Foreword

The Agency for Healthcare Research and Quality (AHRQ) and the Robert Wood Johnson Foundation (RWJF) are pleased to have jointly sponsored the development of this handbook for nurses on patient safety and quality. *Patient Safety and Quality: An Evidence-Based Handbook for Nurses* examines the broad range of issues involved in providing high quality and safe care across health care settings.

We know that nurses are at the center of patient care and therefore are essential drivers of quality improvement. From the Institute of Medicine's reports, including *To Err is Human* and *Keeping Patient's Safe: Transforming the Work Environment of Nurses*, we know that patient safety remains one of the most critical issues facing health care today and that nurses are the health care professionals most likely to intercept errors and prevent harm to patients. For us, both at AHRQ and RWJF, improving patient safety and health care quality is embedded in our mission and at the core of what we do.

We strongly believe that the safety and quality of health care in this nation is dependent upon the availability of the best research possible and on our ability to deliver the results of that research into the hands of providers, policymakers, and consumers so that all can make better decisions. We believe the result will be improved health care and safety practices, which will be manifested in measurably better outcomes for patients.

Given the diverse scope of work within the nursing profession in this country, AHRQ and the RWJF expect that the research and concepts presented in the book will be used to improve health care quality by nurses in practice, nurse-educators, nurse-researchers, nursing students, and nursing leaders. The 89 contributors to this book represent a broad range of nurse-researchers and senior researchers throughout this nation.

The product of this joint effort underscores the commitment of AHRQ and the RWJF to achieving a health care system that delivers higher quality care to everyone. We believe that high-quality health care can be achieved through the use of evidence and an enabled and empowered nursing workforce.

We welcome written comments on this book. They may be sent to Ronda Hughes, Agency for Healthcare Research and Quality, 540 Gaither Road, Rockville, MD 20850.

Preface

Errors pervade our lives in our homes, on the roads, and in our places of work. Each hour of each day, patients and clinicians are affected by near errors and the consequences of adverse events. The effects of health care errors and poor quality health care have impacted all our lives—sometimes directly, at other times indirectly. Even during the writing of this book, many of the authors had firsthand experiences with near errors, adverse events, and a level of poor-quality care that should never have been presented to any patient. Given the importance of health and health care in our lives, the purpose of this book is to bring safety and quality to the forefront in nursing.

Throughout these pages, you will find peer-reviewed discussions and reviews of a wide range of issues and literature regarding patient safety and quality health care. Owing to the complex nature of health care, this book provides some insight into the multiple factors that determine the quality and safety of health care as well as patient, nurse, and systems outcomes. Each of these 51 chapters and 3 leadership vignettes presents an examination of the state of the science behind quality and safety concepts and challenges the reader to not only use evidence to change practices but also to actively engage in developing the evidence base to address critical knowledge gaps. Patient safety and quality care are at the core of health care systems and processes and are inherently dependent upon nurses. To achieve goals in patient safety and quality, and thereby improve health care throughout this nation, nurses must assume the leadership role.

Despite being a relatively new field of inquiry, particularly in terms of how patient safety and quality are now defined, the need to improve the quality and safety of care is the responsibility of all clinicians, all health care providers, and all health care leaders and managers. As clinicians, we are obligated to do our best, regardless of whether we are acting as a clinician or a patient. Just as we say there are “good patients” and “bad patients,” clinicians as patients can unfortunately be considered “bad patients” because they may know too much, ask too many questions, or are not up-to-date on the research or current practice standards. Yet that is a mindset that must end and become a part of history, not to be repeated. Instead, nurses need to ensure that they and other team members center health care on patients and their families. All patients—whether they include ourselves, our loved ones, or the millions of our neighbors throughout this country—need to be engaged with clinicians in their care.

Each of the chapters in this book is organized with a background section and analysis of the literature. At the end of each chapter, you will find two critical components. First, there is a “Practice Implications” section that outlines how the evidence can be used to inform practice changes. Practice leaders and clinicians can use this information, based on the state of the science, to guide efforts to improve the quality and safety of delivering services to patients. Second, there is a “Research Implications” section that outlines research gaps that can be targeted by researchers and used by clinicians to inform and guide decisions for practice. Faculty and graduate students will find innumerable questions and issues that can be used to develop dissertation topics and grant applications to uncover the needed evidence.

In all but a few chapters, you will find evidence tables. These tables were developed by critically assessing the literature, when possible, and present invaluable insight as to the type and quality of research that can inform practice, clarify knowledge gaps, and drive future research. As the reader will observe, the majority of patient safety and quality research presented in the evidence tables represent cross-sectional studies. In fact, 81 percent of the studies exploring the

various aspects of safety and quality employed cross-sectional study designs, predominately representing assessments at single sites of care and using qualitative surveys. This may be the byproduct of the challenges of the research process (including sources of funding) or the challenges of engaging in collaborative research. From this review of the literature, we can learn the importance of the need for longitudinal, multisite analyses to bring us forward into the next generation of evidence-based knowledge.

Great is the importance of nurses being involved throughout the research process and collaborating with interdisciplinary teams throughout care settings. Then, too, it is critical that nursing leaders and managers, clinical leaders, and nurses across care settings engage in a lifelong pursuit of using data and information as well as research evidence to inform practice. Combined with experiential knowledge, analyses, and evidence, nurses will be challenged to continuously improve care processes and encourage our peers and interdisciplinary colleagues to make sure patients receive the best possible care, regardless of where they live, their race or gender, or their socioeconomic circumstances.

The chapters in this book are organized into six sections. Each chapter can be read independently of the others; however, some do make reference to other chapters, and a greater understanding of the breadth and depth of patient safety and quality can be better obtained by reading the book in its entirety. Highlights from the chapters are summarized by section as follows:

In *Section I – Patient Safety and Quality*, patient safety is discussed as being foundational to quality, where nurses can be invaluable in preventing harm to patients and improving patients' outcomes (chapter 1). Even though the quality and safety of health care is heavily influenced by the complex nature of health care and multiple other factors, nurses have been held accountable for harm to patients, even when other clinicians and health care providers and characteristics of the care system in which they work often have—almost without exception—greater roles and, in some respects, have ensured that an error would happen (chapters 2 and 3). With the many challenges facing health care today, the Institute of Medicine's 11-volume Quality Chasm series brings to light the multitude of issues and factors that individuals and organizations, both within and outside of nursing and health care, need to understand and to work together to overcome (chapter 4). Moving toward and securing a culture of safety throughout health care will, by definition, acknowledge the influence of human factors in all clinicians, the results of human-system interfaces and system factors, and will institutionalize processes and technology that will make near errors and errors very rare (chapter 5). This paradigm shift will enable nurses to think more critically and clinically (chapter 6), and to achieve greater insights as to how education, training, and experience are needed and can be leveraged to ultimately achieve high-quality care in every care setting and for all patients.

To improve patient safety and quality, one needs to understand the state of the science at hand, as well as strategies that can be behind effective utilization of evidence and implementation of change, as discussed in *Section II – Evidence-Based Practice*. It is here that one can learn that implementing evidence into practice can be accomplished though several approaches—often more than one simple intervention is possible—and by early on engaging key stakeholders to move toward adoption of change by translating research-based evidence into everyday care (chapter 7). Yet in assessing the state of the science, it becomes apparent that the majority of care afforded patients is not evidence based, emphasizing the need for health services research to examine progress toward safer and higher-quality care and to assess new and innovative practices (chapter 8). While the future of health care is uncertain, clinicians must

continually assess, understand, and meet the needs of patients and prepare themselves to meet emerging health needs we might not expect (chapter 9).

Due to innumerable pressures to improve patient safety and quality, it may be important to focus on those areas of care delivery, as discussed in *Section III – Patient-Centered Care*, that are significantly influenced by nursing care. Providing health care is all about patients and their needs and meeting those care needs in settings where the majority of care is provided by clinicians—or, in certain circumstances, where loved ones and family members supplement nursing care or solely provide for the care needs of patients in community settings. Almost all the adverse events and less-than-optimal care afforded patients can be prevented, beginning by implementing research in practice. Situations in which failure to use evidence can be detected can include when preventable patients falls with injury occur (chapter 10), when illness-related complications are missed and lead to functional decline in the elderly (chapter 11), and when pressure ulcers develop in patients of any age (chapter 12). For nurses, ensuring and/or providing evidence-based, safe, and high-quality care become even more challenging when patients need care in their homes and subsequently rely on care rendered by family members and loved ones—care that can be dependent upon the guidance of nurses (chapter 13). Not only can the resources and functionality of the community or home setting pose potential threats to the safety of patients and may relegate them to care of a lower quality, but those who care for patients may also succumb to the physical and emotional demands of providing informal care; amelioration can require broadening nursing care to caregivers (chapter 14).

Nursing can also have a significant effect on the outcomes of specific groups of patients, particularly in preventing not only adverse events but the lasting effects of comorbidities and symptoms. The reason behind focusing on these specific populations is that their unique needs must not be considered less important than those of the majority. In the case of children, who are some of the most vulnerable patients due to developmental and dependency factors, it is difficult to provide safe, high-quality care that meets their unique needs. Instead, nurses need to use current best practices (chapter 15) to avert potentially lifelong comorbidities and address symptoms—and develop new practices when the evidence is not available. It is also important to focus on simple strategies to prevent morbidity—not just preventing adverse events—and ensure that patients receive preventive care services whenever possible, especially when the use of these services is supported by evidence (chapter 16). Especially for patients with moderate to severe pain, it is also important to prevent the adverse effects of their diseases and conditions by working with patients to manage their pain, promoting healing and improving function (chapter 17). And finally, in the case of potential adverse effects of polypharmacy in the elderly, nurses can also focus on simple strategies to improve adherence to intended therapies and detect unnecessary side effects, thereby improving medication safety (chapter 18).

Beyond the influence of evidence on quality processes and outcomes, there are health care system and organization factors and characteristics to consider. As discussed in *Section IV – Working Conditions and the Work Environment for Nurses*, evidence concerning the impact of health care system factors illustrates that working conditions and the work environment, which are heavily influenced by leaders, can have a greater impact on the safety and quality of health care than what an individual clinician can do. Instead of aggregating the various aspects of working conditions, the chapters in this section define and focus on specific aspects of key factors associated with patient and systems outcomes, centering on the importance of leadership.

The leadership and management of health care organizations and health systems are pivotal to safer and higher quality of care because they direct and influence: which model of care is used

to organize inpatient care services for patients (chapter 19); whether or not the organization embraces and is committed to fostering and sustaining a climate of safety and high-quality care (chapter 21); the impact of external factors, and the functionality and organization of microsystems within the context of the organization and relationships with others (chapter 22); how the specific care needs of patients are met with sufficient numbers of the right types of nurses (chapter 23 and chapter 25); how resource allocations and cost-saving strategies that involve restructuring, mergers, and organizational turbulence impact care delivery and patient outcomes (chapter 24 and chapter 29); the type of work environment that influences work stress and patient outcomes (chapter 26 and chapter 27); and how the actual physical environment and care processes influence the workload and workflow of nursing care (chapter 28, chapter 30, chapter 31).

Taken together, leadership throughout organizations, led by nurse executives and influenced by physicians, is critical in determining whether or not safety and high-quality care can be achieved through daily teamwork, collaboration, and communication (chapter 20). It is because of the importance of senior nursing leadership that emphasis is put on the moral imperative that senior nursing leadership has to lead health care in the quest for safer and higher-quality care (vignette *a*), to demonstrate the right type of leadership (vignette *b*), and to excel in the right competencies (e.g., business skills and principles, communication and relationship management, and professionalism) (vignette *c*).

Nursing leaders must actively work with and enable staff to transform the current work climate and care delivery. *Section V – Critical Opportunities for Patient Safety and Quality Improvement* puts forth several critical opportunities that leaders and staff can work together to achieve success. In almost every care setting and situation, effective communication is essential. Not only do clinicians need to constantly communicate in a professional and technical way (chapter 32) and with team members in a way that is respectful and attuned to individual differences (chapter 33), clinicians must also ensure that the right information is communicated to next caregiver or health care provider so that the safety and quality of care is not compromised (chapter 34).

Other opportunities for improvement center on the necessity to continually assess near errors and errors, not only those events that harm patients, and put in place strategies to avert the recurrence of both the near error and errors. Assessing and evaluating near errors and errors—and the ability to avert the recurrence of errors—is dependent upon having information that is reported by clinicians (chapter 35), so that some errors (e.g., wrong-site surgery) never happen (chapter 36). Many initiatives to improve patient safety and health care quality have focused on medication safety. While many medication errors are prevented from harming patients because a nurse detected the error, monitoring and evaluating both near misses and adverse drug events can lead to the adoption of strategies to decrease the opportunities for errors, including unit dosing, using health information technology (chapter 37), and reconciling a patient's medications (chapter 38).

The nature of the work and the stress of caregiving can place nurses and patients at risk for harm. Moving patients, being in close proximity to therapeutic interventions, the implications of shift work and long work hours (chapter 39 and chapter 40), and ignoring the potential risk of injury and the impact of fatigue can increase the risk of occupational injury. It follows then that, because of the nature of the work, the proximity of nurses to patients, and the chronic and acute needs of patients, particular attention must be given to preventing health care–associated infections through known effective strategies, such as environmental cleanliness, hand hygiene,

protective barriers (chapter 41), and strategies to address ventilator-acquired pneumonia (chapter 42).

The influence of nurse practitioners and of the new generation of doctorate-level nurse clinicians has the potential of enabling significant improvements in critical opportunities for patient safety and quality improvement (chapter 43). The opportunities to demonstrate the influence of these clinical leaders is endless. The last section of this book, *Section VI – Tools for Quality Improvement and Patient Safety*, focuses on the strategies and technologies that can be used to push health care to the next level of quality. One of the tools that can be used is quality methods, including continuous quality improvement, root cause analysis, and plan-do-study-act (chapter 44). Quality and patient safety indicators can also be used to assess performance and monitor improvement (chapter 45). These, as well as other tools, are integral in efforts to develop and demonstrate nursing excellence (chapter 46). With recent developments in information technologies, there are many potential benefits that can be afforded by these technologies that can facilitate decisionmaking, communication of patient information (chapter 47, chapter 48, chapter 49), therapeutic interventions (so long as the information technologies are used and function properly) (chapter 49), and education and training (chapter 51).

All of these various issues and factors come together to define the complexity and scope of patient safety and quality care but also the necessity for multifaceted strategies to create change within health care systems and processes of care. In using evidence in practice, engaging in initiatives to continually improve quality, and striving for excellence, nurses can capitalize on the information from this book and lead health care in the direction that it should and needs to be heading to better care for the needs of patients. What it all comes down to is for us, as nurses, to decide what kind of care we would want as patients then to do all that is possible to make that happen. Today we may be doing what we can, but tomorrow we can improve. With this evidence and the call to action to nurses, in 5 years from now, headlines and research findings should carry forth the message that there are significant improvements in the quality and safety of health care throughout this nation, and it was because nurses led the way.

Acknowledgments

Without a doubt, this could not have been accomplished without the contribution and dedication of many people, both internally and externally to the Agency for Healthcare Research and Quality (AHRQ). A special note of gratitude is extended to each author and peer reviewer, who willingly shared their expertise and dedication to making health care better and safer. This project would not have been possible without financial support from the Robert Wood Johnson Foundation and the AHRQ, as well as the time authors committed to this project. Invaluable support was given by Carolyn Clancy, Helen Burstin, Tonya Cooper, Susan Hassmiller, David Lanier, and David Meyers throughout the 2-year process of bringing this project together.

Sincere gratitude is also extended to AHRQ's Office of Communications and Knowledge Transfer (OCKT), specifically Randie Siegel (project oversight), David I. Lewin (copyediting/production management), and Morgan Liskinsky (marketing plan). Further gratitude is extended to OCKT's editorial contractors (Helen Fox, Roslyn Rosenberg, and Daniel Robinson). Additional thanks go to Joy Solomita, of AHRQ's Center for Primary Care, Prevenrion, and Clinical Partnerships (CP3), for all her efforts during the finalization process.

