongly disagree to 4 = strongly agree) and three open-ended questions. Responses indicated that the HPS increased knowledge of medication side effects (mean = 3.13), increased knowledge of differences in patients' responses (mean = 3.31), increased ability to administer medications safely (mean = 3.06), and increased confidence in medication administration skills (mean = 3.00). Responses to the open-ended questions were overwhelmingly positive.

Alinier and colleagues[47] demonstrated the effectiveness of scenario-based simulation training on nursing students' clinical skills and competence. A sample of 99 undergraduate nursing students in the United Kingdom was divided into control and experimental groups, with the experimental group being exposed to patient simulation training using the Laerdal SimMan. Students in both groups completed a pretest and post-test as well as a questionnaire. There was a statistically significant difference in the mean scores of the two groups from pretest to post-test, with the experimental group demonstrating higher overall scores.

In a recent study, Bremner and associates[48] examined the value of using the human patient simulator as an instructional strategy with novice nursing students. A sample of 41 students completed a questionnaire about their learning experiences with the human patient simulator. The simulator session was rated as good to excellent by 95 percent of the students, and 68 percent recommended it as a mandatory component of their educational program. Over 60 percent of the students indicated that the patient simulation experience increased their confidence in physical assessment skills. Limitations of the technology identified by students included not having enough time to work with the simulator, initial anxiety when first encountering the patient simulator, and a lack of realism.

Advantages of Patient Simulation in Nursing Education

The major advantage of using the patient simulator as an instructional strategy in nursing education is that it provides opportunity for active and interactive learning without risk to an actual patient.[3] Learners can be permitted to make mistakes without fear of harming a live person.

Use of the patient simulator allows for an immersive, experiential learning activity.[50] Students are active participants, not merely recipients of didactic content as in a lecture class. Small numbers of students are typically involved in each scenario, with each student having a role in the simulation. The patient simulator provides a hands-on experience in which students are able to witness the results of their actions in real time.

Clinical simulation with the patient simulator is consistent with adult learning theory. It is a learner-centered approach to education, building on previous knowledge and experiences. The patient simulator provides opportunities for self-study as well as group interaction.[50]

The sophisticated computer technology of the patient simulator has appeal for contemporary learners. Although increasing numbers of nontraditional students continue to enter nursing programs, the majority of learners currently enrolled are younger than 25 years of age. They represent the computer-savvy Generation X and Generation Y, having grown up with gaming systems such as Nintendo®, computers, and the Internet. Individuals from these generations typically possess an inherent fascination with technology and are accustomed to fast-paced communication through means such as instant-messaging. They always want to be in touch; cellular phones, MP3 players, and personal digital assistants (PDAs) have become a way of life.

Effective educational strategies must capture the learners' aptitude with and desire to use technology as they gain and apply necessary skills and knowledge.

Patient simulation scenarios provide a bridge between theory and clinical practice. Working with the patient simulator, students are able to visualize physiological responses that may be difficult to understand simply through didactic classes or readings. Critical thinking and clinical decisionmaking skills are developed and refined as students apply previous knowledge in simulated patient situations. Synthesis learning experiences can be provided through patient simulations. Knowledge and skills attained from classroom and clinical experiences can be applied in patient care situations

Scenarios can be selected or designed to meet specific course objectives and in accordance with learning needs of the students. Simulations allow faculty to expose students to situations that they may never see in their clinical practicum experiences.

The instructor is in control of the events and timing of the scenario and can pause the action as needed for reflection or correction. Scenarios can be repeated to provide consistency of learning experiences across student groups.

Skills and procedures can be practiced in a realistic situation, and immediate feedback is provided as learners observe patient responses and interact with faculty facilitators. If needed, students can be allowed to repeat skills and procedures until proficiency is achieved.

Working in small groups with patient simulation scenarios, learners benefit from each other's successes and mistakes. They also learn to work as a team and can experience a variety of roles as team members.

Learning experiences with the human patient simulator can boost students' self-confidence and help reduce anxiety in the actual patient care setting. Students are able to practice assessment and psychomotor skills and implement nursing interventions under the supervision of faculty so that they feel more confident and competent when they enter the practice setting and are assigned care for patients.

Learning experiences with the patient simulator help students to identify gaps in their knowledge and experience base. The following comments from baccalaureate nursing students illustrate this point (note: "Stan" or "Stan the Man" refers to the human patient simulator):

- Stan stimulates me to want to learn more. I found that when I was in the situation and didn't know what to do, I wanted nothing more than to be able to go and look up what was going on and gain an understanding. After the first day of working with Stan, I went back and read about the specific illnesses that we had encountered in our practice. I found that while we had done many things right, there were many things we had missed.

- During my work with Stan the Man, I realized that my knowledge of normal ranges for central venous pressure, pulmonary pressure, and pulmonary wedge pressure was lacking. Also I realized that I didn't have a firm grasp of the ABCs of emergency care. Stan showed me what happens when these things (airway, breathing, circulation) are not taken care of and in that order. We had a simulation where a spontaneous pneumothorax (which is commonly treated in the ED) resulted in Stan crashing, and ultimately we lost him. This happened mainly because we didn't get a chest tube inserted in time, but had we paid more attention to the ABCs at the beginning of the simulation, we might have been able to avoid him coding on us.

> ♦ I think the most valuable thing I learned was what I do not know. For example, while my group was working with Stan, I discovered that my ability to apply what I thought I had learned in pharmacology is lacking. In several cases I had no idea which drug to use or why. If it had not been for the suggestions from the instructors, I would not have been able to figure out which drugs to use. Thus I have identified pharmacology as a topic that I need to study more.

A major benefit of using the simulator in nursing education is that most students and faculty enjoy this type of learning experience. The dynamic and interactive nature of simulation provides learning experiences that are stimulating and beneficial.[43–45]

Teaching with the patient simulator provides opportunity for faculty development and increased job satisfaction. Nursing educators who enjoy interactive teaching methods may welcome the use of patient simulation into the curriculum and volunteer to participate in training programs and implementation of this technology with students.

As nursing education programs are seeking to hire new faculty, the patient simulation may serve as a recruitment tool. Those schools of nursing that own or have access to patient simulators may be able to attract faculty members who desire to teach using creative and innovative strategies.

Limitations of Patient Simulators

Limitations or disadvantages of the patient simulator are primarily related to its cost, which is prohibitive for many schools. The cost of the equipment can range from approximately $30,000 to $200,000, depending on the manufacturer and features of the patient simulator. Additional expenses include physical space to house the equipment, supplies and equipment needed to simulate the desired clinical environment, the cost of training faculty to utilize the technology, and faculty time involved in developing scenarios.[14, 27]

While a justifiable argument against the use of the human patient simulator is the expense involved in purchase and maintenance, there are ways to make its use more affordable.[27, 30] Educators and administrators need to carefully examine what is the best fit for their agency. They need to identify a plan to integrate the simulator into their curriculum, develop the complexity of the simulated cases, and determine the degree of realism required. As educators become more adept at using the simulator, higher-level performance will be desired of the simulator, so long-term usability and adaptability of the simulator should be weighed against its initial cost. Nursing education programs may procure the simulator through their annual budget, grants, special allocations, or private donations. To help recover some of the costs, some schools of nursing rent the simulator to a variety of groups and agencies, charging an hourly or daily rate.[30]

The portability of the simulators facilitates multicenter sharing. Schools of nursing can partner with hospitals to share the costs of the simulator and training. Realistic clinical environments for simulation can be more easily created through shared props such as intravenous (IV) pumps, dressing supplies, etc. Nursing faculty can collaborate with expert clinicians to develop realistic scenarios that reflect current practice. The two groups can cooperatively teach with the patient simulator. For example, in a university setting, two clinical specialists from the intensive care units at a local hospital lectured to a group of senior students about how to respond in a “code” situation (cardiopulmonary arrest); these two clinical experts provided case studies of actual situations that were developed into scenarios for use with the human patient simulator. The scenarios were used with the seniors and, later, with a group of new intensive care unit staff

nurses. The faculty and the two clinical specialists worked together to facilitate the scenarios for both groups of learners.