Lastly, this book was dependent upon the invaluable assistance of Caryn McManus, Reneé McCullough, Lynette Lilly, and other librarians throughout the country, who helped search for and retrieve thousands of articles and book chapters.

Ronda G. Hughes

This book is dedicated to nurses everywhere.

Contents

Section VI: Tools for Quality Improvement and Patient Safety:

44. Quality Methods, Benchmarking, and Measuring Performance (CQI, TQM, FEMA, RCA) (*Forthcoming*)
    Ronda G. Hughes, Ph.D., M.H.S., R.N.
45. AHRQ Quality Indicators (*Draft—Do Not Reproduce*)
    Marybeth Farquhar, R.N., M.S.N.
46. Magnet Environments for Professional Nursing Practice (*Draft—Do Not Reproduce*)
    Vicki Lundmark, Ph.D.

Chapter 1. Defining Patient Safety and Quality Care

Pamela H. Mitchell

Introduction

The goal of this chapter is to provide some fundamental definitions that link patient safety with health care quality. Evidence is summarized that indicates how nurses are in a key position to improve the quality of health care through patient safety interventions and strategies.

Quality Care

Many view quality health care as the overarching umbrella under which patient safety resides. For example, the Institute of Medicine (IOM) considers patient safety "indistinguishable from the delivery of quality health care."[1] Ancient philosophers such as Aristotle and Plato contemplated quality and its attributes. In fact, quality was one of the great ideas of the Western world.[2] Harteloh[3] reviewed multiple conceptualizations of quality and concluded with a very abstract definition: "Quality [is] an optimal balance between possibilities realised and a framework of norms and values." This conceptual definition reflects the fact that quality is an abstraction and does not exist as a discrete entity. Rather it is constructed based on an interaction among relevant actors who agree about standards (the norms and values) and components (the possibilities).

Work groups such as those in the IOM have attempted to define quality of health care in terms of standards. Initially, the IOM defined quality as the "the degree to which health services for individuals and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge."[4] This led to a definition of quality that appeared to be listings of quality indicators, which are expressions of the standards. Theses standards are not necessarily in terms of the possibilities or conceptual clusters for these indicators. Further, most clusters of quality indicators were and often continue to be comprised of the 5Ds—death, disease, disability, discomfort, and dissatisfaction[5]—rather than more positive components of quality.

The work of the American Academy of Nursing Expert Panel on Quality Health focused on the following positive indicators of high-quality care that are sensitive to nursing input: achievement of appropriate self-care, demonstration of health-promoting behaviors, health-related quality of life, perception of being well cared for, and symptom management to criterion. Mortality, morbidity, and adverse events were considered negative outcomes of interest that represented the integration of multiple provider inputs.[6, 7] The latter indicators were outlined more fully by the National Quality Forum.[8] Safety is inferred, but not explicit in the American Academy of Nursing and National Quality Forum quality indicators.

The most recent IOM work to identify the components of quality care for the 21st century is centered on the conceptual components of quality rather than the measured indicators: quality care is safe, effective, patient centered, timely, efficient, and equitable. Thus safety is the foundation upon which all other aspects of quality care are built.[9]

Patient Safety

A definition for patient safety has emerged from the health care quality movement that is equally abstract, with various approaches to the more concrete essential components. Patient safety was defined by the IOM as "the prevention of harm to patients."[1] Emphasis is placed on the system of care delivery that (1) prevents errors; (2) learns from the errors that do occur; and (3) is built on a culture of safety that involves health care professionals, organizations, and patients.[1, 10] The glossary at the AHRQ Patient Safety Network Web site expands upon the definition of prevention of harm: "freedom from accidental or preventable injuries produced by medical care."[11]

Patient safety practices have been defined as "those that reduce the risk of adverse events related to exposure to medical care across a range of diagnoses or conditions."[12] This definition is concrete but quite incomplete, because so many practices have not been well studied with respect to their effectiveness in preventing or ameliorating harm. Practices considered to have sufficient evidence to include in the category of patient safety practices are as follows:[12]

- Appropriate use of prophylaxis to prevent venous thromboembolism in patients at risk
- Use of perioperative beta-blockers in appropriate patients to prevent perioperative morbidity and mortality
- Use of maximum sterile barriers while placing central intravenous catheters to prevent infections
- Appropriate use of antibiotic prophylaxis in surgical patients to prevent postoperative infections
- Asking that patients recall and restate what they have been told during the informed-consent process to verify their understanding
- Continuous aspiration of subglottic secretions to prevent ventilator-associated pneumonia
- Use of pressure-relieving bedding materials to prevent pressure ulcers
- Use of real-time ultrasound guidance during central line insertion to prevent complications
- Patient self-management for warfarin (Coumadin®) to achieve appropriate outpatient anticoagulation and prevent complications
- Appropriate provision of nutrition, with a particular emphasis on early enteral nutrition in critically ill and surgical patients, to prevent complications
- Use of antibiotic-impregnated central venous catheters to prevent catheter-related infections

Many patient safety practices, such as use of simulators, bar coding, computerized physician order entry, and crew resource management, have been considered as possible strategies to avoid patient safety errors and improve health care processes; research has been exploring these areas, but their remains innumerable opportunities for further research.[12] Review of evidence to date critical for the practice of nursing can be found in later chapters of this Handbook.

The National Quality Forum attempted to bring clarity and concreteness to the multiple definitions with its report, *Standardizing a Patient Safety Taxonomy*.[13] This framework and taxonomy defines harm as the impact and severity of a process of care failure: "temporary or permanent impairment of physical or psychological body functions or structure." Note that this classification refers to the negative outcomes of lack of patient safety; it is not a positive classification of what promotes safety and prevents harm. The origins of the patient safety

problem are classified in terms of type (error), communication (failures between patient or patient proxy and practitioners, practitioner and nonmedical staff, or among practitioners), patient management (improper delegation, failure in tracking, wrong referral, or wrong use of resources), and clinical performance (before, during, and after intervention).

The types of errors and harm are further classified regarding domain, or where they occurred across the spectrum of health care providers and settings. The root causes of harm are identified in the following terms:[8]

- Latent failure—removed from the practitioner and involving decisions that affect the organizational policies, procedures, allocation of resources
- Active failure—direct contact with the patient
- Organizational system failure—indirect failures involving management, organizational culture, protocols/processes, transfer of knowledge, and external factors
- Technical failure—indirect failure of facilities or external resources

Finally, a small component of the taxonomy is devoted to prevention or mitigation activities. These mitigation activities can be universal (implemented throughout the organization or health care settings), selective (within certain high-risk areas), or indicated (specific to a clinical or organizational process that has failed or has high potential to fail).

Nursing As the Key to Improving Quality Through Patient Safety

Nursing has clearly been concerned with defining and measuring quality long before the current national and State-level emphasis on quality improvement. Florence Nightingale analyzed mortality data among British troops in 1855 and accomplished significant reduction in mortality through organizational and hygienic practices.[14] She is also credited with creating the world's first performance measures of hospitals in 1859. In the 1970s, Wandelt[15] reminded us of the fundamental definitions of quality as characteristics and degrees of excellence, with standards referring to a general agreement of how things should be (to be considered of high quality). About the same time, Lang[16] proposed a quality assurance model that has endured with its foundation of societal and professional values as well as the most current scientific knowledge (two decades before the IOM definition was put forth).

In the past, we have often viewed nursing's responsibility in patient safety in narrow aspects of patient care, for example, avoiding medication errors and preventing patient falls. While these dimensions of safety remain important within the nursing purview, the breadth and depth of patient safety and quality improvement are far greater. The most critical contribution of nursing to patient safety, in any setting, is the ability to coordinate and integrate the multiple aspects of quality within the care directly provided by nursing, and across the care delivered by others in the setting. This integrative function is probably a component of the oft-repeated finding that richer staffing (greater percentage of registered nurses to other nursing staff) is associated with fewer complications and lower mortality.[17] While the mechanism of this association is not evident in these correlational studies, many speculate it is related to the roles of professional nurses in integrating care (which includes interception of errors by others—near misses), as well as the monitoring and surveillance that identifies hazards and patient deterioration before they become errors and adverse events.[18] Relatively few studies have had the wealth of process data evident in the RAND study of Medicare mortality before and after implementation of diagnosis-related groups. The RAND study demonstrated lower severity-adjusted mortality related to better

nurse and physician cognitive diagnostic and treatment decisions, more effective diagnostic and therapeutic processes, and better nursing surveillance.[19, 20]

Further, when we consider the key role of communication or communication lapses in the commission of error, the role of nursing as a prime communication link in all health care settings becomes evident. The definition of "error chain" at PSNet clearly indicates the role of leadership and communication in the series of events that leads to patient harm. Root-cause analyses of errors provide categories of linked causes, including "(1) failure to follow standard operating procedures, (2) poor leadership, (3) breakdowns in communication or teamwork, (4) overlooking or ignoring individual fallibility, and (5) losing track of objectives."[21] This evidence was used in developing the cause portion of the National Quality Forum's patient safety taxonomy and is further discussed in other chapters of this book.

Conclusion

Patient safety is the cornerstone of high-quality health care. Much of the work defining patient safety and practices that prevent harm have focused on negative outcomes of care, such as mortality and morbidity. Nurses are critical to the surveillance and coordination that reduce such adverse outcomes. Much work remains to be done in evaluating the impact of nursing care on positive quality indicators, such as appropriate self-care and other measures of improved health status.

Chapter 2. Nurses at the "Sharp End" of Patient Care

Ronda G. Hughes

Background

The work environment in which nurses provide care to patients can determine the quality and safety of patient care.[1] As the largest health care workforce, nurses apply their knowledge, skills, and experience to care for the various and changing needs of patients. A large part of the demands of patient care is centered on the work of nurses. When care falls short of standards, whether because of resource allocation (e.g., workforce shortages and lack of needed medical equipment) or lack of appropriate policies and standards, nurses shoulder much of the responsibility. This reflects the continued misunderstanding of the greater effects of the numerous, complex health care systems and the work environment factors. Understanding the complexity of the work environment and engaging in strategies to improve its effects is paramount to higher-quality, safer care. High-reliability organizations that have cultures of safety and capitalize on evidence-based practice offer favorable working conditions to nurses and are dedicated to improving the safety and quality of care. Emphasis on the need to improve health care systems to enable nurses to not be at the "sharp end" so that they can provide the right care and ensure that patients will benefit from safe, quality care will be discussed in this chapter.

The Everydayness of Errors

Health care services are provided to patients in an environment with complex interactions among many factors, such as the disease process itself, clinicians, technology, policies, procedures, and resources.[2] When these complex factors interact, harmful and unanticipated outcomes (e.g., errors) can occur. Human error has been defined as a failure of a planned action or a sequence of mental or physical actions to be completed as intended, or the use of a wrong plan to achieve an outcome.[2] By definition, errors are a cognitive phenomenon because errors reflect human action that is a cognitive activity. Near misses, or "good catches,"[3] are defined as events, situations, or incidents that could have caused adverse consequences and harmed a patient, but did not.[4] Factors involved in near misses have the potential to be factors (e.g., root causes) involved in errors if changes are not made to disrupt or even remove their potential for producing errors.

Reason[2] described errors as the product of either active (i.e., those that result primarily from systems factors, producing immediate events and involve operators (e.g., clinicians) of complex systems) or latent factors (i.e., factors that are inherent in the system). Latent factors (e.g., heavy workload, structure of organizations, the work environment) are embedded in and imposed by systems and can fester over time, waiting for the right circumstances to summate individual latent factors and affect clinicians and care processes, triggering what is then considered an active error (e.g., an adverse drug event). Leadership and staff within organizations essentially inherit and can create new latent factors through scheduling, inadequate training, and outdated equipment.[5] Latent factors or conditions are present throughout health care and are inevitable in organizations. These factors and conditions can have more of an effect in some areas of an

organization than others because resources can be "randomly" distributed, creating inequities in quality and safety.[5] The number of hazards and risks can be reduced by targeting their root causes. In doing so, the path between active failures when the error occurred would be traced to the latent defects in the organization, indicating leadership, processes, and culture. Then, if organizational factors (e.g., latent factors) become what they should be, few active causes of accidents will come about.

The Institute of Medicine (IOM) stated that safety was dependent upon health care systems and organizations, and patients should be safe from injury caused by interactions within systems and organizations of care.[6] Organizational factors have been considered the "blunt end" and represent the majority of errors; clinicians are considered the "sharp end." Therefore, to prevent errors, the organizations in which humans work need to be adapted to their cognitive strengths and weaknesses and must be designed to ameliorate the effects of whatever human error occurs. The most effective strategies to improve safety target latent factors within organizations and systems of care. This point is emphasized by the IOM, which further stated that the safety and quality of care would be improved by holding systems accountable, redesigning systems and processes to mitigate the effects of human factors, and using strategic improvements.[7]

According to Reason,[2] a large part of mental functioning is automatic, rapid, and effortless. This automatic thinking is possible because we have an array of mental models (e.g., schemata) that are expert on some minuscule recurrent aspect of our lives (e.g., going to work). Many errors result from flaws in thinking that affect decisionmaking.[8, 9] Ebright and colleagues[10] assert that nurses' ability to make logical and accurate decisions and influence patient safety is associated with complex factors, including their knowledge base and systems factors (e.g., distractions and interruptions), availability of essential information, workload, and barriers to innovation. The effects of these factors are complicated by the increasingly complex nature of nursing's roles and responsibilities, the complex nature of preventing errors from harming patients, and the availability of resources.[10]

When errors occur, the "deficiencies" of health care providers (e.g., insufficient training and inadequate experience) and opportunities to circumvent "rules" are manifested as mistakes, violations, and incompetence.[11, 12] Violations are deviations from safe operating procedures, standards, and rules, which can be routine and necessary or involve risk of harm. Human susceptibility to stress and fatigue; emotions; and human cognitive abilities, attention span, and perceptions can influence problem-solving abilities.[2] Human performance and problem-solving abilities are categorized as skill based (i.e., patterns of thoughts and actions that are governed by previously stored patterns of preprogrammed instructions and those performed unconsciously), rule based (i.e., solutions to familiar problems that are governed by rules and preconditions), and knowledge based (i.e., used when new situations are encountered and require conscious analytic processing based on stored knowledge). Skill-based errors are considered "slips," which are defined as unconscious aberrations influenced by stored patterns of preprogrammed instructions in a normally routine activity. Distractions and interruptions can precede skill-based errors, specifically diverting attention and causing forgetfulness.[2] Rule-based and knowledge-based errors are caused by errors in conscious thought and are considered "mistakes."[13] Breaking the rules to work around obstacles is considered a rule-based error because it can lead to dangerous situations and may increase one's predilection toward engaging in other unsafe actions. Work-arounds are defined as "work patterns an individual or a group of individuals create to accomplish a crucial work goal within a system of dysfunctional work processes that prohibits the accomplishment of that goal or makes it difficult"[14] (p. 52). Halbesleben and colleagues[15]

assert that work-arounds could introduce errors when the underlying work processes and workflows are not understood and accounted for, but they could also represent a "superior process" toward reaching the desired goal.

Clinicians' decisionmaking and actions are also influenced by the "human condition." Reason[5, 16] asserted that because of the fallibility of the human condition, we can change the working conditions so that the potential for errors is reduced and the effect of errors that do occur is contained. Humans are limited by difficulty in attending to several things at one time, recalling detailed information quickly, and performing computations accurately.[6] As discussed by Henriksen and colleagues,[17] the scientific field of human factors focuses on human capabilities and limitations and the interaction between people, machines, and their work environment. The focus is on system failures, not human failures, and on meeting the needs of the humans interacting within it. Systems would be redesigned and dedicated to continuous improvement to protect against human error by employing simplification, automation, standardization of equipment and functions, and decreasing reliance on memory.[18] The "work system" would account for the interrelatedness of the individual, tasks, tools and technologies, the physical environment, and working conditions.[19] Conditions that make errors possible would be redesigned to reduce reliance on memory, improve information access, error-proof processes, standardize tasks, and reduce the number of handoffs.[20, 21] Errors would be identified and corrected and over time there would be fewer latent failure modes and fewer errors. However, because patient outcomes are dependent upon human-controlled processes, health care settings will never be 100 percent safe.

The IOM defined patient safety as freedom from accidental injury.[6] Adverse events are defined as injuries that result from medical management rather than the underlying disease.[22, 23] While the proximal error preceding an adverse event is mostly considered attributable to human error, the underlying causes of errors are found at the system level and are due to system flaws;[24] system flaws are factors designed into health care organizations and are often beyond the control of an individual.[25, 26] In other words, errors have been used as markers of performance at the individual, team, or system level. Adverse events have been classified as either preventable or not,[21, 27] and some preventable adverse events (fewer than one in three) are considered to be caused by negligence.[28] The concept of an error being preventable has not been widely understood in its context, and definitions have been conflicting and unreliable,[21, 29] partially because the source of the majority of errors have been ascribed to vague systems factors,[30] and the relationship between errors and adverse events is not fully understood.[30, 31]

Although the true number of errors and adverse events may not be known because of underreporting, failure to recognize an error, and lack of patient harm, it is difficult to understand the pervasiveness of errors because there are differences in definitions of reportable errors and adverse events.[32] Research and quality improvement initiatives have focused predominately on medication safety because of existing information systems and the potential frequency for which errors can occur. In the case of medications, the types and causes of errors describe how nurses are at the "sharp end." Medications pose the largest source of errors, yet many do not result in patient harm.[33, 34] Since errors actually occur during the process of medication therapies, the usual 'practice' has been to blame individuals.[35, 36] A medication intervention goes from prescribing, transcribing, and dispensing to administration. Physicians are primarily responsible for prescribing medications and nurses are primarily responsible for administering medications to patients. Errors made by physicians can be intercepted by pharmacists and nurses, errors made

by pharmacists can be intercepted by nurses, and errors made by nurses could potentially be intercepted by peers or patients.

Several classifications of health care errors have been posed.[37–39] Classifications or categorizations of errors have been based on types of adverse events,[40–42] incident reports,[38, 39] individual blame,[37] and system causes. Given what is known about error causation,[1, 5, 6, 16] particularly what has been learned from root-cause analysis and failure modes and effects analysis, when errors/adverse events involve clinicians, classifications/taxonomies of errors would be centered on all the related systems factors and would consider them the major contributors of the error/adverse event.[5, 16] For example, one classification of errors differentiates endogenous errors (i.e., arise within the individual or team) from exogenous errors (i.e., arise within the environment).[43] Endogenous errors are generally either active or latent[2] and result from departure from normative knowledge-based, skill-based, or rule-based behaviors.[44]

The complexity of factors involved in errors and adverse events is exemplified in medication safety. Researchers have found that between 3 percent and 5 percent,[45] 34 percent,[46] 40 percent,[47] or 62 percent[48] of medication errors are attributable to medication administration. For an administration error to not occur, the nurse would be at the "sharp end," having the responsibility to intercept it. Administration errors have been found to be the result of human factors, including performance and knowledge deficiencies;[49] fatigue, stress, and understaffing were found to be two major factors for errors among nurses.[50] Administering medications can take up to 40 percent of the nurse's work time,[51] and medication administration errors have been found to be due to a lack of concentration and the presence of distractions, increased workloads, and inexperienced staff.[48, 52, 53] If we consider what has been learned in other industries, medication administration errors would also be caused by systems factors, such as leadership not ensuring sufficient training, maldistribution of resources, poor organizational climate, and lack of standardized operating procedures.[54]

Since the publication of the IOM's *To Err Is Human*,[6] millions of dollars of research funds—e.g., from the Agency for Healthcare Research and Quality (AHRQ) and the Robert Wood Johnson Foundation—have been devoted to building the evidence base in patient safety research. Findings reported from the IOM and other related research is being disseminated on key aspects of patient safety. It is interesting to note that before the publication of *To Err Is Human*, the major focus of patient safety was on individual blame and malpractice.[55] Since the publication of *To Err Is Human,* that has no longer been the case and there is more focus on the need to improve health care organizations,[56] but the concerns associated with malpractice have not dissipated. In fact, concerns about malpractice have thwarted many patient safety improvement efforts primarily because of the need for data collection and analysis as well as performance measures to inform patient safety changes.[57]

The focus on the responsibilities and influences of systems does not negate the challenge of understanding error and accepting the inevitability of many errors while concurrently increasing the quality of health care. It is not possible for every aspect of health care and every setting of care to be 100 percent error free, and leaders and clinicians are challenged to define what is an acceptable level of error. Because safety is foundational to quality,[58] one way to define quality is providing "the right care, at the right time, for the right person, in the right way."[59] In doing so, efforts to improve safety and quality need to address concerns with potential overuse, misuse, and underuse of health care services that can threaten the quality and safety of care delivered to patients. Since patient safety, and quality in many respects, "is a new field, identifying which safe practices are effective has presented a significant challenge"[60] (p. 289), in part because of

the resource requirements, the complex nature of changing practice, and the influences of units within the whole.[60]

The Importance of High-Performing Organizations

The quality and safety of care is associated with various factors within systems, organizations, and their work environments—the combination of which influences the type of quality and safety of care provided by nurses.[1] Donabedian's[61] definition of quality of care represents the entire continuum from structure to process and to outcome. Structures, processes and outcomes are interdependent, where specific attributes of one influence another according to the strength of the relationship.[61–63] When organizational structure factors support the care processes and enable teamwork, nurses are more satisfied with their jobs[64, 65] and patients receive higher-quality care.[65] Leaders who engage in transactional (e.g., establish trust in relationships with staff, provide structure and expectations)[66, 67] and transformational leadership (e.g., develop a stronger collective identity and commitment to change)[68, 69] and who view change as opportunities to learn, adapt, and improve[70] organizations to improve health care quality. When teams function well and organization structure factors support their work, outcomes are better, even at institutions that have a high intensity of specialized care for those particular needs.[71, 72] The effectiveness of individuals and teamwork is dependent upon leadership, shared understanding of goals and individual roles, effective and frequent communication,[72-74] having shared governance,[75] and being empowered by the organization.[76]

In his seminal work, Shortell asserted that the characteristics of high-performing health care organizations included "a willingness and ability to: stretch themselves; maximize learning; take risks; exhibit transforming leadership; exercise a bias for action; create a chemistry among top managers; manage ambiguity and uncertainty; exhibit a 'loose coherence;' exhibit a well-defined culture; and reflect a basic spirituality"[77] (page 8). These organizations are engaged in continuous improvement to improve outcomes. Since then, Shortell and colleagues[78] furthered his seminal work, finding that what distinguished high-performing organizations was certain key factors, such as having a quality-centered culture, reporting performance, and the ability to overcome quality improvement redesign barriers by "(1) directly involving top and middle-level leaders, (2) strategically aligning and integrating improvement efforts with organizational priorities, (3) systematically establishing infrastructure, process, and performance appraisal systems for continuous improvement, and (4) actively developing champions, teams, and staff"[79] (p. 599).

The significance of these characteristics of high-performing organizations was furthered by findings from an evaluation of 12 health care systems, where factors critical to redesigning current systems to achieve quality and safety goals and improve patient outcomes were found to be successful when there was an "(1) impetus to transform; (2) leadership commitment to quality; (3) improvement initiatives that actively engage staff in meaningful problem solving; (4) alignment to achieve consistency of organization goals with resource allocation and actions at all levels of the organization; and (5) integration to bridge traditional intra-organizational boundaries among individual components"[80] (p. 309). Yet to address these factors in redesigning care systems and processes, Lucas and colleagues found that organizations needed to have "(1) mission, vision, and strategies that set its direction and priorities; (2) culture that reflects its informal values and norms; (3) operational functions and processes that embody the work done in patient care; and (4) infrastructure such as information technology and human resources that support the delivery of patient care"[80] (p. 309).

Yet, many organizations do not meet the standards of high-reliability organizations (HROs). Reason and colleagues[81] described the "vulnerable system syndrome" as a cluster of organizational pathologies that interact, making some systems more liable to unsafe practices that threaten patient safety. These pathologies (e.g., blame, denial, and the pursuit of financial excellence) are perpetuated in work environments by leaders and peers targeting individuals at the "sharp end," simultaneously failing to question core beliefs, recognize systemic causes, or to implement systemwide reforms. Reason and colleagues further asserted that indicators of vulnerabilities of the work environment, such as a culture of individual blame, were associated with workplace cultures that influenced safety and could be categorized as (1) high reliability (where recognizing how safety can be improved is rewarded), (2) pathological (where punishment and covering up of errors/failures are pervasive and new ideas are discouraged), or (3) bureaucratic (where failures are considered isolated, systematic reforms are avoided, and new ideas are problematic). An indicator of the presence of work environment vulnerabilities and patient safety improvements could be whether or not an organization has Joint Commission accreditation.[82]

Nurses perceive multiple and complex work environment factors that influence nurse and patient outcomes, including the quality of leadership and management, staffing resources, workload,[83] job stress and anxiety, teamwork, and effective communication.[84] Heath and colleagues asserted that in healthy work environments, nurses "feel valued by their organization, have standardized processes in place, have staff empowerment, have strong leadership, feel a sense of community, and recognize that strategic decision-making authority [influences] how their units were run and how scarce resources were disseminated"[85] (p. 526–7). Healthy work environments are also places where safe and high-quality nursing care is expected and rewarded. Healthy work environments also need to foster effective communication, collaborative relationships, and promote decisionmaking among all nurses.[85] Unhealthy work environments can have adverse consequences on the quality of care delivered as well as nurses' intention to leave the profession.[1, 86–88]

As proposed by Stone and colleagues,[89] there are microclimates (e.g., a unit or department) that function within the larger context of the organization. These microclimates or "microsystems" have a core team of health care professionals; a defined population of patients they are responsible for; and information, staff, and health technologies that provide support to the work of the clinicians.[90]

Yet, the majority of this research has examined outcomes at the hospital-wide level, and not at the unit level. Since the work environment within microclimates/microsystems can be different than that found organization-wide, it would be important to focus on these subunits to support efforts to standardize common care processes, to better examine process and outcome measures and what subunit factors and organization-wide factors contribute to less-than-optimal care, to emphasize the impact of multidisciplinary teams throughout the organization, and to ascertain how lessons learned in these subunits could be applied organization-wide.[90]

High-Reliability Organizations

Inherently related to high-performing organizations, HROs are defined as organizations that function daily under high levels of complexity and hazards. Reliable organizations have "procedures and attributes that make errors visible to those working in the system so that they can be corrected before causing harm"[6] (p. 152) and produce consistent results. Accordingly, the

IOM has advocated for hospitals to transition into HROs to improve the quality and safety of care.[6] In HROs, reliability and consistency are built into organizational routines where errors can have catastrophic consequences. In health care, reliability is defined as the "measurable ability of a health-related process, procedure, or service to perform its intended functions in the required time under commonly occurring conditions"[91] (p. 82). Applying the theory behind high reliability organizations and normal accident theory (e.g., understanding how health system factors affect safety), patient safety improvements have been linked to high-reliability safety interventions, including double checking, and improving the validity of root-cause analyses.[92]

Because improving safety is complex and should be continuous,[2, 4, 11] HROs continually measure their performance, learn from experience, and take action to resolve problems when they are discovered. HROs have a (1) preoccupation with avoiding failure, (2) reluctance to simplify interpretations, (3) sensitivity to operations, (4) commitment to resilience, and (5) deference to expertise.[93, 94] A preoccupation with avoiding failures is based on comprehensive error reporting, where human failure is accepted as being inevitable, and being overconfident because of successes is considered highly risky. A reluctance to simplify interpretations is supported by thoroughly examining situations. Being sensitive to operations involves being constantly concerned about the unexpected and recognizing that active errors result from latent errors in the system. Committing to resilience involves being able to identify, control, and recover from errors, as well as developing strategies to anticipate and responds to the unexpected. Having deference to expertise means that everyone is involved and decisions are made on the front line.[94]

Health care leaders and researchers have been looking to HROs in industry, such as the National Aeronautics and Space Administration, aviation, and the U.S. Postal Service,[21, 94, 95] to apply their lessons learned to health care. HROs are known to approach safety from a systems perspective, involving both formal structures and informal practices, such as open inquiry and deep self-understanding that complement those structures.[96] Through careful planning and design, HROs have been found to share common features: (1) auditing of risk—to identify both expected and unexpected risks; (2) appropriate reward systems—for safety-related behaviors; (3) system quality standards—evidence-based practice standards; (4) acknowledgment of risk—detecting and mitigating errors; and (5) flexible management models—promoting teamwork and decentralized decisionmaking.[97] Shapiro and Jay asserted that health care organization can become HROs though "(1) attitude change, (2) metacognitive skills, (3) system-based practice, (4) leadership and teamwork, and (5) emotional intelligence and advocacy"[98] (p. 238).

Implementing quality and safety improvement strategies in organizational microclimates/microsystems, and for that matter organization-wide, should be predicated on increasing the subunits' awareness of how they function and mindfulness of the reliability of their outcomes. Mindfulness is a "combination of ongoing scrutiny of existing expectations, continuous refinement and differentiation of expectations based on newer experiences, willingness and capability to invent new expectations that make sense of unprecedented events, and a more nuanced appreciation of context and ways to deal with it, and identification of new dimensions of context that improve foresight and current functioning"[94] (p. 42). Mindfulness speaks to the interrelationships among processes of perception and cognition that stimulate a rich awareness of and hypervigilance for emerging factors and issues that could threaten the quality of care and enable the identification of actions that might be taken to deal with the threats to quality.[94] Weick and Sutcliff[94] argue that organizations can become HROs when they become

mindful, as manifested by being preoccupied with failure, reluctant to simplify interpretations, sensitive to operations, committed to resilience, and deferent to expertise.

What Is It Going To Take To Improve the Safety and Quality of Health Care?

Changes in health care work environments are needed to realize quality and safety improvements. Because errors, particularly adverse events, are caused by the cumulative effects of smaller errors within organizational structures and processes of care, focusing on the systemic approach of change focuses on those factors in the chain of events leading to errors and adverse events.[5, 99] From a systems approach, avoidable errors are targeted through key strategies such as effective teamwork and communication, institutionalizing a culture of safety, providing patient-centered care, and using evidence-based practice with the objective of managing uncertainty and the goal of improvement.

The Right Work Environment

The major focus of the IOM's report, *Keeping Patients Safe: Transforming the Work Environment of Nurses*,[1] was to emphasize the dominant role of the work environment within health care organizations and the importance of the work environment in which nurses provide care to patients. Research reviewed by the IOM committee reported that nurses were dissatisfied with their work and wanted better working conditions and greater autonomy in meeting the needs of patients. The significance of these and many other findings led to the committee recommending significant changes in the way all health care organizations were structured, including "(1) management and leadership, (2) workforce deployment, (3) work processes, and (4) organizational cultures"[1] (p. 48). After the release of that report, the American Association of Critical-Care Nurses (AACN) expanded upon these concepts and put forth the following standards for establishing and sustaining healthy work environments: (1) effective, skilled communication; (2) true collaboration that is fostered continuously; (3) effective decisionmaking that values the contributions of nurses; (4) appropriate staffing that matches skill mix to patient needs; (5) meaningful recognition of the value of all staff; and (6) authentic leadership where nurse leaders are committed to a healthy work environment and engage everyone.[100] To achieve these standards, many organizations will need to significantly change the work environment for nurses.