The cost of the simulator can be shared by a variety of health care disciplines. The simulator can be used in a multidisciplinary environment where medical, nursing, and other health care specialists work as a team to assess, intervene, and evaluate care provided to simulated patients in specific situations. Collaboration among schools of nursing, medical schools, and other health care disciplines can result in the development of scenarios designed to incorporate the knowledge, skills, and experience of all the related professions.

Schools of nursing and health care institutions can partner with community agencies in purchasing the patient simulator. Community agencies that wish to utilize the patient simulator may be able to barter with schools or hospitals, trading other services for personnel and time to use the human patient simulator. Although use of the human patient simulator began in inpatient health care, its use has extended into the field for training programs that prepare first responders, military, and health care professionals to respond to natural disasters or acts of bioterrorism.

The complex nature of the technology requires a commitment to training educators in the use of patient simulation. This means that faculty time and energies are involved in learning to operate and incorporate simulation into existing curriculum. Since faculty workloads are already heavy, this may seem to be an additional burden. Faculty time involved in actual teaching with simulation has been cited as a potential disadvantage of its use.[45] Student/faculty ratios are typically lower when teaching with a patient simulator. While traditional clinical groups may consist of 8–10 students, the maximum number of students that can be accommodated in a patient simulated learning experience is 5 or fewer, depending on the scenario.

Another potential disadvantage or limitation of the patient simulation that has been identified is lack of realism in the scenarios and patient responses. The realism of any simulation depends upon multiple factors, including the fidelity of the simulator, the environment, props, and the description of the scenario. Realism is also affected by the facilitator's expectation of students to suspend disbelief and treat the simulator as a patient. As realism is enhanced, the effectiveness of the scenario as a learning tool is increased.[41]

Student anxiety related to the use of patient simulation is a potential limitation to its effectiveness.[43, 48] Unfamiliarity with the simulator and fear of the unknown may evoke anxiety. Students may worry about their ability to manage a critical care situation. They may experience some discomfort about working under the direct supervision of faculty facilitators. If students are being evaluated and assigned grades for their participation in scenarios, anxiety may be elevated. The authors' experience with undergraduate nursing students demonstrates that although students may be somewhat anxious when they first encounter the simulator, this anxiety is not necessarily a negative influence. Having participated in scenarios using the METI® HPS, one student commented, "The experience was outstanding! I was terrified, but teamwork got us through. This forced me to deal with my fear of what do I do when a patient comes in. I was proud of myself and the group. Together we did it."

Patient Simulation and Undergraduate Nursing Education

The use of human patient simulators for undergraduate nursing education and evaluation offers an excellent means by which to provide learning experiences and to measure competency of knowledge and skills.[14] In the simulation lab, students collaborate in patient care as they conduct assessments; monitor physiologic parameters such as vital signs, heart sounds, breath sounds, and symptoms; perform nursing interventions; obtain and carry out physician's orders;

administer medications; and evaluate patient responses. This type of learning activity allows the learners to synthesize and apply knowledge they have gained from structured courses and/or clinical experiences.

The use of human patient simulation as an instructional strategy can enhance patient safety and optimize outcomes, providing a means of allowing nursing students to "practice" critical thinking, clinical decisionmaking, and psychomotor skills in a safe, controlled environment, without potential risk to a live patient. Errors can be allowed and corrected without concern for patient safety.

Simulation allows a condensing of vital learning experiences that assists the learner in developing clinical reasoning and decisionmaking skills. Additionally, a simulation can be repeated to allow students to correct misconceptions, fill in knowledge gaps, and hone clinical skills. This can be beneficial in boosting self-confidence and self-esteem as students are learning to think and act like nurses.

The patient simulator is intended as an adjunct teaching strategy to complement—not to replace—the traditional clinical practicum. It may be an addition to clinical hours or may be utilized as a means of remediation for students who encounter difficulties in the clinical setting. Scenarios using the patient simulator can be useful for students who may have been away from the clinical setting for a period of time; for example, students who must drop out of the program temporarily may benefit from patient simulations to refresh clinical knowledge and skills before they return to the clinical area.

The patient simulator provides an alternative to traditional clinical experiences. As enrollments in schools of nursing are rising, there is increased competition for clinical sites. The use of the human patient simulator is one means of providing clinical learning experiences outside the health care institutional setting. Faculty may elect to send students through care scenarios with patient simulation in lieu of a day or portion of a day on the clinical unit in the hospital. The simulation experiences may be used instead of a clinical conference. The time spent in a well-structured simulation experience can be powerful and far outweigh what can be accomplished in a traditional clinical conference.

The patient simulator can help faculty address problems related to lack of consistency in students' clinical experiences. The traditional model of undergraduate clinical education dictates that students are assigned to groups of 8 to 10, supervised by a clinical faculty, working in a health care setting for several hours at a time. Students are placed throughout hospitals and community agencies, working on a variety of units. There is inevitably lack of consistency in student learning experiences. Even students assigned to the same unit will encounter individual patients with unique problems and needs. It is impossible to assure that every student who graduates from a nursing education program will have had the same opportunity to provide care for any specific type of patient. Many variables influence student learning experiences in the clinical setting. These include such things as patient acuity and diagnosis, facility access, time of day, as well as clinical and teaching expertise of clinical instructors and nursing staff. Use of the human patient simulator allows for greater consistency in learning experiences. Learning occurs in a controlled environment where groups of students are exposed to the same scenarios, under the same conditions. Simulation is an efficient way to offer "standardized [experiential] learning in concentrated periods of time"[51] (p. 13).

The versatility of the technology means that patient simulation can be incorporated into courses throughout the nursing education curriculum. It can be used in beginning nursing courses to demonstrate such things as pathophysiological and pharmacological principles, normal and

abnormal physiologic parameters, and responses to interventions. Faculty can utilize the patient simulation with beginning students in physical assessment courses to demonstrate principles and techniques of systematic assessment. Students can hone their assessment skills with the simulator as they practice assessment of specific body systems and as they learn the head-to-toe examination. The simulator can be used to help students understand the concept of doing an initial patient assessment, assist them to understand how to approach a patient, and provide them with introductory interaction skills.

Patient simulation is an instructional strategy that bridges theory and practice in a variety of courses throughout the undergraduate curriculum (e.g., medical-surgical nursing, pediatrics, obstetrics, community health, psychiatric nursing, geriatric nursing). Undergraduate nursing faculty often employ the patient simulator as part of a synthesis learning experience with students enrolled in "capstone" medical-surgical nursing courses.[30] Students are expected to apply theory from current and previous didactic courses and to draw from their previous clinical experiences as they respond in the various scenarios. In the last semester prior to graduation, students enrolled in the nursing program at the University of North Carolina at Chapel Hill participate in a series of medical-surgical simulations cases: congestive heart failure that has progressed to pulmonary edema, tension pneumothorax, and ventricular tachycardia that leads to a full "code." These three cases are presented in a 1-hour time frame. The congestive heart failure/pulmonary edema case takes approximately 30 minutes and is provided as an example in Appendix A. The next two cases move more rapidly due to the emergent status of the patient and the necessary interventions. Later in the semester the students return to the simulation lab for a second hour where they encounter a hyperglycemic hyperosmolar nonketotic coma case that incorporates factors such as cultural issues, use of herbs, use of an interpreter for a non-English speaking patient, regulations under the Health Insurance Portability and Accountability Act (HIPAA) regarding family communications, and issues related to access to care.

Teaching with simulation offers opportunities to experience and act in common situations that students are likely to encounter in the clinical setting. Likewise, simulation can be used to teach students how to respond in situations that are relatively uncommon, yet warrant prompt action to prevent deleterious consequences.