The nursing "practice environment" is defined by organizational characteristics that can either facilitate or constrain professional nursing practice.[101] Changes to the nurses' work environment need to focus on enabling and supporting nurses to provide high-quality and safe care.[102] To do so, there needs to be significant changes in the way health care is organized that also address nursing workforce resources, training, and competencies. Researchers have found that nurses may experience greater professional fulfillment when strategies are implemented that promote autonomous practice environments, provide financial incentives, and recognize professional status.[103] Whether because of unequal distribution of nurses or expected nursing workforce shortages with the aging of practicing nurses and faculty,[104, 105] staffing shortages increase a nurse's stress, increases their workload, and can adversely impact patient outcomes. More important, clinicians in practice will need new skills and empowerment to work effectively with colleagues within their work environments. Nurses also need to possess certain

competencies that reflect the nature of nursing in improving patient and systems outcomes, including evidence-based practice, patient-centered care, teamwork and collaboration, safety, quality improvement, and informatics.[106]

Opportunity, power, and the composition of the workforce within organizations influence what nurses are able to do and how they are able to use resources to meet patients' needs. Lashinger and colleagues[76, 107–109] have found that the empowerment of staff nurses increased with greater responsibilities associated with job advancements and was related to the nurses' commitment to the organization, burnout, job autonomy, their ability to participate in organizational decisionmaking, as well as job strain and work satisfaction.[110] Because work environment factors influence the perceptions of nurses as being supported in their work, having a sense of accomplishment,[111] and being satisfied with their work, it is important to empower staff to manage their own work, collaborate in effective teams,[112] and practice nursing in "optimal" conditions.[113] Professional empowerment in the workplace is derived from competence and interactions with colleagues and other clinicians within organizations—and with patients—as well as by demonstrating knowledge and gaining credibility.[114] For nurses, structural empowerment can have a direct effect on their experience of providing care in their work environment.[115] Models of care, such as a professional practice model, not only can improve work satisfaction, but they can facilitate patient and nursing outcomes.[116]

Patient-Centered Care

In *Crossing the Quality Chasm*, the IOM recommended that "all health care organizations, professional groups, and private and public purchasers should adopt as their explicit purpose to continually reduce the burden of illness, injury, and disability, and to improve the health and functioning of the people of the United States"[7] (p. 39). For this recommendation to be realized, the IOM asserted that health care would have to achieve six aims: to be safe, effective, patient-centered, timely, efficient, and equitable. The IOM also asserted that health care for the 21st century would need to be redesigned, ensuring that care would be based on a continuous healing relationship, customized inclusion of patient needs and values, focused on the patient as the source of control, and based on shared knowledge and the free flow of information. Patient-centered care would improve health outcomes and reduce or eliminate any disparities associated with access to needed care and quality.[117–119]

Patient-centered care is considered to be interrelated with both quality and safety.[7] The role of patients as part of the "team" can influence the quality of care they receive[120, 121] and their outcomes.[122, 123] The IOM recommended that clinicians partner with patients (and the patient's family and friends, when appropriate)[124] to realize informed, shared decisionmaking, improve patient knowledge, and inform self-management skills and preventive behaviors. Patients seek care from competent and knowledgeable health professionals to meet their physical and emotional needs. Within this framework, the clinician's recommendations and actions would be customized to the patient and informed by an understanding of the patient's needs, preferences, knowledge and beliefs,[125] and when possible, would enhance the patient's ability to act on the information provided. It follows then that an effective clinician-patient partnership would include informed, shared decisionmaking and development of patient knowledge and skills needed for self-management of chronic conditions.

Patients and families have been and are becoming more involved in their care. Findings from several studies have indicated that patients who are involved with their care decisions and

management have better outcomes than those patients who are not,[126, 127] although some researchers indicate that the evidence concerning the impact of patient-centered care is variable.[128] Patient self-management, particularly for chronic conditions, has been shown to be associated with improvements in quality of life[129] and health status, decreased utilization of services,[130] and improved physical activity.[131, 132] The Chronic Care Model developed by Wagner and colleagues[133–135] similarly emphasized the importance of actively engaging patients in achieving substantial improvements in care. Patient-centeredness is increasingly recognized as an important professional evolution[124] and holds enormous promise for improving the quality and safety of health care. Yet, patient-centered care has not become the standard of care throughout care systems and among all clinicians as recommended by the IOM.[7, 136] For patient-centered care to become the "standard" care process, care processes would need to be redesigned and the roles of clinicians would need to be modified[137, 138] to enable effective teamwork and collaboration throughout care settings.

Teamwork and Collaboration

It is nonsensical to believe that one group or organization or person can improve the quality and safety of health care in this Nation. In that patient safety is inextricably linked with communication and teamwork,[6] there is a significant need to improve teamwork and communication.[139, 140] Teamwork and collaboration has been emphasized by the Joint Commission. The Joint Commission has found communication failures to be the primary root cause of more than 60 percent of sentinel events reported to the Joint Commission.[141] Ineffective communication or problems with communication can lead to misunderstandings, loss of information, and the wrong information.[142] There are many strategies to improve interdisciplinary collaboration (e.g., physician and nurse),[140, 143] including using multidisciplinary teams as a standard for care processes.

Interprofessional and intraprofessional collaboration, through multidisciplinary teams, is important in the right work environments. Skills for teamwork are considered nontechnical and include leadership, mutual performance monitoring, adaptability, and flexibility.[144] Teamwork and interdisciplinary collaboration[139] have the potential to mitigate error and increase system resilience to error.[145] Clinicians working in teams will make fewer errors when they work well together, use well-planned and standardized processes, know team members' and their own responsibilities, and constantly monitor team members' performance to prevent errors before they could cause harm.[6, 146, 147] Teams can be effective when members monitor each other's performance, provide assistance and feedback when needed,[147] and when they distribute workloads and shift responsibilities to others when necessary.[144]

The importance of training members to work effectively in multidisciplinary teams to achieve high reliability in patient (e.g., no adverse events) and staff outcomes (e.g., satisfaction working with team members and improved communication)[145, 148–151] was found to be especially significant when team members were given formal training to improve behaviors.[145] Resources such as AHRQ's TeamSTEPPS™ (visit http://www.ahrq.gov/qual/teamstepps) can provide teams with the opportunities the members need to improve the quality and safety of health care. TeamSTEPPS™ is an evidence-based teamwork system that teams can use to improve communication and other essential teamwork skills.

Conversely, lack of effective teamwork—such as poor communication and collaboration[139] within and between disciplines—was found to have negative effects on patient outcomes (e.g.,

surgical errors)[152] and higher mortality.[153] Poor teamwork as well as disrespectful, rude, and insulting behaviors have no place in health care and can potentially increase unsafe practices.[154–156] In a comparison of medicine to aviation, physicians were found to be significantly more supportive of hierarchical models of practice, where junior physicians would not question their seniors.[152] Hierarchical structures have been found to have an adverse influence on communication among team members and patient outcomes.[157, 158] Nursing's participation in teams is further limited under a hierarchical, mechanistic structure when nurses focus on tasks.[159] Other barriers that have been found to inhibit the effectiveness of nurses in teams were their perceptions of teamwork, having different teamwork skills, and the dominance of physicians in team interactions.[160] When physicians view hospitals as a "platform[s] for their work and do not see themselves as being part of [the] larger organization"[1] (p. 144), physicians may not only thwart the work of nurses, but the organization's efforts to improve the quality and safety of care. When anyone within organizations exhibit intimidating or disruptive behaviors and when there are inappropriate hierarchies, breakdowns in teamwork, and loss of trust, decreased morale and turnover are expected among staff; patients can expect to be harmed and will likely seek care elsewhere.[1, 161–163]

The work environment, communication and collaboration among clinicians, and decisionmaking are also linked to leadership and management within health care organizations.[164–166] Some authors have argued that performance of organizations and the use of evidence in practice were factors dependent upon leadership, particularly among middle/unit-based clinical management.[167–169] The personality and attitudes of leaders has been shown to have an impact on safety[170, 171] and on perceptions about how safety is managed.[172] Visible, supportive, and transformational nursing leadership to address nursing practice and work environment issues is critical as is nursing and medical leadership to ensure that the work environment supports caregivers and fosters collaborative partnerships. However, giving encouragement is not generally stated as a high-priority role of health care supervisors. Traditionally, technical skills and productivity on the job were aspects that received the supervisor's primary focus. However, there is a growing appreciation that encouragement is a transformational leadership technique that is related to productivity on the job and to quality work. Use of encouragement is a leadership technique that fits in today's people-oriented work climate.[1]

Evidence-Based Practice

Evidence should be used in clinical decisionmaking whenever possible. The need for improving quality using evidence was described by Steinberg and Luce as "the recognition that there is much geographic variation in the frequency with which medical and surgical procedures are performed, the way in which patients with a given disease are managed, patient outcomes, and the costs of care, which cannot be explained by differences in patients' demographic or clinical characteristics"[173] (p. 80). Indeed, findings from research continue to provide information that illustrates that only some patients are receiving the recommended quality of care,[117, 174–176] and errors continue to adversely impact patient outcomes. Steinberg and Luce go on to state that there is "strong evidence that much of the care that is being provided is inappropriate (that is, likely to provide no benefit or to cause more harm than good)" and that there are "indications that many patients are not receiving beneficial services"[173] (p. 80). Some examples of these concerns are associated with determining health care interventions and

medication safety. Patients can be harmed if their symptoms and needs are not assessed accurately,[177] if the wrong type of intervention is selected,[178–180] and if patients do not receive information they need to manage their care.[181] Certain types of medication errors, such as the wrong drug, wrong dose,[182] and polypharmacy,[183] threaten the quality of therapeutic interventions and the safety of patient care by aggravating the patient's preintervention health status.

Another reason that health care quality needs to improve and be based on evidence is "continuously rising health care costs"[173] (p. 80). In a country that spends more per capita than anywhere else in the world, patients do not necessarily have better outcomes.[184] Often without knowing it, clinicians have one of the greatest roles in controlling (or increasing) the cost of health care. What type of care is given to patients is sensitive to clinicians (e.g., nurses and physicians) as well as organizational structures, policies, and resources. The skill mix and number of nurses has been found to be associated with adverse events, longer lengths of stay in hospitals, and higher health care costs.[185–187] Findings from research have indicated that understaffing is associated with an increase in errors and adverse events, such as medication errors, pressure ulcers, health care associated infections, and increased mortality rates in hospitalized patients.[86, 185, 188–195] To address workforce shortages, organizations have used financial and shift work incentives, used part-time workers, and improved the image and job satisfaction, among other things.[196, 197] All of these strategies increase the cost of health care.

The combined concern about the growing cost of care and the effects of poor-quality care on patients has resulted in action by the Centers for Medicare and Medicaid Services (CMS) and other insurers to put in place financial penalties for hospitals that have preventable events, such as readmission, never events (e.g., wrong-site surgery), health care associated infections,[198] pressure ulcers, and patient falls with injury. These financial penalties reflect policy based on research that has indicated a significant association between nurse staffing and adverse patient outcomes,[185, 187, 192] and quality measures that have been put forth as being sensitive to nursing care.[199, 200] Adverse patient outcomes are also sensitive to the care directed by physicians, even when physicians and hospitals have a financial incentive to provide specific elements of quality care. This was recently found in a comparison of treatments and outcomes for 5 conditions at 54 hospitals participating in a Medicare pay-for-performance pilot program to the treatments and outcomes at 446 hospitals not participating in the program. The researchers in this investigation found the financial incentive of pay-for-performance was not associated with significant improvement in quality of care or outcomes.[201] Because health care costs are expected to continue to increase, it is important to ensure that costs of health care are not unnecessarily high and that patients receive quality care and are not exposed to preventable adverse events. Nurse leaders and clinical practitioners should be required to be actively engaged with other clinicians and leaders in assessing and monitoring the care of patients and their outcomes, as well as in driving quality improvement efforts to prevent the reoccurrence of these high-risk adverse events.

However, not all evidence is equal. It can be based on research that is not generalizable to other settings and populations[173, 202, 203] and may be difficult to translate into practice without further testing and the development of guidelines.[203] Even when research is available, it is often not used in practice,[204, 205] and adapting the research to practice can be challenging because of numerous barriers and deficits of facilitators to change.[206, 207] A systematic review of interventions aimed at increasing the use of evidence in practice found that greater success was achieved when clinicians were involved in education about and in intervention strategies that

were centered on using evidence in practice with local opinion leaders and multidisciplinary teams. The investigators further asserted that to effectively use research in practice, nurses should use the right evidence to inform and evaluate practice change interventions, longitudinally assess the effects of the intervention using the measures for multiple outcomes, and use a methodologically rigorous approach to design the implementation and evaluation of the intervention.[208]

Evidence-based practice has been defined as using data and information, often from diverse sources, to guide practice. When evidence is available, clinicians must locate and then consider the generalizability of its findings and usability in the practice setting. Randomized controlled trials (RCTs) have been considered the best standard for clinical practice, but they are not available for many common clinical situations and are generalizable only to the population studied during the trial. Clinicians use a broad range of practice knowledge, especially when evidence is not available. Sandars and Heller[209] proposed using the concept of knowledge management, which involves generating research-based evidence, synthesizing the evidence base, communicating that knowledge, and applying it to care processes. Another option would be to employ quality improvement methods, such as Plan-Do-Study-Act, to inform practice.[50] Horn and Gassway[210] proposed using practice-based evidence for clinical practice improvement that is based on the selection of clinically relevant alternative interventions, includes a diverse study population from heterogeneous practice settings, and utilizes data about a broad range of health outcomes.[210] Thus, when evidence is not available, clinicians should use their experience and data and information from other forms of inquiry.

A Culture of Safety

The IOM encouraged the creation of cultures of safety within all health care organizations.[6] A safety culture is defined as "the product of the individual and group values, attitudes, competencies and patterns of behavior that determine the commitment to, and the style and proficiency of, an organization's health and safety [programs]"[211] (p. 2). An organization's culture is based on its history, its mission and goals, and its past and current leadership. Gadd and Collins[211] found that organizations with a positive safety culture were characterized by communication guided by mutual trust, shared perceptions of the importance of safety, and confidence that error-preventing strategies would work.

The terms "culture" and "climate" have been used interchangeably. Organizational climate refers to the atmosphere of aggregate attitudes and perceptions of how individuals feel about their places of work, which are associated with both individual and team motivation and satisfaction. The climate within an organization represents a moveable set of perceptions related to conditions within the workplace,[212] which can be changed by the values, attributes, skills, actions, and priorities of organization leaders and mangers. A safety climate is a type of organizational culture and is the result of effective interplay of structure and processes factors and the attitude, perception, and behavior of staff related to safety. A climate of safety is represented by employee perceptions of: the priority of safety within the work environment on their unit and across the organization, and is influenced by management decisions; safety norms and expectations; and safety policies, procedures, and practices within the organization.[211]

It follows then that the higher the safety culture, the safer and better the quality of care. When researchers compared the safety cultures of hospitals to the aviation industry—which has been associated with high safety cultures—they found that the safety climate in hospitals was

worse; and within hospitals, the safety culture was worse in operating rooms and emergency departments.[213, 214] The perceptions of safety within a hospital have been found to be more positive among leaders and managers than among those directly involved in care;[215] nurses reported the lowest numbers for a safety culture.[216] Hospital staff have been found to understand the importance of safety in their work and their role in patient safety, and to judge patient safety according to their perception of workplace safety and leadership commitment.[217] The perceptions of hospital staff of the patient safety culture have also been found to be associated with empowerment (e.g., being able to practice nursing optimally) and characteristics of Magnet hospitals.[113] Additionally, more errors were found in organizations and units with poor safety cultures. In fact, some researchers found that the safety climate predicted the occurrence of medication errors, that the level of safety was associated with the unit-specific and hospital-wide climates, and that a positive safety climate in a unit could compensate for the detrimental effects of a low hospital-wide climate.[218]

Developing and transitioning to a culture of safety requires strong, committed leadership by executives, hospital boards, and staff.[5] According to the IOM, the essential elements of an effective safety culture include the commitment of leadership to safety and empowering and engaging all employees in ongoing vigilance through communication, nonhierarchical decisionmaking, constrained improvisation, training, and rewards and incentives.[1] The Association of Operating Room Nurses issued guidance about creating such a patient safety culture, emphasizing the necessity of the following components: (1) a reporting culture, (2) a flexible culture, (3) a learning culture, (4) a wary culture, and (5) a just culture.[219]

Yet, it should be understood that changing the culture within an organization is difficult and can happen only over time.[2, 5] Throughout time, nurses have frequently been treated differently if they were involved in an error/adverse event, being at the sharp end of blame because they can stand between errors.[220, 221] Thus, for nurses to not be at the sharp end of blame, it is important for organizational leaders and managers to establish a just culture that values reporting, where errors can be reported without fear of retribution;[222-224] where staff can trust leaders to make a distinction between blameless and blameworthy; and where the organization seeks to ferret out the root causes of that error, focusing on systems and process factors. Just as important, organizational leaders, managers, and staff need to learn from the continuous assessment of safety culture and make efforts to continually improve organizational performance[4, 5] and demonstrate success in safety improvements.[215]

If an organization's culture is based on secrecy, defensive behaviors, professional protectionism, and inappropriate deference to authority, the culture invites threats to patient safety and poor-quality care.[225] Several factors can impede the development of a culture of safety, including (1) a clinician's tendency to view errors as failures that warrant blame, (2) the focus of nurse training on rules rather than knowledge, (3) punishing the individual rather than improving the system,[226, 227] and (4) assuming that if a patient was not injured, that no action is required.[227] Each of these factors stems from organizations and the people in them having unrealistic expectations of clinical perfection, refusing to accept the fallibility of humans, and discounting the benefit of effective multidisciplinary teams.[1, 151]

Changing an organization's culture of safety should begin with an assessment of the current culture, followed by an assessment of the relationship between an organization's culture and the health care quality[228, 229] and safety within the organization. Several tools have been developed to measure the safety culture within organizations to inform specific interventions and opportunities for improvement. They have focused on dimensions of a patient safety climate, including

leadership and management (e.g., personality and attitudes), teamwork, communication, staffing, attitudes/perceptions about safety, responses to error, policies, and procedures. Some of these tools could be used for individual or team assessment, or to compare organization-wide perceptions or unit-specific perceptions.[230] A recent tool that was developed can be used to differentiate patient from staff safety and types of clinicians.[218] Another of these tools (www.ahrq.gov/qual/hospculture/#toolkit) developed for AHRQ has been used to compare safety cultures among hospitals.

The Challenge of Change

The question has been whether efforts to improve the quality and safety of care have been moving quickly enough. Many leaders and researchers[231–234] have raised concern that clinicians, administrators, policymakers, and researchers have *not* been moving quickly enough toward safe care. A few researchers have found improvements in some areas, but little if any change in others.[32, 235–238] Amalberti and colleagues[239]argued that the cultural and historical emphasis on individualism and autonomy in health care, its drive for economic productivity, and structural elements such as chronic staff shortages must be overcome if rapid progress is to be made toward ultrasafe health care. These authors warn that, to achieve progress, we will need to identify closely held values and traditions that enforce the status quo and change them in support of safety and quality.

Organizations such as the IOM, AHRQ, the Joint Commission, and CMS have been emphasizing the need for significant improvements in quality and patient safety. Yet depth and breadth of organizational quality and safety improvement changes are variable. For example, groups such as the Leapfrog Group have been influential in moving safety forward by setting standards for intensivist physician staffing levels in intensive care units,[240, 241] yet many hospitals have been challenged to implement physician staffing standards because of the resource implications (e.g., financial and staffing)[242, 243] and lack of clearly defined leadership.[121] Also, efforts to improve safety by understanding and targeting systems factors through public reporting have been championed in some States, such as Texas (www.texashasp.org) and Pennsylvania (www.psa.state.pa.us), but other States lag behind. The Joint Commission has emphasized national patient safety goals (www.jointcommission.org/PatientSafety/NationalPatientSafetyGoals) to improve safety in areas it has identified as high risk associated with sentinel events reported to the Joint Commission. Furthermore, starting in October 2008, the CMS (as well as other insurers) will begin to deny reimbursement to care providers for care delivered to patients that involved never events, such as health care–associated infections, wrong-site surgery, and hospital-acquired pressure ulcers. Given the role and influence of these various external drivers, health care leaders and managers will need to be actively engaged in quality and safety improvement efforts.

Organizations should be flexible to keep pace with the rapid changes in health care and the growing evidence base. To do so, they need to be willing to adopt new knowledge and innovations, which entails "a social and political process, which nearly always involve[s] debate and reference to others' views"[168] (p. 44), a process that needs to include all leaders, managers, and staff. Those employees within organizations, particularly nurse leaders and staff, will need to redesign care processes and revisit the roles and responsibilities of team members.[244] Pronovost and colleagues[245] emphasized the importance of recognizing that creating change is complex and that improvement strategies need to (1) prevent errors from occurring, (2) raise awareness of

errors and near misses, and (3) be better at diminishing patient harm if an error occurs. For these reasons, changes to the error-producing structural factors of an organization by themselves do not lead to expected improvements in quality.[246, 247] Several organizations have reported difficulties in improving patient safety because of the need for transparency in reporting on performance measures, lack of standardization and functionality of information technology, and no clear pathway identified for improvement.[248] Other difficulties could be associated with the results of the improvement initiative itself. For example, the introduction of computerized provider order entry systems for medication therapy prevented some errors from happening (e.g., related to illegible handwriting), but introduced other errors that might have been avoided with better implementation strategies.[249]

There are many change strategies, from single focus to multifaceted, that have centered on a structural approach and have been used successfully to create quality and patient safety improvements. One approach would be to implement bundles of evidence-based interventions to simultaneously improve multiple outcomes,[207] using health information technology when possible. Other strategies have focused on the components of the change process that need to be addressed. Caramanica and colleges[250] asserted that a successful quality improvement strategy was based on the alignment of the goals of the organization with goals for quality and patient safety improvement, collaboration using interdisciplinary teams, applying evidence-based practice, and monitoring and assessing excellence. Quality improvement strategies that align with the values and beliefs of individuals and build on current processes can determine the pace and diffusion of change.[251] As discussed in chapter 44, "Quality Methods, Benchmarking, and Measuring Performance," many organizations have used the Plan-Do-Study-Act approach to implement change, particularly rapid-cycle improvement. A similar strategy used the Reach-Effectiveness-Adoption-Implementation-Maintenance framework to translate research into practice.[252] The Department of Veterans Affairs has approached patient safety improvement by targeting key strategies, including leaders creating an environment of acceptance, establishing clear goals, creating a fair system that does not focus on blame, creating a transparent system for decisionmaking, facilitating root-cause analysis, requiring leadership and management to be visibly involved, and evaluating performance.[253, 254] While organizations' characteristics differ, as do characteristics of leaders and managers, success can be realized through continuous improvement with careful attention to finding a balance that avoids so much change that change fatigue results.[255]

The IOM asserted that improvements must target organizational factors by using information technologies, developing effective teams, standardizing procedures with evidence, and using data and information to monitor performance.[7] Focusing on the role, the influence, and the complexity of health care systems by thinking about the "big picture" involves understanding how a specific issue or outcome of concern interacts with numerous factors, both within and external to the system. In doing so, it may be more feasible to solve recurring problems with ineffective processes and poor outcomes, even when previous attempts have failed.[256] In the case of medication safety, efforts to significantly reduce medication administration errors must also consider errors associated with prescribing, transcribing, and dispensing errors, as well as errors associated with health information technologies, product labeling,[257] therapeutic consistency across care settings (e.g., medication reconciliation), and miscommunication of drug allergies. For health care systems and organizations to improve safety and quality, they need to learn to improve existing knowledge and processes, understand what is and is not working well, and both adopt and discover better ways to improve patient outcomes.[258]

Organizational changes should be targeted using multifaceted strategies and interventions that focus on redesigning structural factors (e.g., staffing levels, roles and responsibilities of nurses, etc.), revising policies and procedures,[259] and using multidisciplinary teams.[260] Because the factors and issues involved in patient safety and quality improvement are complex, mirroring the complexity of health care systems, no one single intervention will accomplish performance goals and standards. Using a systematic approach to changing practice based on evidence when possible is required to improve patient safety and contribute to the evidential knowledge base and generalizability that can be used eventually for purposes of diffusion.[261] Improving the quality and safety of health care may require the use of mixed or multiple methodologies to continually monitor and evaluate the impact and performance, because no one single method would be expected to be appropriate for the depth and breadth of change interventions.[262–264]

Change can be slow because it is a process that involves many people and issues. Efforts to improve quality and safety need champions throughout the key areas within the organization as well as executive and midlevel managers.[70, 259] Champions can also be found among individuals for whom adverse events have had incredible impact on their lives.[265] It would follow then that when an opportunity is present to adopt new knowledge and evidence into practice, "that individual professionals and professional groups (particularly the doctors) have the power to impede or to facilitate the diffusion process"[168] (p. 50). Adoption of new knowledge and evidence for change is a process that needs leadership involvement and support, fostering effective relationships and enabling action, utilizing ongoing monitoring and evaluation, and demonstrating flexibility according to findings from evaluation and changing needs.[254, 258] Yet the effect of this could be mitigated by the commitment and direction of senior leadership, who co-lead/co-coach with clinical leaders[266] to use evidence in practice, and to continuously evaluate progress and make changes accordingly, to therefore improve organizational performance and patient outcomes.[267]

For changes of care processes that support safe and quality care to be effective, interventions must not be first-order, short-term problem-solving that offers quick fixes but not lasting change. Instead, second-order problem-solving should be used, where the underlying causes and processes are examined.[268] Even when processes and procedures have changed and demonstrated positive effects on patient outcomes, there is a concern about sustainability over time because the tendency of health care providers to deliberately deviate from the new standard of practice may be unavoidable.[95] Ongoing monitoring and management of these new processes and procedures is required.[95] How do you institutionalize change? Change initiatives are successful when they are built on the current way of doing things,[251] are visible and have positive outcomes, are consistent with employees' values and beliefs, are manageable,[269] and are generalizable to the organization.[270]

Practice Implications

To bring the effects of the sharp end away from nurses and put them squarely on the shoulders of health care organizations and systems, there needs to be significant changes in how health care is structured and how it is delivered to patients. While the roles and responsibilities of nurses have changed over the years, including "risk management, quality assurance, case management, clinical trials coordinator, and patient care manager among numerous others,"[271] the diversity of skills, roles, and training[272] places nurses in critical positions to lessen the

incidence of variation by collecting and assessing data, working with interdisciplinary teams, examining performance, and driving evidence-based practice.

From the literature reviewed in this chapter, there are key strategies that can be used to effect change, and subsequently, the quality and safety of care will be improved. The major factor in creating improvement is understanding and accounting for the complexity of health care organizations, health care systems, care processes, and patient needs. To begin, senior nurse leaders need to work with staff to identify and prioritize areas and establish goals to address the issues that are associated with poor-quality and unsafe care. Executive leadership and managers need to be committed to investing both their time and resources to improving the safety and quality of care. As organizations begin plans and reassess the need for changes, nurses will need to be proactive in redesigning care models and redefining the work of nurses,[273] whether the initiatives will initially impact only a single unit or group of clinicians, or are aimed at being systemwide. Furthermore, efforts to improve quality and safety must have involvement and commitment from all stakeholders.

The foundation of quality and safety improvement initiatives needs to be centered on systems factors, not individuals. Nurse leaders, colleagues, and State boards of nursing registration should understand the significant impact of systems factors in any instance when individual culpability is sought, particularly when appraising and disciplinary action is unfortunately taken against an individual clinician (e.g., State boards of licensure and malpractice cases). The responsibility of nurse leaders and State boards of nursing is to determine when errors and adverse events result from deliberate malfeasance as opposed to a mixture of systems factors. Without considering the nature and effect of systems factors, action taken against an individual would not appear to be evidence-based and latent factors will continue, waiting to "ensnare" another nurse.

To improve patient safety and the quality of care, it is important to determine the best strategy and be willing to alter the strategy if necessary to create change. Not all strategies that have been successful in other organizations will be successful in your organization; some interventions have too small a sample size or information about them to be considered as a possible strategy in your organization. As an initiative is implemented, it could be that what was thought to have been generalizable needs to be tailored to the unique characteristics of your organization. Change initiatives should be either evidence based or based on data and information internal to your organization (e.g., incident reports), and should address measures to evaluate improvements in patient safety and quality.[199, 274] Throughout the process of implementing changes, it is important for data and information to be continually monitored and assessed to track performance. It is only through strategic decisions and interventions that the sharp end held against nursing will transition to the organizations in which nurses work.

Research Implications

The nurse's role in and ability to change patient safety and quality improvement within health care systems is a relatively new field of research, but consideration must be given to more than 60 years of nursing research that has implications for both safety and quality processes and nursing, patient, and organizational outcomes. Future research will need to better define the theoretical foundations behind the relationships between organizational systems factors, clinical processes, and patient safety and quality outcomes. It is also important for future research to focus on improving and widening the assessment of the impact of patient safety and quality

improvements on the incidence of the broad array of errors that can and do occur in nurses' work environments. For example, leaders and clinicians need to understand the association between an organization's culture of safety and patient outcomes as well as how nurses can influence executives to lead working environment improvements. In addition, and probably more important, future research needs to address how research and evidence can be translated into and become the new standard of practice, avoiding the lengthy process now involved, which could take as long as 10 to 17 years.[275]

Conclusion

Everything about health care is complex. There are complex care processes, complex health care technologies, complex patient needs and responses to therapeutic interventions, and complex organizations. There are tremendous opportunities and challenges in improving the quality and safety of health care, but the majority require purposeful redesign of health care organizations and processes. Organizations that are committed to high-quality and safe care will not place nurses at the "sharp end" of care, but will focus on system improvements. Recognizing the complexity of care and how several factors combine at a specific time and result in errors and adverse events, organizations, leaders, and clinicians will dedicate themselves to using data and evidence and to continuously improve the quality and safety of care, even when there are complex challenges.

Chapter 3. An Overview of *To Err is Human*: Re-emphasizing the Message of Patient Safety

Molla Sloane Donaldson

Introduction

On November 29, 1999, the Institute of Medicine (IOM) released a report called *To Err is Human: Building a Safer Health System*.[1] The IOM released the report before the intended date because it had been leaked, and one of the major news networks was planning to run a story on the evening news.[2] Media throughout the country recognized this opportunity for a headline story describing a very large number of hospital deaths from medical errors —possibly as great as 98,000 per year. The problem in other care settings was unknown, but suspected to be great.

The search was on to find out who was to blame and how to fix the problem. Congressional hearings were subsequently held. Governmental agencies, professional groups, accrediting organizations, insurers, and others quickly responded with plans to define events and develop reporting systems. Health care organizations were put on the defensive. Recognizing that individual accountability is necessary for the small proportion of health professionals whose behavior is unacceptable, reckless, or criminal, the public held organizational leadership, boards, and staff accountable for unsafe conditions. Yet imposing reporting requirements and holding people or organizations accountable do not, by themselves, make systems safer.