The patient simulator allows for purposeful exposure to critical care scenarios that the learner may not encounter in the clinical practicum. Acquisition of this type of experience is important because the nurse needs to intervene promptly to prevent adverse patient outcomes. Simulation allows students to be immersed in critical care scenarios, requiring them to be active participants identifying pertinent changes in patient status and intervening appropriately, in a timely manner, to effectively treat the changes or to limit adverse outcomes. Even if they do not intervene appropriately or quickly enough and the simulated patient dies, there is educational value to be gained through debriefing.

Most nursing students have minimal opportunities to work in a critical care setting during their clinical practicum, yet it is important that they recognize signs of deterioration in patient status and are knowledgeable about appropriate assessments and interventions. Students on the clinical unit have limited opportunities to participate in emergent situations. If a patient develops cardiac or respiratory arrest and a "code" is called, the team of experts rushes in; the student is typically pushed to the periphery to act as an observer. Students can be taught how to respond in a "code" situation. A cardiopulmonary arrest can be simulated and students are expected to intervene, calling the "code" team and participating in the resuscitation. Students can actually use the portable defibrillator to "shock" the mannequin.[52]

Communication with the team and the health care provider is an important element of any patient simulation scenario. As student nurses working on a clinical unit, there is typically little opportunity for students to contact health care providers directly to discuss concerns or questions about their patients. For example, students do not make calls to physicians to report a patient's declining health status. In simulation, they may be asked to notify the provider, conveying pertinent information in a concise, professional manner and acting as an advocate for the patient. As orders are received from the provider, the student must document and communicate accurately to the team so that they may proceed with implementation.

Scenarios using simulation also provide important lessons about the importance of documentation, particularly in fast-moving critical care cases. One student may be assigned to record everything that is happening, ranging from the patient's vital signs to steps in cardiopulmonary resuscitation. The old adage, "if it is not documented, it was not done," can be emphasized and important lessons reinforced.

Role of the Educator in Patient Simulation

Just as the construction industry emphasizes the importance of using the "right tool for the job," so it is with the choice of an instructional strategy in nursing education. While the uses for the human patient simulator are broad, it is not intended as a panacea that can be implemented effectively at any place and time within a nursing curriculum. There must be careful thought in selecting patient simulation as the instructional method of choice to meet specific learning objectives.

Benner[53] (p. xiv) states that "providing nursing care involves risks for both nurse and patient, and skilled nursing requires well-planned education programs. Experience-based skill acquisition is safer and quicker when it rests upon a sound education base." When planning an educational activity, it is helpful to consider what type of tool will be most appropriate to teach the task at hand and to optimize the situation for the learner. Beaubien and Baker[2] dispel the myth that simulation is a unidimensional concept that has been used to describe the capabilities of the equipment such as high or low fidelity. It is not the level of the simulation fidelity that determines the effectiveness as an educational tool, but rather the faculty who designs the educational experience. Simulation is a multidimensional concept requiring the educator to examine not only the equipment, but also the environment and the psychological perceptions of the learner and educator.[2]

The patient simulation is only as effective as the faculty who are using it. The creativity, clinical knowledge, teaching expertise, and technological abilities of the faculty are highly influential in the effective use of patient simulation. A combination of standardized patients, part task trainers, and static mannequins can be coupled with the mannequin-based high-fidelity simulator to provide a more comprehensive learning experience. Patient simulation is a learner-centered instructional strategy where faculty act primarily as facilitators. The role varies somewhat, depending on whether the patient simulation is utilized for student learning or as a means of evaluating student performance.[4]

It is important to acknowledge that the patient simulator is a highly sophisticated, technologically advanced teaching tool. Training is required to enable faculty to effectively utilize the simulator. In most institutions, one or two faculty members are initially trained and are subsequently charged with training other faculty members in use of the patient simulator. It is helpful to have a "champion" who can present the patient simulator to faculty in a positive way,

citing the advantages to be gained in educating students with this teaching tool. Faculty who are unfamiliar with the simulator can be invited to orientation sessions where they can have hands-on experience with the mannequin and witness the capabilities of the technology. They can also be invited to observe teaching sessions in which students are involved in patient care scenarios using the simulator. Faculty who see the potential benefits of patient simulation may be more likely to want to use the simulator in their teaching. Those who are innovative, creative, and enjoy learning through active participation may be more apt to try the patient simulator as a teaching strategy.

While the novelty and versatility of patient simulation technology can be very appealing, learning to use the equipment can be daunting. This may be especially true for older faculty who have grown accustomed to traditional teaching methods, while younger faculty who have grown up with computer technology may be more interested and adept at learning to use patient simulators. Teaching assistants, who are often graduate students, are utilized in some settings to operate the patient simulator and to assist faculty in writing and running scenarios.

The time factor associated with use of patient simulation may be seen as a disadvantage.[30, 45] Typically, the student/faculty ratios are lower than in classroom or clinical settings, which means that more faculty time is required to offer the simulation experience to students. Faculty may be unwilling to commit more of their time, particularly if they already feel stretched. Those faculty who see the value of the learning experience for the students may be more likely to commit to using the simulator. Using patient simulated scenarios in place of clinical hours may enhance the appeal of this technology; substituting a day of clinical practice for equivalent time in the simulation lab may be an option. In many curricula the credit hours allotted to labs and clinical are the same and allow for 1:1 hour exchange between the two learning environments.

Developing and Using Patient Simulation Scenarios

Manufacturers of patient simulators provide a variety of predefined scenarios for use in health care education. Both METI HPS and Laeradel's SimMan have preprogrammed patient care scenarios. These standardized cases serve as the foundation for other scenarios that can be created by the user to fit curricular and learning needs. The METI Program for Nursing Curriculum Integration™ focuses on nursing educational concepts and competencies. It provides a strategy for implementing simulation use across a 4-semester nursing curriculum. The 90 clinical simulations include objectives, pre-scenario questions, evidence-based references, and more.

Faculty members may choose to adapt or create their own patient simulator scenarios to be more consistent with specific learning objectives and student needs. When adapting an existing simulated program or developing a case scenario, there are important considerations:

- **Q: Are there preprogrammed scenarios that can be used, or is it necessary to develop a scenario?**
  A: Even if an existing program is used, it is likely that the faculty will choose to elaborate and embellish it, including information to make it seem more realistic, framing the scenario with patient background and history. The patient simulator may be used in conjunction with other instructional strategies such as unfolding case studies or problem-based learning activities. Other types of simulation such as part task trainers may be used in conjunction with the patient simulator. If faculty choose to create their own simulated scenarios, they may draw ideas and data from previous experiences, from staff members,

or from students. As a course assignment, students may be asked to write a critical incident paper that can provide ideas for simulated cases. Students may be asked to create cases that can be adapted to the simulator. Of course, patient anonymity must be protected.

- **Q: What are the goals of the experience?**
  A: It is important to identify specific learning objectives. There may be primary and secondary objectives. For example, one of the primary goals may be for students to identify physiologic responses to hemorrhage, while a secondary objective may relate to recognition of cultural and religious beliefs related to use of blood products. Beyond the major objectives, the educator should think about what other teaching points can be incorporated into the case, such as family dynamics, cultural issues, use of alternative therapies, HIPAA regulations, working with an interpreter, etc.

- **Q: Is there an evaluation component to the simulation?**
  A: Students tend to be less anxious in working with the simulator when their performance is not being evaluated. Prior to beginning the case, it should be made clear to the students whether or not any type of evaluation would be done during the simulation. If there is evaluation involved, students should be provided with clear information about the criteria used for evaluation.

- **Q: What is the context of the patient simulation learning experience?**
  A: If used within a specific course, it is important to consider didactic and clinical content that precedes use of the patient simulator. Additionally, previous courses or clinical experiences that students have had should be considered. The patient simulator provides an excellent opportunity for a synthesis experience in which students can apply what they have learned previously to the current situation.

- **Q: What is the level of the students? Are these beginning students who have not yet started the first clinical practicum, or are these advanced students who will be graduating in a few weeks?**
  A: Cases are developed to match the level of the learners. Ideally, students can be introduced to the simulator early in the curriculum as they practice assessment and other basic psychomotor skills. Then, as they progress through the program, they can be involved in patient simulation scenarios that increase in complexity as their knowledge level increases. Ultimately, the patient simulator can be used as a synthesis experience in which students are expected to apply knowledge, experience, and skills that they have acquired up to that point in the program.

- **Q: How much time is allotted for the scenario?**
  A: In general, the more complex the scenario, the greater the time required for completion. It is reasonable to think that most scenarios can be conducted in 30 minutes. It is important to allow time for debriefing when the scenario is over.

- **Q: How many students will be assigned to each scenario?**
  A: Generally, small groups of no more than five students work well together in a simulated scenario. The case is designed with consideration of the number of roles that students can assume and the tasks that are to be accomplished during the case. Although

there is benefit to having students act as observers if space allows, there is greater learning potential when there is hands-on participation in the scenario.

- **Q: Have the students had previous experience with the patient simulator? If so, how much?**
  A: Orientation to the equipment and the technology is essential prior to having students participate in an actual case scenario. There is some anxiety associated with encountering a new teaching method, particularly when it is novel and unfamiliar. Both students and faculty need the opportunity for hands-on orientation to the mannequin, doing such things as listening to breath and heart sounds, being informed of the capabilities of the system, viewing the bedside computer display, and identifying the location of supplies and equipment within the environment.

- **Q: How many faculty/staff are available to assist with the scenario?**
  A: Ideally, there are at least two to three persons involved in running a patient simulated case. It is advantageous to have a coordinator or team leader who is familiar with all aspects of the simulation. This person is responsible for assigning and delegating tasks to other team members, checking the setup and equipment, directing, and troubleshooting as the scenario progresses.[41] The team leader may also be involved in facilitating the scenario, although there are usually one or two other faculty members serving in that capacity. There must be an operator who runs the computer and makes the simulation happen in real time, making adjustments as necessary according to learning needs and actions of the participants. The operator, facilitator, or other staff assistants may periodically move into acting as family members, friends, or other health care personnel who may be involved in the scenario. All faculty/staff who are serving as facilitators will need to be flexible to also assume such roles intermittently as needed during the case.

- **Q: What type of environment is needed to represent the clinical setting for the scenario?**
  A: The educator needs to examine the situation, props, and environment to determine if they are as realistic as possible. Realism of the situation is critical to the learning experience for the student during the scenario. Suspending disbelief by creating a situation as realistic as possible encourages learners to immerse themselves in the experience with minimal distractions. Gaba[3] suggests that learners who are immersed in experiential learning are more able to suspend disbelief and perform as they would in a real-life situation. Additionally, it may enhance the ability to transfer what has been learned in the scenario to an actual patient situation. While the patient simulator is typically housed in a particular room or space, it may be possible to adapt the environment to increase the realism of the simulated case. Real patient care equipment should be used whenever possible. Visual and auditory props may be as simple as a telephone that can be used to simulate phoning the health care provider. Gather the props and equipment and have the environment prepared in advance of the case. For example, intravenous fluids or blood products may need to be mixed and hung. Depending on the patient being simulated, the mannequin may need transforming with makeup, masks, or a wig.

- **Q: What audiovisual equipment is needed and available?**
  A: A whiteboard, blackboard, or flipchart is needed for recording patient data and nursing interventions during the scenario. Video recording of a simulation session is useful in providing feedback for the participants. Video playback can be a powerful teaching tool as participants are able to observe and critique the scenario. The video recording is also helpful for the operator and others to see the simulation from all angles.[41]

- **Q: Is there time for debriefing?**
  A: The debriefing is a critical part of the patient simulated scenario, providing participants with an opportunity to reflect on their learning experience. During this time, participants may be asked to consider key questions such as: "What went well?" "What could have been done better?" "How did you feel in the role of _____?" (See Postsimulation.) The debriefing is also a time to review key concepts and knowledge related to the scenario. Important points can be discussed; pathophysiology of patient symptoms and responses to interventions can be reviewed; rationale for interventions can be identified; actions, dosages, side effects, and administration of medication can be discussed.

Presimulation

Presimulation Faculty

Prior to use of the simulator with students, faculty must be fully prepared to facilitate the learning experience. This means familiarity with the equipment and with the particular scenarios that are to be used. The computer operator needs to be skilled in the technology of the simulator. They need to know how to set up the equipment, connecting the mannequin to the computer, and initiating the program to be used. If a preprogrammed scenario is used, the operator starts the program and allows it to run. However, if the scenario allows physiological parameters to change outside of the program, the operator must be knowledgeable about how to make the necessary adjustments as students are in the midst of the scenario. For example, if students do not intervene promptly and appropriately in recognizing and treating hemorrhage, the "patient" may progress to hypovolemic shock and subsequently arrest. The operator can determine how quickly the patient's condition deteriorates and the patient's response to interventions.

It is important to provide all involved in the case with a script a few weeks prior to the simulation so that they can prepare adequately to be a facilitator. You might color code each role in the script to allow ease of following the case. The script should be in a large font and double-spaced, allowing quick referencing during the case. It is helpful to rehearse the simulation scenario before utilizing it with students. This allows for refining and adjusting the scenario and/or roles as needed prior to implementation to promote its effectiveness as a learning strategy. Because this is an unfamiliar educational method for most nursing educators, faculty may benefit from in-service classes about teaching with the simulator. Additionally, they need the opportunity for hands-on learning with the simulator so that they are better able to assist students and facilitate their learning experiences. Having faculty participate as students in scenarios can be very effective in increasing their comfort level with the patient simulator.

Using clinical faculty as facilitators of patient simulator scenarios can be very effective, particularly with their own clinical groups. This can provide opportunity for faculty to gain

insights into how the students function as team members; to identify leadership qualities; to assess communication, critical thinking, and skill performance; and to observe how students react under pressure if a critical situation occurs.

Using the METI HPS With Baccalaureate Nursing Students

The following paragraphs describe how the METI HPS is used with senior students in the baccalaureate nursing education program at the University of North Carolina at Chapel Hill. Simulation is used to provide students with a synthesis learning experience in which they have the opportunity to utilize previous knowledge and experiences as they assess, intervene, and evaluate the care of a rapidly deteriorating patient. This critical care experience requires that students demonstrate competency in assessment, critical thinking, communication, teamwork, skill performance, and documentation. It is an excellent means of reviewing important concepts as students prepare to take the National Council Licensure Exam for Registered Nurses (NCLEX-RN) and enter practice within a few months.

Presimulation logistics. The course coordinator for the senior-level capstone medical surgical nursing course assigns students to groups for the simulation experience. Each clinical group is divided into two groups of five students. (Five seems to be the maximum number for effective use of the HPS.) Each clinical faculty member assists with the simulation experience for his or her group. Students spend a total of 2 hours in the simulation lab during the semester as they encounter four simulation scenarios involving care of an acutely ill adult patient. The cases that are typically used include congestive heart failure progressing to pulmonary edema, tension pneumothorax, hyperglycemic hyperosmolar nonketotic coma, and cardiac arrest. These cases were adapted from preprogrammed HPS scenarios.

The HPS is located in a room that is dedicated to its use. The room houses the mannequin on a stretcher, the patient monitor display, a cart with medications and emergency supplies (oxygen, IVs, syringes, etc.), a set of cabinets that includes a countertop and sink, a white erase board, resource books, and a telephone. There is an adjoining control room that houses the operating tower and computer interface. A one-way mirror enables the computer operator to observe the students and faculty as they participate in the scenario. An infant sound monitor is placed near the head of the mannequin and the receiver is placed in the control room so the operator can hear what is being said in the simulation room.