What was often lost in the media attention to hospital deaths from medical errors cited by *To Err is Human* was the original intent of the IOM Committee on Quality Health Care in America, which developed the report. That committee believed it could not address the overall quality of care without first addressing a key, but almost unrecognized component of quality; which was patient safety. The committee's approach was to emphasize that "error" that resulted in patient harm was not a property of health care professionals' competence, good intentions, or hard work. Rather, the safety of care—defined as "freedom from accidental injury"[3] (p. 16)—is a property of a system of care, whether a hospital, primary care clinic, nursing home, retail pharmacy, or home care, in which specific attention is given to ensuring that well-designed processes of care prevent, recognize, and quickly recover from errors so that patients are not harmed.

This chapter focuses on the principles described in the IOM report, many of which can be mapped to what are now called safe practices[4] and all of which are valuable guides. This chapter is not intended to address the growing body of evidence; rather, the chapter summarizes the starting point—the IOM recommendations based on the literature and the knowledge of the committee members who developed the report.

Moving the Focus From Errors to Safety

Errors occur in health care as well as every other very complex system that involves human beings. The message in *To Err is Human* was that preventing death and injury from medical errors requires dramatic, systemwide changes.[1] Among three important strategies—preventing, recognizing, and mitigating harm from error—the first strategy (recognizing and implementing

actions to *prevent* error) has the greatest potential effect, just as in preventive public health efforts.

The IOM committee recognized that simply calling on individuals to improve safety would be as misguided as blaming individuals for specific errors. Health care professionals have customarily viewed errors as a sign of an individual's incompetence or recklessness. As a result, rather than learning from such events and using information to improve safety and prevent new events, health care professionals have had difficulty admitting or even discussing adverse events or "near misses," often because they fear professional censure, administrative blame, lawsuits, or personal feelings of shame. Acknowledging this, the report put forth a four-part plan that applies to all who are, or will be, at the front lines of patient care; clinical administrators; regulating, accrediting, and licensing groups; boards of directors; industry; and government agencies. It also suggested actions that patients and their families could take to improve safety.

The committee understood that need to develop a new field of health care research, a new taxonomy of error, and new tools for addressing problems. It also understood that responsibility for taking action could not be borne by any single group or individual and had to be addressed by health care organizations and groups that influence regulation, payment, legal liability, education and training, as well as patients and their families. The report called on Congress to create a National Center for Patient Safety within the Agency for Healthcare Research and Quality, to develop new tools and patient care systems that make it easier to do things right and harder to do things wrong. This handbook is a direct result of the implementation of those recommendations.

Improving Safety by Understanding Error

Every day, physicians, advance practice nurses, nurses, pharmacists, and other hospital personnel recognize and correct errors and usually prevent harm. Errors, defined as "the failure of a planned action to be completed as intended or the use of a wrong plan to achieve an aim,"[1] do not all result in injury or harm. Errors that do cause injury or harm are sometimes called *preventable adverse events*—that is, the injury is thought to be due to a medical intervention, not the underlying condition of the patient. Errors that result in serious injury or death, considered "sentinel events" by the Joint Commission (formerly the Joint Commission on Accreditation of Healthcare Organizations [JCAHO]),[5] signal the need for an immediate response, analysis to identify all factors contributing to the error, and reporting to the appropriate individuals and organizations[7] to guide system improvements.

The key question for the IOM, as for many health professionals now, was what could be done to improve safety. To differentiate between individual factors and system factors, the report distinguished between the "sharp" end of a process in which the event occurs (e.g., administration of the wrong dose of medication that is fatal, a mishap during surgery) and the "blunt" end in which many factors (called latent conditions), which may have seemed minor, have interacted and led to an error.[6] These latent conditions may be attributable to equipment design or maintenance, working conditions, design of processes so that too many handoffs occur, failures of communication, and so forth.[7-9]

Leape[8] greatly enhanced our understanding of errors by distinguishing between two types of cognitive tasks that may result in errors in medicine. The first type of task occurs when people engage in well-known, oft-repeated processes, such as driving to work or making a pot of coffee. Errors may occur while performing these tasks because of interruptions, fatigue, time pressure, anger, distraction, anxiety, fear, or boredom. By contrast, tasks that require problem solving are

done more slowly and sequentially, are perceived as more difficult, and require conscious attention. Examples include making a differential diagnosis and readying several types of surgical equipment made by different manufacturers. Errors here are due to misinterpretation of the problem that must be solved and lack of knowledge. Keeping in mind these two different kinds of tasks is helpful to understanding the multiple reasons for errors and is the first step in preventing them.

People make errors for a variety of reasons that have little to do with lack of good intention or knowledge. Humans have many intellectual strengths (e.g., large memory capacity and an ability to react creatively and effectively to the unexpected) and limitations (e.g., difficulty attending carefully to several things at once and generally poor computational ability, especially when tired).[12] Improving safety requires respecting human abilities by designing processes that recognize human strengths and weaknesses.

There are many opportunities for individuals to prevent error. Some actions are clinically oriented and evidence-based: communicating clearly to other team members, even when hierarchies and authority gradients seem to discourage it; requesting and giving feedback for all verbal orders; and being alert to "accidents waiting to happen." Other opportunities are broader in focus or address the work environment and may require clinical leadership and changing the workplace culture: simplifying processes to reduce handoffs and standardizing protocols; developing and participating in multidisciplinary team training; involving patients in their care; and being receptive to discussions about errors and near misses by paying respectful attention when any member of the staff challenges the safety of a plan or a process of care.

However, large, complex problems require thoughtful, multifaceted responses by individuals, teams, and organizations. That is, preventing errors and improving safety require a systems approach to the design of processes, tasks, training, and conditions of work in order to modify the conditions that contribute to errors. Fortunately, there is no need to start from scratch. The IOM report included some guidance based on what was known at the time, and other specific evidence has accumulated since then that can be put in practice today. Designing for safety requires a commitment to safety, a thorough knowledge of the technical processes of care, an understanding of likely sources of error, and effective ways to reduce errors.

A Report From the Trenches—Systems, not Shame

Nurses sometimes comment:

- "We are really short-staffed. Sometimes I am so busy and distracted that I am sure I must make mistakes when calculating the doses of meds. I haven't killed anyone, but I know when I've made a mistake. How can I make sure I don't make errors?"
- "I was supposed to administer chemotherapy to a patient. Even though I tried hard, I couldn't figure out from the chart what kind of cancer the patient had. What can I do to make sure this sort of thing doesn't happen again?"
- "There is a piece of equipment on our unit that is an accident waiting to happen. The experienced staff knows about it and has learned how to work around it, but what happens when new staff are assigned?"

These types of questions are by no means unusual. Partly because of its sheer complexity and the number of different individuals with different training and approaches, health care is prone to harm from errors—especially in operating rooms, intensive care units (ICUs), and emergency

departments where there is little time to react to unexpected events—and consequences can be very serious. Although most early studies focused on the hospital setting, medical errors present a problem in all settings, including outpatient surgical centers, physician offices and clinics, nursing homes, and the home, especially when patients and families are asked to use increasingly complicated equipment.

Patients should not be harmed by the health care system that is supposed to help them, but the solution does not lie in assigning blame or urging health professionals to be more careful. In what seems to be a simple example, an ICU nurse was wheeling a patient on a gurney to radiology when his knee struck a fire extinguisher hanging on the wall, resulting in the patient needing extra care. In response, the nurse may have been scolded by her supervisor and told to be more careful, or punished in some other way; everyone would feel the problem had been solved. Yet, would that make the hospital safer? Would it prevent other events that are similar but slightly different in circumstances from happening with other staff and patients in other units? The answer is an emphatic no.

Improving safety, arises from attention to the often multiple latent factors that contribute to errors and in some cases, to injury. In the above example, such factors included: 1) the nurse having to move the patient herself because transport had never arrived; 2) a change in hospital policy, so that only one instead of two people guide gurneys; 3) the failure to mount the fire extinguisher in a recessed niche; 4) the decision to transport a seriously ill patient rather than having mobile equipment come to him, requiring extra "handoffs" and opportunities for injury; and 5) poor gurney design, making steering difficult, and possibly still other factors.

The IOM's Four-Part Message

The IOM committee sought what could be learned from other disciplines and applied in health care by clinical and administrative leadership. It described actions that health care professionals can take now in their own institutions, whether they are new trainees, experienced clinical leaders, or instructors. The major thrust of the report was a four-part plan, intended to create financial and regulatory incentives to create a safer health care system and a systematic way to integrate safety into the process of care (the focus of this chapter). The four parts of the IOM recommendations are described below:

- **Part 1: National Center for Patient Safety** – The IOM recommended the creation of a National Center for Patient Safety in the U.S. Department of Health and Human Services's Agency for Healthcare Research and Quality (AHRQ), because health care is a decade or more behind other high-risk industries in its attention to ensuring basic safety, establishing national safety goals, tracking progress in meeting them, and investing in research to learn more about preventing mistakes. This center would also serve as a clearinghouse and source of effective practices that would be shared broadly.
- **Part 2: Mandatory and Voluntary Reporting Systems** – To learn about medical care associated with serious injury or death and to prevent future occurrences, the IOM recommended establishing a nationwide, mandatory public reporting system, where Federal legislation would protect the confidentiality of certain information (e.g., medical mistakes that have no serious consequences). The intent was to encourage the growth of voluntary, confidential reporting systems so that practitioners and health care organizations could learn about and correct problems before serious harm occurs.

- **Part 3: Role of Consumers, Professionals, and Accreditation Groups** – The IOM believed that fundamental change would require pressure and incentives from many directions, including public and private purchasers of health care insurance, regulators (including the Food and Drug Administration), and licensing and certifying groups. A direct result was the announcement of new standards on safety from the Joint Commission and a report, *Safe Practices for Better Health Care. A Consensus Report*, by the National Quality Forum.[10]
- **Part 4: Building a Culture of Safety** – The IOM urged health care organizations to create an environment in which safety becomes a top priority. This report stressed the need for leadership by executives and clinicians and for accountability for patient safety by boards of trustees. In particular, it urged that safety principles known in other industries be adopted, such as designing jobs and working conditions for safety; standardizing and simplifying equipment, supplies and processes; and avoiding reliance on memory. The report stressed medication safety in part because medication errors are so frequent[11] and in part because a number of evidenced-based practices were already known and needed wider adoption. Though at the time of publication, the levels of evidence for each category varied, the members of the committee believed that all were important places to begin to improve safety.

The committee recognized that some actions could be taken at the national level as described in the recommendations contained in Parts 1–3. Yet if patient safety were really to improve, the committee knew it would take far more than reporting requirements and regulations. Creating and sustaining a culture of safety (Part 4) is needed, which would require continuing local action by thousands of health care organizations and the individuals working in these settings at all levels of authority. Hospital leadership must provide resources and time to improve safety and foster an organizational culture that encourages recognition and learning from errors. A culture of safety cannot develop without trust, keen observation, and extensive knowledge of care processes at all levels, from those on the front lines of health care to those in leadership and management positions.

Basic Concepts in Patient Safety

Opportunities to improve safety have been drawn from numerous disciplines such as engineering, psychology, and occupational health. The IOM report brought together what had been learned in these fields and then applied the opportunities to health care, as described in the nine categories that follow.

1. User-Centered Design

Understanding how to reduce errors depends on framing likely sources of error and pairing them with effective ways to reduce them. The term "user-centered design" builds on human strengths and avoids human weaknesses in processes and technologies.[12] The first strategy of user-centered design is to make things visible—including the conceptual model of the process—so that the user can determine what actions are possible at any moment, for example, how to return to an earlier step, how to change settings, and what is likely to happen if a step in a process is skipped. Another principle is to incorporate affordances, natural mappings, and constraints into health care. Although the terms are strange, their meaning can be surprisingly easily applied to common everyday tasks, both in and out of the workplace.

An affordance is a characteristic of equipment or workspace that communicates how it is to be used, such as a push bar on an outward opening door that shows where to push or a telephone handset that is uncomfortable to hold in any but the correct position. Marking the correct limb for before surgery is an affordance that has been widely adopted. Natural mapping refers to the relationship between a control and its movement, for example, in steering a car to the right, one turns the wheel right. Other examples include using louder sound or a brighter light to indicate a greater amount.

Constraints and forcing functions guide the user to the next appropriate action or decision. A constraint makes it hard to do the wrong thing. A forcing function makes it impossible to do the wrong thing. For example, one cannot start a car that is in gear. Forcing functions include the use of special luer locks for syringes and indwelling lines that have to be matched before fluid can be infused, and different connections for oxygen and other gas lines to prevent their being inadvertently switched. Removing concentrated potassium chloride from patient units is a (negative) forcing function because it should never be administered undiluted, and preparation should be done in the pharmacy.

2. Avoid Reliance on Memory

The next strategy is to standardize and simplify the structure of tasks to minimize the demand on working memory, planning, or problem-solving, including the following two elements:

- **Standardize process and equipment.** Standardization reduces reliance on memory and allows newcomers who are unfamiliar with a given process or device to do the process or use a device safely. For example, standardizing device displays (e.g., readout units), operations, and doses is important to reduce the likelihood of error. Other examples of standardizing include standard order forms, administration times, prescribing protocols, and types of equipment. When devices or medications cannot be standardized, they should be clearly distinguishable. For example, one can identify look-alike, but different, strengths of a narcotic by labeling the higher concentration in consistent ways, such as by shape and prominent labeling.

  When developed, updated, and used wisely, protocols and checklists can enhance safety. Protocols for the use of anticoagulants and perioperative antibiotics have gained widespread acceptance. Laminated dosing cards that include standard order times, doses of antibiotics, formulas for calculating pediatric doses, and common chemotherapy protocols can reduce reliance on memory.[13]
- **Simplify key processes.** Simplifying key processes can minimize problem-solving and greatly reduce the likelihood of error. Simplifying includes reducing the number of steps or handoffs that are needed. Examples of processes that can usually be simplified are writing an order, then transcribing and entering it in a computer, or having several people record and enter the same data in different databases. Other examples of simplification include limiting the choice of drugs and dose strengths available in the pharmacy, maintaining an inventory of frequently prepared drugs, reducing the number of times a day a drug is administered, keeping a single medication administration record, automating dispensing, and purchasing equipment that is easy to use and maintain.

3. Attend to Work Safety

Conditions of work are likely to affect patient safety. Factors that contribute to worker safety in all industries studied include work hours, workloads, staffing ratios, sources of distraction, and shift changes (which affect one's circadian rhythm). Systematic evidence about the relative importance of various factors is growing with particular emphasis on nurse staffing.[14-16]

4. Avoid Reliance on Vigilance

Individuals cannot remain vigilant for long periods of time. Approaches for reducing the need for vigilance include providing checklists and requiring their use at regular intervals, limiting long shifts, rotating staff, and employing equipment that automates some functions. The need for vigilance can be reduced by using signals such as visual and auditory alarms. Also, well-designed equipment provides information about the reason for an alarm. There are pitfalls in relying on automation, if a user learns to ignore alarms that are often wrong, becomes inattentive or inexpert in a given process, or if the effects of errors remain invisible until it is too late to correct them.

5. Train Concepts for Teams

People work together throughout health care in multidisciplinary teams, whether in a practice; for a clinical condition; or in operating rooms, emergency departments, or ICUs. In an effective interdisciplinary team, members come to trust one another's judgments and expertise and attend to one another's safety concerns. Team training in labor and delivery and hospital rapid response teams are examples. The IOM committee believed that whenever it is possible, training programs and hospitals should establish interdisciplinary team training.

6. Involve Patients in Their Care

Whenever possible, patients and their family members or other caregivers should be invited to become part of the care process. Clinicians must obtain accurate information about each patient's medications and allergies and make certain this information is readily available at the patient's bedside. In addition, safety improves when patients and their families know their condition, treatments (including medications), and technologies that are used in their care.

At the time of discharge, patients should receive a list of their medications, doses, dosing schedule, precautions about interactions, possible side effects, and any activities that should be avoided, such as driving. Patients also need clear written information about the next steps after discharge, such as followup visits to monitor their progress and whom to contact if problems or questions arise.