Two nurse educators who act as facilitators and a graduate teaching assistant who operates the computer usually conduct the simulation scenarios. The nurse educator who is most knowledgeable and experienced with the HPS takes the lead and directs the simulation. The other nurse educator (usually the clinical faculty) assists and supervises students' performance. Both faculty members assume additional roles as needed, such as a family member and physician or nurse practitioner. The graduate teaching assistant operates the computer from the control room, initiating and managing the physiologic responses of the mannequin in accordance with each particular scenario or simply starting and stopping a preprogrammed scenario. The teaching assistant also is the voice of the patient (the HPS mannequin has a voice box in his neck), responding to the students' history and assessment questions. The infant sound monitor allows the teaching assistant to hear the students' questions.

Presimulation student instructions. In an effort to promote realism in the cases, students and faculty dress as they would for the clinical experience in the hospital. In addition, they are asked to wear identification badges and to bring their stethoscopes. It is made clear to students that the HPS simulation is a required experience. Students are expected to come to the HPS

simulations with some background knowledge and experience. They may have assigned readings or written assignments to complete prior to the simulation. A completed written assignment (e.g., study questions) may be used as a student's admission ticket to the scenario.

Presimulation briefing. All simulation scenarios begin with a presimulation briefing (see Simulation Box 1). During this time, students are oriented to the mannequin and the learning environment. A faculty member who will be assisting with the subsequent scenarios conducts this session.

Each group of students enters the simulation room, accompanied by one of the nursing educators who will facilitate the cases. The first time students encounter the human patient simulator, the technology and equipment involved with the mannequin are explained (see Simulation Box 2). Students are encouraged to uncover and examine and touch the mannequin, listen to the heart and breath sounds, palpate the pulses, and observe pupil response. The voice of the mannequin is demonstrated. It is important to remind students that they are to treat the mannequin as they would a patient in the scenarios. Students are oriented to the environment, including the computer display and the location of equipment and supplies. After each student has had an opportunity to become acquainted with the mannequin and the environment, the group of four or five is escorted outside the simulation lab where they receive instructions about how the scenarios will proceed. Each student is assigned a specific role during the scenario: primary nurse, secondary nurse, communicator, recorder, and resource/medication nurse (see Simulation Box 3). The students draw 5" × 7" index cards to determine their assigned roles. Each card identifies the responsibilities of that particular role. In subsequent scenarios, role assignments are changed so that no student repeats a role they have already performed. During the briefing, students are given a concise report on the patient they will meet in the scenario. The setting (e.g., emergency department, intensive care unit), patient history, presenting problem, family situation, and other pertinent details are described to the students.

The use of index cards to assign specific student roles evolved after conducting a few simulations in which students appeared disorganized and confused about what each one should be doing. For example, one student would think of something to do and all the students in the group would set about attempting to perform that intervention. There was no evidence of teamwork. In an attempt to remedy this problem, students were asked to volunteer for a role in the scenario (primary nurse, secondary nurse, communicator, recorder, and resource/medication nurse). Students were hesitant and took too long deciding who would perform each role. Subsequently, faculty developed index cards to identify each role and the associated responsibilities of that role. During the presimulation briefing, a faculty facilitator shuffles the cards and asks students to draw their roles prior to each scenario. In addition to saving some time, this technique provides the students with some direction as they begin the scenario.

Simulation Box 1. Presimulation Student Preparation

Instructions to the student:

- Prior to simulation, complete assigned readings, case materials.
- Be prompt to your assigned simulation time.
- Dress as in clinical.
- Wear name badge.
- Bring stethoscope.
- Address and treat mannequin as though a patient.

Simulation Box 2. Presimulation Briefing—Orientation to Simulator & Learning Environment

Orientation to the mannequin:

- Heart and lung sounds
  - Instruct students to listen to the heart and lungs sounds so that they are be able to differentiate from normal, which is what they are hearing during orientation, and abnormal, which is what they will hear when the scenario begins. Help students to adapt to the mechanical sounds associated with the heart and lung sounds.
- Palpate peripheral pulses (no posterior tibia pulse).
- Perform PERRL (no A or accommodation).
- Explain to students what mannequin does not do/have:
  - Bowel sounds
  - Sweat
  - Seizure
  - Change color such as cyanotic, flushed, or pale
- Demonstrate how to connect mannequin to monitor.
- Inform students that patient data is located on the patient care monitor. Detail the data as presented so that they can interpret later in a case.
- Differentiate for them what data they can expect to get from the monitor and what will require their assessment.

Orientation to the learning environment:

- Monitor
- Mannequin on stretcher or hospital bed
- Oxygen and delivery devices
- Defibrillator
- Medications
- Suction
- Patient chart
- Realistic lab values, chest x-rays, EKGs
- Phone to call physician/nurse practitioner and labs

Simulation Box 3. Role Assignment Cards

Position:	**Role**:
Primary RN	Team leader, assessment, history, sets priorities, and delegates.
Secondary RN	Assists with assessment, performs nursing skills and medication administration as directed by primary nurse.
Recorder	Writes down pertinent information on whiteboard.
Communicator	Speaks to family, health care provider, lab, radiology, etc.
Resource/Medication RN	Looks up needed information for team (e.g., safe medication dosage, rate of administration of medications) and administer medications as needed**.**

**The roles are printed on colored 5" X 7" index cards with the role name on one side and the responsibilities of role on the other side. These cards are laminated and used over and over for each simulated case.*

Intrasimulation

The actual simulation begins as students enter the simulation room. If it is their first encounter with the simulator, they may need some assistance and encouragement in getting started. The faculty facilitators coach the students as needed. The students acting as primary and secondary nurses are expected to introduce themselves to the patient and family. The communicator assumes the position near the telephone, the recorder goes to the whiteboard, and the resource/medication nurse locates the reference materials. The primary nurse begins the assessment and directs the secondary nurse to assist or to do other tasks as needed. Based on the assessment findings and any physiologic changes that may occur, the primary nurse determines the interventions that are needed. He or she may collaborate with the secondary nurse or other team members as necessary. The recorder documents all assessment findings on the whiteboard. At the point it is determined that a call to the health care provider is warranted, the communicator gathers the necessary data and contacts the provider by telephone. Using the SBAR communication method, pertinent information is relayed to the provider and orders are obtained. The communicator documents the orders. As soon as she or he is finished, the facilitator uncovers a foam board with the orders prewritten large enough that they are visible to the entire team. The orders are implemented at the direction of the primary nurse, who is also involved in carrying out the orders. The resource nurse looks up any medications that are ordered to identify the type of drug, the actions, dosage, administration, and potential incompatibilities with other medications. This information is communicated to the team prior to administering any medications. The primary nurse can delegate some of the medication administration to the resource nurse.

The faculty facilitators may be involved in numerous aspects of the simulation. One may be assisting with medications, while another may be helping with skills such as applying oxygen or testing blood sugars on the patient. If the students do not intervene appropriately, the patient may go into respiratory arrest and/or experience cardiac arrhythmias. Faculty assist the students as they perform CPR and administer emergency medications. The simulation ends at the predetermined “end” of the case, when the patient “expires,” or as determined by the faculty.

Postsimulation

Debriefing is used to correct any misinformation or improper practice techniques the students may demonstrate. Beaubien and Baker[2] stress the importance of feedback to enhance the ability of students to integrate correct behaviors into their skill set. Through the simulation, gaps in knowledge are identified in individual students that would otherwise go undetected. Additionally, in the debriefing students are asked to reflect on their own skills and knowledge. They identify what they have done well and areas that warrant improvement. Because there are multiple activities occurring throughout the simulation and students may be focused only on their specific roles, debriefing can be used to review key points about the simulation. This includes discussion of the events that occurred, psychomotor skills such as setup of a chest tube drainage system, selection of oxygen delivery method and application, rate and technique for IV push medications, etc. (see Simulation Box 4)

Simulation Box 4: Postsimulation Debriefing and Discussion

Ask students:

- What do they think they did well? – Validate what they know and affirm what they are currently doing well.
- How did this case make them feel?
- What would they do differently if they had to do it again? – Critique their performance as a group and assist them to identify additional learning needs.
- How did they like working with the HPS?

Review key concepts:

- Describe and interpret scenario.
- Students will
  - Discuss roles of team members – point out teamwork, communication, and use of appropriate and inappropriate delegation.
  - Highlight areas for potential patient safety issues – communication with each other, transcription of orders, handoff and transfer of patient.
  - List what signs and symptoms Mr. Jones exhibited.
  - State how Mr. Jones' presenting signs and symptoms varied from the textbook picture.
  - Identify what precipitated Mr. Jones' CHF and pulmonary edema – past medical history and pathophysiology.
- Discuss pathophysiology of CHF and pulmonary edema.
- Review lab reports, x-ray, EKG.
- What should be immediate interventions? (Focus on ABCs.)
- Review communication with health care provider:
  - SBAR
  - Key points to include
- Discuss rationale for each of the health care provider's orders.
- Identify important nursing considerations:
  - Conserve Mr. Jones' energy – do not ask complete history while he has dyspnea.
  - Explain to Mr. Jones what you are doing – be brief, concise.
  - Communicate with Mrs. Jones – provide information, but do not offer false reassurance; have staff member escort her out of room.
- Do a skill review:
  - Non-rebreather mask and why it is best choice for oxygen delivery
  - Insertion of IV: choice of angiocath size, insertion site, fluid, rate of administration
  - IV push medications and technique for administration
  - Foley catheter to straight drainage (urometer for hourly outputs)

It is important to provide students with an opportunity to evaluate their experiences and the use of the patient simulator as an instructional strategy. This is done as part of the debriefing, but should also be part of a computerized or written evaluation. It may be part of a course evaluation or a separate evaluation tool specific to the patient simulation experience.

Student Evaluations of HPS Scenarios

The students who have participated in METI HPS simulations in the baccalaureate of science in nursing and continuing education programs have given overwhelmingly positive evaluations of the simulator as an instructional strategy. This is consistent with other reports of student evaluations in nursing[43–45, 48] and medical education.[51, 54, 55] One student commented, "Simulation was very effective. It took into account many facets of care, for example, assessment, communication with family, doctor's orders, medications, including herbs."

Many students feel that the simulation experience taught them all they know. This concept is evident in the following student evaluative comment:

> The simulator was awesome and so realistic. We were required to do rapid assessments of a critically ill patient and to pull it all together to provide care. Now I better know what I do not know and can work on improving. I learned more in this hour than I have my whole curriculum.

Students do not recognize that the simulation provides a synthesis experience in which they draw from previous knowledge and experiences. The didactic and clinical components of their educational experience to date have been instrumental in preparing them to think and act like nurses. The "aha!" experience of patient simulation promotes student confidence in their critical-thinking and clinical-decisionmaking skills and in their ability to practice as safe, competent nurses as they enter the workplace.[46, 48]

Practice Implications—The Future of Patient Simulation in Nursing Education

Use of the patient simulator as an instructional strategy holds great promise for nursing education. Simulation can become an integral part of nursing education because of its ability to improve patient care and patient safety. No live patients are placed in jeopardy at the expense of the learner. Simulation provides standardization of cases, promotes critical thinking, allows mastery of patient care, provides immediate feedback, and helps students integrate knowledge and experience. It is an ideal synthesis learning experience.

Because the patient simulator is a relatively new educational tool, nursing educators must become acquainted with the technology, its potential uses, and benefits to learners. Toward that end, it is important that the nursing literature on patient simulation is increased, both in descriptive articles and in research reports. As faculty become more aware of the advantages of educating students with patient simulation, its utilization in educational programs should increase.

Because of the investment of money and faculty time associated with patient simulation, it is imperative that administrators and educators see the value of teaching with simulation. Administrators need to commit financial resources to procuring patient simulation equipment and training faculty in its use. Faculty time must be dedicated to the development and implementation of simulation programs.

Nursing faculty need to look for new ways to utilize the patient simulation technology with all types of learners. Schools of nursing can optimize the use of a patient simulator and increase its cost effectiveness by incorporating it into undergraduate, graduate, and continuing education programs.

Research Implications

The paucity of nursing research on the use of patient simulation demonstrates the need for further study. Studies are needed to investigate the best ways to utilize patient simulation in nursing education.[39] Evaluative studies are needed to examine the success and effectiveness of patient simulation in all types of nursing education programs. Research is also needed to demonstrate that knowledge and skills acquired in a simulated environment are transferable to actual patient care situations. The cost effectiveness of using simulation also needs to be explored.[47, 56–58]

Conclusion

The use of patient simulators in nursing education is a relatively new instructional methodology. The rationale for using simulation as an educational strategy includes the absence of risk to a live patient; the ability to provide standardization of cases; the promotion of critical-thinking, clinical-decisionmaking, and psychomotor skills; the provision of immediate feedback, and the integration of knowledge and behavior. Through patient simulation scenarios, essential elements of patient safety can be emphasized, such as prevention of medication errors, promotion of effective communication, and the importance of teamwork. Learners can be exposed to critical care scenarios and have the opportunity to respond without fear of harming a live patient.

By providing students with exposure to a variety of clinical situations through clinical practicum experiences and patient simulations, they can be better equipped to provide safe, effective care and work as contributing members of the health care team.

The challenge is for faculty to embrace patient simulation as an instructional strategy and to seek its effective implementation in nursing education programs. The exciting technology of patient simulation is only as good as the faculty who use it. The potential benefits to learners outweigh the costs of the equipment and faculty training.

Table1. Teaching/Learning Strategies Using Simulation

Type of Simulation[59]	Description[59]	Advantages[60, 61, 62]	Disadvantages[60, 61, 62]
Low-tech (static) task trainers e.g., food items: oranges for injections, chicken breast for biopsy, pigs feet for suturing, injecta pads, adult/child/infant mannequins, breast and gyn/prostate models, eye/ear models, IV arms, CPR mannequins, case studies, etc.	Props, models, or mannequins used to practice skills and procedures	No threat to patient safety Readily available Reusable Develop role memorization Allows for return demonstration of skills Large groups of learners Low to moderate cost	Task training Consistency Learner – memorization Lower veracity Return demo without critical thinking
Simulated patients e.g., standardized patient (trained actors), learner/learner, educator/learner, patients playing role of patient, female and male human models for pelvic and prostate exams, unfolding case studies	Role-play patients for training, simulates assessment of history taking, physical exams, communication, and therapeutic psychiatric interventions	No threat to patient safety Great tool for high communication skills Provides relatively consistent experience for all students	Moderate to high cost with each use Limited learners
Screen-based computer simulators e.g., computer-assisted instruction (CAI), virtual reality excursions (VRE), Web-based programs	Programs to train and assess clinical knowledge and decisionmaking.	No threat to patient safety Provides relatively consistent experience for all students Reusable	Variable amount of critical thinking Moderate cost
Complex task trainers e.g., virtual reality devices such as bronchosocpy, laparoscopic surgery, IV access (Cath Sim^{R}), haptic (touch cue) simulators such as pelvic exam, cardiac catheterization and stent placement, respiratory intubation, neonate (umbilical artery, lumbar, intubation) models	High-fidelity visual, audio, touch cues with interfaces with computers	No threat to patient safety Provides relatively consistent experience for all students Promotes realism Improves psychomotor skills	Moderate to high cost Limited learners