Family caregivers deserve special attention in terms of their ability to provide safe care, manage devices and medication, and to safely respond to patient needs. Yet they may, themselves, be affected by physical, health, and emotional challenges; lack of rest or respite; and other responsibilities (including work, finances, and other family members).

Attention is now being given to problems resulting from lack of patient and family health literacy. For example, information may be too complex to absorb or in a language unfamiliar (even to educated and English-speaking patients)—and frightening. A simple example is rapidly given instructions on home care of a Foley catheter when, as often occurs, the patient is being

discharged shortly after surgery and knows nothing about sterile technique or the design of the device. Another ubiquitous example is the warnings and dosage information on medication bottles, which many patients cannot understand how to apply.

7. Anticipate the Unexpected

The likelihood of error increases with reorganization, mergers, and other organization-wide changes that result in new patterns and processes of care. Some technologies, such as computerized physician order entry systems (CPOE), are engineered specifically to prevent error. Despite the best intentions of designers, however, all technology introduces new errors, even when its sole purpose is to prevent errors. Indeed, future failures cannot be forestalled by simply adding another layer of defense against failure.[17-19] Safe equipment design and use depend on a chain of involvement and commitment that begins with the manufacturer and continues with careful attention to the vulnerabilities of a new device or system. Health care professionals should expect any new technology to introduce new sources of error and should adopt the custom of automating cautiously, always alert to the possibility of unintended harm, and should test these technologies with users and modify as needed before widespread implementation.

8. Design for Recovery

The next strategy is to assume that errors will occur and to design and plan for recovery by duplicating critical functions and by making it easy to reverse operations and hard to carry out nonreversible ones. If an error occurs, examples of strategies to mitigate injury are keeping antidotes for high-risk drugs up to date and easily accessible and having standardized, well-rehearsed procedures in place for responding quickly to adverse events. Another strategy is to use simulation training, where learners practice tasks, processes, and rescues in lifelike circumstances using models or virtual reality.

9. Improve Access to Accurate, Timely Information

The final strategy for user-centered design is to improve access to information. Information for decision-making (e.g., patient history, medications, and current therapeutic strategies) should be available at the point of patient care. Examples include putting lab reports and medication administration records at the patient's bedside and putting protocols in the patient's chart. In a broader context, information is coordinated over time and across settings.

Conclusion

Now, 7 years after the release of *To Err is Human*, extensive efforts have been reported in journals, technical reports, and safety-oriented conferences. That literature described the magnitude of problems in a variety of care settings, the efforts to make change, and the results of those efforts in improving patient safety. Many of those studies are referenced and discussed throughout this book. Other authors have written incisively about what progress has and has not been made in the past 7 years and the challenges in creating cultures of safety.[20, 21] The greatest challenge we all face is to learn, use, and share better information about how to prevent harm to patients.

Chapter 4. The Quality Chasm Series: Implications for Nursing

Mary K. Wakefield

Introduction and Background

Exhaustive research documents the fact that today in America, there is no guarantee that any individual will receive high-quality care for any particular health problem. Health care is plagued with inappropriate utilization of health services and errors in health care practice.[1] The quality and safety of health care in this nation were assessed through a series of 11 reports from the Institute of Medicine (IOM). Some of the most significant components of the first two reports are a set of aims to achieve high-quality care and new rules to guide the redesign of the broken health care system. The needed transformation and steps to achieving redesign are substantial because the chasm between what currently exists in health care and what should exist to achieve high-quality care is sizeable. While only four of the IOM reports will be discussed in this section—other reports are discussed in other chapters later in this book—each has significant implications for nursing and for how care should be delivered.

In 1999, the IOM released its landmark report, *To Err Is Human: Building a Safer Health System*.[2] The chilling conclusion of that report was that thousands of people were injured by the very health system from which they sought help. Tens of thousands of Americans die each year and hundreds of thousands are injured. That report and its companion, *Crossing the Quality Chasm*,[3] have had a profound impact on how health care is viewed. The information and perspectives moved conversations regarding patient safety and quality care from inside health care institutions to the mainstream of media, corporate America, and public policy. The reports raised awareness of the depth and complexity of quality challenges and prompted the marked expansion of quality improvement efforts through research and other means.

The most significant barrier to improving patient safety identified in *To Err Is Human* is a "lack of awareness of the extent to which errors occur daily in all health care settings and organizations. This lack of awareness exists because the vast majority of errors are not reported, and errors are not reported because personnel fear they will be punished"[2] (p. 155). While these statements describing the essence of the challenges facing health care are simple and straightforward, the level and complexity of effort needed to address them is not. Since the release of the two reports, broad-based efforts have begun to bring more sophistication and precision to measuring and improving the safety and quality of health care. Nevertheless, substantial work in both academic and practice settings remains to be done.

While the IOM reports initiated tectonic shifts in attention and effort, the reports were not the first set of clear statements of concern regarding safety and quality. Nor were these reports the first efforts at calling attention to the need for data, public reporting, and the consideration of health care quality in light of payment for care. More than 140 years earlier, Florence Nightingale, the founder of modern nursing, raised these same issues. In spite of the passage of well over a century between Nightingale and the release of the IOM reports, seemingly little attention was paid in the interim to creating safer health care environments.

Three comparisons of Nightingale's concerns and recommendations with those expressed in the IOM reports illustrate similar problem identification as well as a shared view regarding the building blocks essential to creating solutions. First, in her publication, *Notes on Hospitals*,[4] Nightingale identified the paradox of the problem at hand: "In practice a hospital may be found only to benefit a majority, and to inflict suffering on the remainder" (p. 20). Well over a century later, *To Err Is Human* says, "… a person … should not have to worry about being harmed by the health system itself"[2] (p. 5). Nightingale goes on to say, "Even admitting to the full extent the great value of hospital improvements of recent years, a vast deal of suffering, and some at least of the mortality, in these establishments is avoidable"[4] (p. 3). Similarly, *To Err Is Human* notes, "A substantial body of evidence points to medical errors as a leading cause of death and injury"[2] (p. 26).

Finally, in a search for solutions and with an eye toward measurement, developing evidence, public reporting, and linking payment with quantifiable performance, Nightingale advances[4] (p. 3), "It is impossible to resist the conviction that the sick are suffering from something quite other than the disease inscribed on their bed ticket—and the inquiry … arises in the mind, what can be the cause?" Related to this, *To Error Is Human* notes, "Sufficient attention must be devoted to analyzing and understanding the causes of errors in order to make improvements"[2] (p. 87). In addition, the report notes, "Group purchasers have the ability to consider safety issues in their contracting decisions"[2] (p. 152).

As is evident in the similarity of statements between Nightingale and the IOM, concerns about medical error and compromises in patient safety bridge a significant passage of time. It is difficult not to speculate about what safety in health care would look like today had Nightingale's calls to action been heeded. Rather than lagging behind, health care in the 21st century might have been the leader in safety among high-risk industries such as aviation and nuclear power production. Instead, clinicians, policymakers, and many others search for safety and quality lessons to apply in health care delivery from these and other high-risk but safer industries. Irony exists in that these industries, nonexistent during Nightingale's time, have made substantially more progress than health care in creating safe environments.

The Quality Chasm Series

Since the release of *To Err Is Human* and *Crossing the Quality Chasm*, the IOM has produced 9 additional related reports. The IOM Quality Chasm Series (see Table 1) includes reports linking quality to a range of issues, from health professions education, to health care in rural America, to improving health care quality for mental health and substance-abuse systems. Threaded through this series are key concepts of the framework presented in the original two reports. In each report, facets of the framework are expanded or applied to specific populations or system characteristics. The language of most of the reports tends to group members of health care disciplines by the terms "providers" or "clinicians," with an occasional mention of specific professional groups such as medicine or nursing. Generally speaking, the content of the reports are directly or indirectly applicable to all health care professionals. Consequently, each of the 11 reports has implications for aspects of nursing practice, research, education, and public policy engagement.

Table 1. The IOM Quality Chasm Series

- *To Err Is Human: Building a Safer Health System,* 2000[2]
- *Crossing the Quality Chasm,* 2001[3]
- *Leadership by Example: Coordinating Government Roles in Improving Health Care Quality,* 2002[5]
- *Fostering Rapid Advances in Health Care: Learning From Systems Demonstrations,* 2002[6]
- *Priority Areas for National Action: Transforming Health Care Quality,* 2003[7]
- *Health Professions Education: A Bridge to Quality,* 2003[8]
- *Patient Safety: Achieving a New Standard for Care,* 2003[9]
- *Keeping Patients Safe: Transforming the Work Environment of Nurses,* 2004[10]
- *Quality Through Collaboration: The Future of Rural Health Care,* 2004[11]
- *Preventing Medication Errors: Quality Chasm Series,* 2006[12]
- *Improving the Quality of Health Care for Mental and Substance-Use Conditions: Quality Chasm Series,* 2006[13]

This section focuses on nursing implications associated with selected issues, concepts, findings, and recommendations specifically embedded in 4 of the 11 reports: *To Err Is Human*, *Crossing the Quality Chasm*, *Health Professions Education: A Bridge to Quality*, and *Quality Through Collaboration: The Future of Rural Health Care* (often referred to as the rural report). The identified nursing implications in these four reports give a sense of the relevance and utility of these reports to the nursing discipline. The first two reports discussed in this chapter established the scope of the problems associated with compromises in quality of health care and offered a framework for addressing those problems. The third report, on health professions education, described the critical role health professions education plays in facilitating or impeding the delivery of consistent, high-quality health care. The nursing profession, central to health care delivery, is a pivotal audience for this report.

The Future of Rural Health Care addresses the long-standing lack of attention brought to rural health care quality in spite of the fact that between one-fourth and one-fifth of the population resides in rural America. This report sheds light on the unique features of rural health care and tailored approaches to addressing quality shortcomings. Particularly relevant to nurses, however, is that *The Future of Rural Health Care* introduced innovative approaches that move beyond health care and focus on the quality of the health of populations. Whether viewed from a rural or urban context, the latter orientation is an important focus for nurses to consider in their future work and research.

To Err Is Human: Building a Safer Health System

As the first report in the IOM Quality Chasm series, *To Err Is Human* frames the scope of the challenge for improving safety in health care systems. Safety is defined as freedom from accidental injury.[2] Articulated in the report is the heavy toll associated with safety compromises and health care errors in terms of human lives, suffering, and financial burden of health care services. Financial burden is borne by individuals, employers, insurance companies, and governmental programs such as Medicare and Medicaid. Approximately 30 research studies

were reviewed and established the evidence base for the IOM's Committee on Quality of Health Care in America determination that error is a cause of very significant and widespread injury and mortality. Many of the research studies focused on activities that incorporated nursing functions such as medication processes. Additionally, a number of the reviewed studies helped to illuminate the predeterminants of error.

Due to the dearth of evidence to serve as the basis for some of the conclusions and recommendations in this report, the IOM acknowledged that current understanding of the epidemiology of errors was fragmented. Calls for research efforts were evident throughout the report. "Research and analysis are not luxuries in the operation of safety systems. They are essential steps in the effective redesign of systems"[2] (p. 181). Clearly there is opportunity for nurse researchers, along with others, to make significant and important contributions to address this knowledge deficit with needed evidence.

In addition to increasing awareness of the scope and significance of medical errors, a set of strategies and recommendations were advanced to encourage patient safety and quality improvement. Major emphasis is placed on (1) the essential role of leadership in addressing errors, (2) the need for and structure of error reporting systems, (3) the development of performance standards, and (4) recommendations regarding elements key to safety design in health care systems. The committee producing the report devoted considerable attention to making the case that perfection based on human performance—while a long-standing expectation of the work of nurses, physicians, and others—is both faulty and dangerous. In reorienting expectations from a focus on individuals to a focus on systems, the report clearly and firmly stated that to eliminate the source of a vast majority of errors and near misses, health care systems must be designed to make it very hard for nurses and others to make errors. This orientation runs directly counter to long-held views by both the public and health care providers themselves: that mistakes are solely the result of individual provider actions and that blame should be assigned accordingly. The report refocused attention on the need to construct systems that make it easy for nurses and others to engage in safe practices and difficult to execute actions that are unsafe.

External Drivers of Safety and Quality

The report described external drivers that can improve the safety and quality of health care, including nursing care. External drivers that influence the quality of nursing care included regulation and legislation, accrediting organizations, efforts to link payment with performance, the need for interdisciplinary guidelines, the commitment of professional organizations, and the level of public engagement. The report included a number of observations about the role that licensing and credentialing processes can have in building appropriate performance standards and expectations for all health professionals. Examples of regulation and legislation that impact nursing care quality included State scope-of-practice laws that govern what nurses are legally licensed to do and stipulate performance expectations. Subsequently, there are concerns about whether current methods of licensing and credentialing adequately assess the safety and competence of skills across health professionals, including nurses. More than 20 States now have laws requiring error reporting, and with recent Federal reporting legislation, serious errors that reflect nursing and other care processes are now governed by reporting expectations from outside the health care system.

Accrediting organizations influence nursing care quality through their safety and quality standards. Highly influential in this regard has been the marked expansion of safety expectations

of accrediting bodies, such as the Joint Commission (formerly known as the Joint Commission on Accreditation of Healthcare Organizations [JCAHO]). The Joint Commission National Patient Safety Goals (NPSGs) are very prescriptive and explicit in their impact on aspects of nursing practice. For example, the Joint Commission's safety goals include standardizing handoff communications, including an opportunity to ask and respond to questions, and a goal to encourage the active involvement of patients and their families in the patient's care as a patient safety strategy[14] (e.g., patient- and family-centered care).

External drivers also include steps being taken by the Centers for Medicare and Medicaid Services to link reporting performance on quality indicators with payment. These payment changes reward hospitals that publicly report their performance on a predetermined set of quality indicators, many of which are directly or indirectly influenced by nursing actions. Private sector entities such as insurance companies are moving in similar directions. The intense interest in aligning payment with performance (i.e., health sector income and patient outcome) has significant implications for nursing. Put simply, maintaining and strengthening the financial health of hospitals and other segments of the health care delivery system is linked in no small part to the practice of nursing in these facilities. Consequently, alignment of reimbursement with quality is redirecting the attention of health care administrators. To the extent that research continues to link nursing practices, staffing, and other characteristics (e.g., educational background and number of hours worked) to the quality of patient care, nursing will be positioned to receive considerably more attention from health care system leadership.

Recognizing that more could be done to improve patient outcomes the report called for the incorporation of patient safety considerations into clinical practice guidelines, as well as the development of guidelines specifically focused on patient safety. Particular attention is paid to the need for engaging interdisciplinary approaches to guideline development. Nurses' expertise and functions clearly overlap with a number of other disciplines in particular content areas (e.g., mental health care and critical care). This overlap makes this recommendation difficult to pursue, but appropriate to nursing as well as other disciplines. Nursing education, as well as State and national nursing organizations, can expand efforts to engage interdisciplinary partners in developing shared academic curricula and conference and meeting content. Additionally, nurse clinicians, researchers, and others should further the development of safety aspects of clinical guidelines development in concert with representatives of other health care disciplines.

Another report recommendation called for professional organizations to firmly commit to an agenda focused on patient safety, with specific efforts targeted toward health professions education. Efforts can emerge through curriculum development, the inclusion of safety content on conference agendas, and ongoing in-service education. Various nursing organizations have responded to aspects of this recommendation. However, in light of many competing priorities, expanding and sustaining this focus over time and across multiple venues will challenge nurses and the nursing profession.