Type of Simulation[59]	Description[59]	Advantages[60, 61, 62]	Disadvantages[60, 61, 62]
Human Patient Simulators ***Low-fidelity*** e.g., Noelle birthing mannequin – uses compressor to birth newborn every 7 minutes ***Moderate-fidelity*** e.g., Laerdal™ SimMan™ ***High-fidelity*** e.g., METI Human Patient Simulator®	Full-length human mannequins Simulated anatomy and physiology Computer-driven scenarios that responds as programmed Computer-driven physiologically based that responds in real time to interventions	No threat to patient safety High degree of realism and veracity Low educator/learner ratio (1:5) Active involvement of learner Decreases emphasis on memorization Consistent experience for all students: serious or uncommon clinical problems can be presented to all learners Creates a standardized setting for honing and enhancing critical-thinking, problem-solving, and decisionmaking skills Enhances ability to assess variations in patient responses and the learners' ability to pick up important assessment data Increases competence and ability to formulate a strategy for a specific situation Learners are better prepared for clinical practicum Practice communication with multidisciplinary team members. Teamwork and leadership skills can be practiced Communication and delegation skills can be fine tuned Psychomotor skills can be applied and refined Increased organization of patient care	High cost (startup and ongoing cost) Maintenance Resource intensive: monetary and faculty Limited learners High staffing ratio No validation of transfer of learning to clinical setting Learner's disbelieving attitude Hypervigilance because being observed Anxiety of learner interferes with performance Lack of knowledge at time of simulation experience of learner Physical space for simulator and associated teaching sessions needed Lack of comfort with simulator as teaching strategy for educators

Table 2. Key Terms and Definitions

Terms and Acronyms	Definitions
ABCs	airway-breathing-circulation
ABG	arterial blood gases
ACLS	advanced cardiac life support
ADE	adverse drug event
ASA	aspirin
BSN	baccalaureate of science in nursing
BP	blood pressure
CAI	computer-assisted instruction
Capstone	A course occurring at the end of a curriculum allowing students to synthesize what they have learned.
CBC	complete blood count
Champion	A person who will be a leader in the use of a new technology, helping to bring additional faculty along in their implementation of the technology across the curriculum.
Chem 7	Blood work that is done on serum examining seven chemical tests: blood urea nitrogen (BUN), serum chloride, carbon dioxide, creatinine, glucose, potassium, and sodium.
CHF	congestive heart failure
Code	Respiratory and/or cardiac arrest
Complex task trainer	Highly sophisticated computer technology that provides training on specific skills or procedures; includes virtual reality and haptic systems.
CPR	cardiopulmonary resuscitation
CRM	Crew Resource Management
CXRs	chest x-rays
ED	emergency department
EKG	electrocardiogram
Fidelity	The degree to which the appearance and function of the simulator resemble the simulated system; low, intermediate, or high[5]
FiO_2	fraction of inspired oxygen
Generation X	Refers to the generation of people born between 1961 and 1981 (dates vary among different sources) and describes behaviors in terms of life experiences.
Generation Y	Refers to the generation of people born between 1977 and 2003 (dates vary among different sources) and describes behaviors in terms of life experiences.
GYN	gynecological
Haptic	Technology that interfaces with the user via the sense of touch.
High-fidelity patient simulators	Highly sophisticated computerized mannequins, capable of realistic physiologic responses.
HHNC	hyperglycemic hyperosmolar nonketotic coma
HIPAA	Health Insurance Portability and Accountability Act
HOB	Head of bed
HPS	human patient simulator; high-fidelity computerized mannequin, produced by Medical Education Technologies Incorporated (METI®).
HR	heart rate
Hypovolemic	Decreased circulating blood volume.
ICU	intensive care unit
I/O	intake and output
Integrated simulators	Simulators that combine computer technology and part- or whole-body mannequins.
Injecta pad	Gel-filled pad used to teach and practice giving intramuscular and subcutaneous injections.
IVs	intravenous line or intravenous fluid
K-Dur	Oral form of potassium chloride, a potassium supplement.
JCAHO	Joint Commission on Accreditation of Healthcare Organizations (now known as the Joint Commission)
Laparoscopy	Minimally invasive surgery in the abdomen or pelvic area where thin instruments are used to view, remove, or repair areas through small incisions.
mEq	milliequivalents
METI	Medical Education Technologies Incorporated
mg	milligram(s)

Terms and Acronyms	Definitions
MD	medical doctor
ml	milliliter(s)
MP3 player	MPEG-1, Audio-3, a portable, compressed, digital encoding device that allows a person to listen to music and/or watch video.
MSO_4	morphine sulfate
NASA	National Aeronautics and Space Administration
NRB mask	non-rebreather mask for delivery of oxygen
NCLEX-RN	National Council Licensure Exam for Registered Nurses
NS @ KVO	normal saline (intravenous fluid) at keep-the-vein-open rate (30 ml per hour)
O_2	oxygen
Part task trainers	Low-tech or static task trainers, designed to replicate a portion of the body or the environment; many represent selected anatomical areas of the human body and are used to teach basic psychomotor skills and procedures.
Patient simulators	High-fidelity computerized mannequins.
PC	personal computer
PDA	personal digital assistant, a hand-held data device.
Pedal edema	Excessive fluid in the extremities. When the tissue is pressed with a finger over a bony prominence, the depression remains, and the amount of depression is graded from 0 to 3+ to indicate severity of the fluid overload.
PERRLA	pupils equal round and reactive to light and accommodation
PERRL	pupils equal round and reactive to light
PMH	past medical history
PO	*Per os,* Latin for "by mouth"
Pulmonary edema	Fluid collecting in the lungs primarily due to left-sided heart failure but may occur with right-sided heart failure.
QD	every day
Q 5 min	every 5 minutes
RN	registered nurse
RR	respiratory rate
SBAR	Situation, background, assessment, recommendation: A model of communication that is clear, concise and to the point. Sharing key information about situation, background, and assessment, and providing a recommendation.
Screen-based computer simulators	Computer programs designed to model various aspects of human physiology, specific tasks, or environments; learners use information to make clinical decisions and observe the results in action; feedback is provided during and/or after the interaction.
SimMan™	High-fidelity patient simulator produced by Laerdal™
Simulated patients	Live persons acting as patients through role play; student partners practicing assessment skills or procedures; live actors as trained patients.
Simulation	A technique or device that attempts to create characteristics of the real world; in health care, a device representing a patient or part of a patient that can respond and interact with actions of the learner;[3] activities that mimic a clinical environment, designed for use in demonstrating procedures and promoting decisionmaking and critical thinking.[4]
SL	sublingual
SOB	shortness of breath
Stat	*Statim,* Latin for "immediately" or "now"
T	Temperature
Tension pneumothroax	A patient care emergency where air enters the pleural cavity but cannot exit, causing increased pressure in the pleural space and leading to the collapse of the lung on the affected side. This change in pressure will eventually compress the heart and major vessels, and the lung on the affected side will not be able to expand.
TV	television
VRE	virtual reality excursions

Appendix A: Simulation Case Presentation

Simulation Scenario: CHF Pulmonary Edema

Simulation participants:

- Lead faculty: director and facilitator
- Clinical faculty: facilitator, assume additional roles (wife, MD), assist students with psychomotor skills, etc.
- Computer technician: (in control room, behind two-way mirror): "patient" voice and computer operator
- Students

Note: To facilitate ease of role identification, when we prepare scripts for the faculty, we color code all the different roles, double space, and highlight key points. The case is then bound and distributed to all the facilitators.

Facilitator: Role context is an RN who has worked the night shift in a busy emergency department (ED). Students are told they are coming reporting to work on the day shift in the ED. It is 7:00 a.m. and time for report.

> *Thank goodness you all are here. We have had a terrible night. There is a code going on down the hall, so I'll be quick. I need for you to take over care of the patient in room 1. His name is Alex Jones; he is a 62-year-old Caucasian male, just brought in by his wife. He is complaining of shortness of breath and chest pain. He says he has been up all night, and his wife finally made him come to the ED because it had gotten so bad. His wife has gone to park the car and has all of his meds. I'm sorry; all we have done so far is get him in a room. He hasn't been connected to the monitor, and no one has assessed him yet. Thanks for taking him over! I'll check on you later. I have to run back to the code.*

Facilitator: Escorts students into the simulation room. Direct communicator to area where phone (phone is a prop and is not connected) is located; direct recorder to white erase board and resource nurse to reference materials. If students are hesitant to begin their assessment, provide encouragement.

Students:
Primary and secondary nurses should introduce themselves to Mr. Jones and begin to do the following:

- Connect patient to the monitor.
- Obtain vital signs.
- Auscultate heart and lungs.
- Administer O_2 – 100 percent non-rebreather (be sure to fill bag with O_2 before putting mask on patient).
- Start IV – NS @ KVO.
- Elevate HOB.

- Assess pain (rate and describe).
- Assess for peripheral edema (he has on puffy socks to simulate 3+ pedal edema).
- Obtain history – recognize the need to limit questions due to his SOB.

Facilitator: Students need to ask patient appropriate questions. If they seem like they are getting off track, give redirection and guidance to their assessment and history. (The primary and secondary nurses may take directions/suggestions from the other team members.)

Computer technician: (Computer operator on other side of one-way mirror is the voice of Mr. Jones, voice is transmitted through microphone).
Voice of Mr. Jones: Make voice sound very anxious, keep repeating until nurse intervention, *"I just can't catch my breath," "It hurts all over my chest," "I can't take lying down like this,"* and *"You've got to help me."*

When asked by the students, Mr. Jones gives the following responses:

- Pain: *"10" on a scale of 1–10, all over my chest, feels different from when I had heart attacks.*
- PMH: *I've had four heart attacks. When? The first one was when I was 36 and my last one was 2 years ago. I've never had open-heart surgery.*
- Medications: *"Oh, honey, I can't keep track of all of them. My wife is bringing them in." "I took all of them this morning at about 3:00 a.m. before we came in."*
- Social history: *No alcohol, quit smoking 20 years ago.*
- Recent changes: *"When I take my socks off, my leg looks like they are still on," "I tell my wife that I fall asleep watching TV every night in the recliner, because I don't want her to worry. But, the truth of the matter is, I just can't sleep lying down anymore,"* and *"I thought maybe I just ate too much at (fill in appropriate holiday), because I've gained 10 lbs in the past 2 weeks."*

Faculty facilitator: (One of the faculty facilitators acts as wife of Mr. Jones.) At some point, preferably when the students are engaged with the patient, a concerned wife runs into the room, anxiously asking about her husband, trying to get to him to hold her hand. Ask the nurses, *"Is he okay? What is going on? Is he having another heart attack?"* Continue to be "in the way" until one of the students responds to you and takes you aside to talk to you.

Give the paper bag full of his medication bottles from home to one of the students.

List of meds:

- Nitrostat 0.3mg SL prn chest pain Q 5min x 3 doses
- Ramipril 2.5 mg PO QD
- K-Dur 20 mEq PO QD
- Furosemide 20mg PO QD
- Tenormin 50mg PO QD
- Lanoxin 0.25mg PO QD
- ASA 81mg PO QD

Student: The student acting as **communicator** should take the wife out into the hall and identify herself/himself and explain who she/he is and what role they have in the care of Mr. Jones.

Use therapeutic communication to explain that Mr. Jones's heart rhythm is regular, which is a good sign, but that you will have to do an EKG and additional tests to determine if he is having/has had another heart attack. Assure her that the team is doing everything they can for him. Attempt to calm the wife down and give her no more than two tasks. Tell her that the secretary will accompany her to registration/admitting and then she should come back to the waiting room. Tell her your name again, and explain that you will be here for the next 12 hours. Tell her you will be out very soon to update her on her husband's condition. Thank her for bringing in his meds and reassure her that she did the right thing by bringing him to the ED.

Note: Since the "wife" is a faculty/facilitator she/he can come out of role and give the student feedback and direction as needed during or after the interaction.

Computer technician: When you think that the students are starting to pick up on the diagnosis of congestive heart failure [can be cured by lead faculty], begin coughing (as Mr. Jones).

Facilitator: Once Mr. Jones starts coughing, hand the students the emesis basin with pink, frothy sputum.

Recipe: Pink, frothy sputum can be simulated by mixing a small amount of red powdered Jell-O, ivory dish detergent, and water, shaking it vigorously, pouring off liquid, and putting pink suds in emesis basin.

Students: The students should recognize this as a cardinal sign of pulmonary edema. If they feel that they have enough data, they need to anticipate the following orders:

- Diuretic
- Narcotic analgesic
- Nitroglycerine
- EKG
- Chest X-ray
- Blood gases
- CBC, Chem 7, cardiac enzymes
- Foley catheter (strict I/O)
- Continue 100 percent oxygen per non-rebreather mask

Students: When the students feel they are ready, the **communicator** places a call to the health care provider. A prop telephone is available for the student to use. The student is expected to do the following: (If student is having difficulty, they can use the script that follows. Faculty hands card with script to **communicator**.) Using principles of SBAR (situation, background, assessment, recommendation), student accomplishes the following:

- Introduce yourself and state where you are located.
- State who the patient is and describe him.
- State chief complaints and relevant signs and symptoms.
- Provide brief history with relevant information for current status.
- Give quantitative vital signs, always include FiO_2 with pulse ox.
- Identify interventions that have been done.
- State what you think is going on with the patient.
- Ask health care provider for further orders.

Figure 1. Communication With Health Care Provider

"Dr. _____, This is [*state your name*], one of the nurses in [*state your department*].

We have a new patient, [*patient's name*], a [*age*] year-old, [*race*], [*gender*]. He came in with complaints of_____

_____, which started at [*time of onset*].

His vital signs are [*HR*], [*RR*], [*BP*], [*T*], and [*pulse ox, amount of O_2 and type of delivery*].

He has a history of _____.

On assessment, we found_____.

So far, we have [*tell what interventions you have done so far*].

I think he may have _____.

I think he needs some_____.

What else you would like for us to do?"

Restate what needs to be done, including reading back the orders.

Confirm when the health care provider will arrive to assess the patient.

Facilitator: (One of the faculty facilitators acts as the health care provider responding to the student's call.) The health care provider gives the following orders and states she/he will be down to see the patient shortly. The student should write down the orders and read them back to the health care provider. After this is done, the orders are displayed on a prewritten foam board so that they can be seen by all the students simultaneously.

The orders are as follows:

- Lasix 40mg IV stat
- Morphine 4mg IV stat
- Nitroglycerine 0.4mg/spray 2 sprays SL stat
- Normal saline at 30 ml per hour
- Stat ABG
- Stat EKG and serial EKGs
- Stat CBC and Chem 7
- Stat cardiac enzymes
- Stat portable CXR
- Foley catheter to straight drainage
- Hourly intake and output
- Continue 100 percent NRB mask

Students:
The primary nurse delegates tasks to secondary nurse (med administration, Foley, etc.) and directs communicator to call lab, x-ray, and EKG.
The resource nurse needs to look up the proper rate of administration for Lasix and MSO_4. The primary and secondary nurses administer the Lasix and morphine IV push through the peripheral IV that they placed earlier.
The communicator places a call to lab, radiology, and EKG to request stat testing.

Facilitator: State "After about 15 minutes, you get the test results on Mr. Jones."

- EKG: Sinus tachycardia, indicative of old MIs **(Give students EKG.)**
- CXR: Enlarged heart, enlarged hila with indistinct margins (perivascular edema), and prominence of veins draining the upper lobes (cephalization of flow) **(Show students CXR.)**
- Lab results: respiratory acidosis **(Show students ABG.)**

Students should recognize and state need to call results to the health care provider as soon as possible.

Facilitator: "Where do you think Mr. Jones should be transferred?"
Students should state that Mr. Jones will likely go to an intensive care unit.

SCENARIO ENDS

Debriefing

This is one of the most important aspects of simulation. It is imperative that it is done well in order to help students have the best possible synthesis experience.

Take the students outside the simulation room. Begin debriefing (see Simulation Box 4) while other simulation staff reset the room and mannequin for the next case. Distribute handouts with key points and materials for the student to take with them and review.

Remind students they are not to share information with their fellow students because

- All students should have the same opportunity to learn.
- It is best for the student to move through the case as they did, experiencing the hot seat as they did.
- To discuss the case is similar to sharing answers from a test and would be considered an Honor Code violation.