The final external driver addressed in the report addressed whether or not the public is engaged in safety improvement efforts. Professional organizations, particularly those that represent nurses, can help to accomplish this by working with both the public and policymakers. Some national nursing organizations already have made safety part of their public policy agenda (e.g., the Association of Operating Room Nurses). Nevertheless, there is substantial work that could occur to create new efforts that educate and engage the broader public in health care safety activities. As a profession, nursing commands considerable trust from the American public. Also, nursing places high value on the importance of educating individuals, families, and communities

about health and health care in order to fully engage them as partners in their health. Consequently, nurses are particularly well positioned to engage in the challenging work of assisting the public to understand both the complexity of patient safety and error, and the actions they can engage in to help ensure they receive safe health care. Individual nurses can engage this type of effort in concert with other health team members. This work can also be done through nursing organizations and in tandem with insurers, employers, and others who recognize the pivotal role health care consumers can play in ensuring the delivery of safe care.

Principles for the Design of Safe Systems

Internal drivers that impact the safety and quality of care include policies, management decisions, and other organizational features that either help to prevent or predispose individuals to committing errors. The IOM report identified internal drivers as being most hazardous to safety in complex systems (e.g., health care), because generally speaking, the internal drivers' influence on error is not readily apparent.[2] Applied to nursing, quality and safety are products of interactions between nurses and others, between nurses and technology, and between nurses and care processes. To address threats to quality and safety by internal drivers, five principles for the design of safe systems are articulated in *To Err Is Human*, each of which has direct relevance to nursing practice.

- **Principle 1: The commitment of senior level managers and leaders of health care institutions is essential to moving a quality and safety agenda forward in care settings.**

Nurse leaders, in tandem with other institutional leaders, have a role in ensuring that patient safety is a priority corporate objective, a responsibility shared by everyone, and that expectations for safety oversight are clearly articulated and assigned. Efforts directed toward highlighting the importance and expectations of the quality and safety agenda need to reach up to boards of directors and across to all employees within health care settings. Nursing leadership has a core responsibility to help ensure that this orientation is pervasive within the institution and that it is firmly embraced by the senior ranks of the organization.

- **Principle 2: Human limits in care processes need to be explicitly identified and strategies put in place to minimize the likelihood that these limitations are expressed in the work environment.**

Nurses should be attuned to determining and addressing sources of potential error. Protocols and checklists that help guide nursing actions should be readily available and used. Determining ways to simplify processes, such as reducing the number of handoffs and standardizing actions, devices, or doses to minimize the likelihood of error, should involve all nurses.

- **Principle 3: Effective team functioning, promoted and fostered by the institution, is an essential component of health care systems that are quality and patient safety driven**.

This includes team training approaches as well as involving patients in safety design and care processes. Features of this principle are more fully developed in the IOM report, *Health Professions Education: A Bridge to Quality*, and will be discussed in that section.

- **Principle 4: The redesign of systems for safe care involves anticipating the unexpected and adopting proactive approaches to ensuring safe care.**

This principle covers such important attributes as improving access to accurate and timely information and designing for recovery. Since the release of *To Err Is Human*, specific evidence-based activities designed to anticipate the unexpected are being implemented. For example, the deployment of rapid response teams in health care environments is designed to prevent serious

adverse events such as cardiac or respiratory arrest.[15] With the help of nursing knowledge and research, other equally important high-impact care processes will be developed over time.

- **Principle 5: Creating a learning environment addresses the extremely complex work of changing organizational and academic cultures so that error is viewed as an opportunity to learn.**

A learning environment does not seek to fix blame, but ensures that reporting systems have well-developed approaches for communicating how identified problems will be addressed. Also important, given the historical power gradient among nurses and physicians and others, is the free flow of information without the inhibiting hierarchies.[2] Learning environments ensure that all staff have high comfort levels in communicating any and all safety concerns. Some of the most complex patient safety work involves creating organizational cultures and expectations that embrace these features. Redesigning the education of the next generation of nurses so they are capable of maximizing their contributions in these environments is a necessary component.

Nurse leaders should play key roles in ensuring that patient safety programs inside health care organizations are highly visible, implement nonpunitive reporting processes, and incorporate safety principles into daily practice, all of which are called for in the recommendations of *To Err Is Human*. The second report, *Crossing the Quality Chasm*, describes at greater length the use of internal and external approaches to meaningfully improve the quality of health care.

Crossing the Quality Chasm

Broader quality challenges described in *Crossing the Quality Chasm*[3] are equal to patient safety in their complexity. While the entire *Quality Chasm* report is highly relevant to nursing concerns, only a small set of key concepts with implications for nursing will be presented here. This discussion is for the purpose of illustrating the implications of this report for the nursing profession, and to highlight ways that nurses individually and collectively can align their efforts with the content of these highly regarded reports. Challenges to quality are divided into three types: (1) overuse, which refers to the application of health care services where the potential for harm exceeds the potential for benefit; (2) underuse, which is the absence of a service when it is indicated; and (3) misuse, which is in the provision of an appropriate service, a preventable injury occurs.[3]

The *Quality Chasm* report described the work of health care as being "characterized by more to know, more to manage, more to watch, more to do, and more people involved in doing it at any time in the nation's history"[3] (p. 25). The statement is certainly descriptive of nursing as well. All too familiar to nurses is the growing complexity of both health care and the nature of nursing knowledge and nursing practice. Given these complexities, individual nurses, as with other clinicians, cannot possibly recall and apply all knowledge necessary for the delivery of safe, high-quality patient, family, or community care. The complexity of nursing and medical practice has markedly increased, the technologies are more numerous and complex, and the evidence base underlying practice is rapidly expanding. Recognizing these challenges, the first recommendation in the *Quality Chasm* report restated the purpose of the health care system as articulated by President Clinton's Advisory Commission on Consumer Protection and Quality in the Health Care Industry: "All health care organizations, professional groups, and private and public purchasers should adopt as their explicit purpose to continually reduce the burden of illness, injury and disability, and to improve the health and functioning of the people of the

United States."[3] (p. 39). In contemplating this statement, nurses might ask what the collective contribution of nursing is and should be to achieving this purpose. How do we pursue this goal? How do we know whether we and other stakeholders in the U.S. health care system are making progress toward achieving it? The *Quality Chasm* report adds more specificity to this recommendation by setting out six aims (see Table 2). To achieve the aims of the purpose statement articulated above, the *Quality Chasm* report suggests that these six aims should be the focus of nurses and other clinicians, and should be pursued in all health care settings.

Table 2. IOM's Six Aims for Improving Health Care Quality

Aim	Description
1. Safe care	Avoiding injuries to patients
2. Effective care	Providing care based on scientific knowledge
3. Patient-centered care	Providing respectful and responsive care that ensures that patient values guide clinical decisions
4. Timely care	Reducing waits for both recipients and providers of care
5. Efficient care	Avoiding waste
6. Equitable care	Ensuring that the quality of care does not vary because of characteristics such as gender, ethnicity, socioeconomic status, or geographic location.

Illustrations of the relevance and integral nature of nursing to achieving these aims are illustrated below.

- **Aim 1—Safe Care**

The Quality Chasm noted, "The health care environment should be safe for all patients, in all of its processes, all of the time. This standard of safety implies that organizations should not have different, lower standards of care on nights and weekends or during times of organizational change"[3] (p. 45). Recognizing the particular danger that handoffs can pose to patients, the report notes that handoffs are frequently the first place where patient safety is compromised. Clearly, part and parcel of the work of nurses are the transactions that occur among nurses and others as information, components of care processes, and patients themselves are handed off to others. Nursing work is punctuated by patient transfers from one environment to another (e.g., inter- and intra-institutional transfers of patients), from shift to shift, or communication from one clinician to another (e.g., information given by a nurse to different physical therapists caring for the same patient). Moreover, because of their ongoing contact with patients and their families, nurses are in pivotal positions to both inform and incorporate the observations and concerns of these individuals into creating safe care environments. To do so require nurses to consider all information conveyed to them by patients and family members and to encourage that communication.

- **Aim 2—Effective Care**

The provision of effective nursing care rests on the development and use of nursing evidence, as well as evidence produced by other disciplines with relevance to nursing practice. Effective care is based on evidence derived from four types of research: laboratory experiments, clinical trials, epidemiological research, and outcomes research, including case reports.[3] Outcomes research, critical to improving care quality, uses information about how well interventions work on a large, generalizable scale. Nurse researchers engage in all four types of research, and each

type is capable of informing aspects of care delivery and care quality. Nevertheless, there is a paucity of research to undergird the application of many interventions, nursing and non-nursing alike. Looking to the future, the *Quality Chasm* report suggests that "the knowledge base about effective care and its use in health settings will constantly expand through improved methods of accessing, summarizing and assessing information and making it available at the point of care for the patient"[3] (p. 48), Already, information technology systems in some health care settings provide immediate access to clinical guidelines, step-by-step approaches to procedures, and other information that is based on research evidence or, in its absence, expert judgment.

In addition to expecting the further development of and adherence to an evidence base, the *Quality Chasm* report also highlights the importance of nurses and other clinicians systematically and continually reviewing the outcomes of the care that they provide. Currently, care results are rolled up and reflected in overall performance indicators for nursing homes and hospitals. With some exceptions, there is relatively limited information that is currently collected, assessed, and fed back to nurses to help them better understand their individual impact on care quality and thereby assist them in improving their performance. Clearly, efforts that have resulted in the development of nursing indicators are a step in this direction. This is one more important area in which nurses can engage to further the quality improvement agenda.

- **Aim 3—Patient-Centered Care**

Aspects of patient-centered nursing care have long been incorporated in nursing education programs. However, the meaning of the term has evolved and the extent to which it is met is variable. Gerteis and colleagues[16] put forward a set of dimensions of patient-centered care, including respect for patients' values, preferences, and expressed needs; coordination and integration of care; information, communication, and education; physical comfort; emotional support; and involvement of family and friends. Considerable nursing and other research remains to be done to better delineate the outline of this concept and strategies for addressing it. A related concept, population-centered care, is discussed extensively in the IOM report *Quality Through Collaboration: The Future of Rural Health.* This important concept has even less evidence-based approaches to help guide its achievement.

- **Aim 4—Timely Care**

Timeliness of care delivery is often compromised, almost regardless of where a consumer comes in contact with health care. From emergency rooms to schools, nurses see first hand the difficulties in providing timely access to care. Timeliness is compromised when patients needing immediate medical attention find themselves in overcrowded emergency rooms, or individuals without health insurance are delayed in accessing health care or there is a lack of available clinicians. Delays like these are too often the norm. Many factors, both internal and external to the care environment, impact timeliness. Internal to delivery systems, analyzing and refining the actual design of effective processes is overlooked. Instead, the blunt instrument used to drive timeliness is often the expectation for nurses and other clinicians to do more and, in some cases, faster. This approach itself can, at times, compromise care quality.

Efforts to improve timeliness are multifaceted. One of the essential tools to address parts of this challenge is technology. The expanded use of call-a-nurse lines, e-mail exchanges between clinicians and patients, and consumer access to telemedicine applications linking rural and urban facilities, are part of the developing technology-based toolkit needed to increase timely access to care.

- **Aim 5—Efficient Care**

Efficiency is not necessarily a hallmark of the U.S. health care system. In fact, some quality experts indicate that adding more financial resources to the health care delivery system is highly inefficient, given the high level of waste in current practices. Since nurses are on the front lines of health care, nurses are well positioned to work within their institutions at the local level as well as through their associations at the national level to develop and promote agendas designed to increase efficiency, ultimately making better use of the significant financial resources currently directed to health care.

Additionally, nurse researchers can play an exceedingly important role in achieving efficiency. For example, Naylor[17] found that elderly patients receiving a comprehensive intervention delivered by advanced practice nurses (APNs) in the hospital and followed in the home significantly decreased expensive hospitalizations. APN care resulted in average per capita expenditures of $6,152 compared to the control group expenditure of $9,618. As a result, efforts are underway to help move this intervention into the broader practice environment.

As the growth in health care expenditures continues to rise nationally, public policymakers, insurers, and others will be far more open to nursing practice models as well as other strategies that help to rein in high costs while sustaining or improving care quality. Efforts toward achieving this aim provide new opportunities for nurses to create models that maximize the contribution of nursing care and innovation in quality improvement.

- **Aim 6—Equitable Care**

Equity refers to universal access to health care services.[3] Challenges surrounding equity are reflected in disparities in health care by ethnic and socioeconomic groups, lack of health insurance or underinsurance, and geographic inequity that influences the services available. Equity as an aim tied to geographic access is discussed later in this section on the IOM report, *Quality Through Collaboration: The Future of Rural Health Care.*

Ten Rules of Health Care Redesign

In addition to advancing a core set of improvement aims, the *Quality Chasm* report also put forward 10 rules to guide the redesign of health care. The report recommended that this redesign effort incorporate the full complement of health care stakeholders, including patients, payers, clinicians, and others. Many of these rules have underlying evidence to support them. However, some of the rules do not, and in those cases, the report included supporting rationale. The current set of rules that guides health care delivery and the rules proposed to guide the redesign of health care are delineated in Table 3.

Table 3. Simple Rules for the 21st Century Health Care System

Current Approach	New Rule[3]
Care is based primarily on visits	Care based on continuous healing relationships
Professional autonomy drives variability	Customization based on patient needs and values
Professionals control care	The patient as the source of control
Information is a record	Shared knowledge and free flow of information

Current Approach	New Rule[3]
Decisionmaking is based on training and experience	Evidence-based decisionmaking
Do no harm is an individual responsibility	Safety as a system property
Secrecy is necessary	The need for transparency
The system reacts to needs	Anticipation of needs
Cost reduction is sought	Continuous decrease in waste
Preference is given to professional roles over the system	Cooperation among clinicians

As with the aims for improvement, implementing this entire set of rules in the redesign of health care systems has implications for nursing practice, education, and research. While nursing can be considered in the context of each of the current and new rules, only a few of the rules are discussed here in order to illustrate their relevance to nursing. For example, operationalizing the first new rule, care based on continuous healing relationships, focuses on ensuring that patients have the care they need when they need it. Continuity and coordination should trump fragmented, disconnected care efforts. Conceivably, this rule could directly influence where, how, and when nursing care is available to patients. Moreover, the Internet is likely to play a pivotal role in its application. Another example, the third rule—the patient is the source of control—is designed to facilitate decisionmaking by patients rather than authoritarian or paternalistic decisionmaking by health care providers. While often considered in the context of physician-patient communication, this rule has implications for the approaches nurses bring to patient engagement. However, in addition to individual nurse efforts to incorporate this orientation into patient care, major system-level changes will be needed to allow patients to exercise their preferred degree of control. Such system-level redesign, particularly as it relates to nurse-patient interactions, will benefit from nursing input.

Regarding new rule four, shared knowledge and free flow of information, *Quality Chasm* cited evidence that giving patients access to their own health and clinical information improves care processes and health outcomes. Clearly, electronic personal health records and Web-based information have considerable potential to enhance patient knowledge and stimulate healthy behavior. However, there is limited information about how nurses can help patients to fully harness these information resources. Nurses can lead efforts to make these rules actionable across health systems, particularly as they influence the redesign of nursing practice, the nurse-patient relationships, the relationships between nurses and other disciplines, and the relationship of nurses to care processes. Additionally, these expectations should be incorporated into nursing curricula to ensure that nurses are able to engage and support the refinement and application of important features of redesigned health care systems. In the process, nurses learn not just the changes necessary for improving quality of care, but also the skills and knowledge essential to fully participate in the change process associated with quality improvement efforts.

Deploying these rules requires the participation of virtually all stakeholders. Nursing is clearly a key partner in the convening of health profession associations as well as key industry and quality organization representatives to lead this transformation, expand the research underlying the rules, and develop an agenda to examine progress and next steps related to actions supporting the application of this rules set. A total of 7 years has passed since the release of the

Quality Chasm report. No doubt progress in health care redesign vis-à-vis the rules set has occurred during this time. However, there is considerably more work to be done in each of these areas.

Health Professions Education: A Bridge to Quality

Much of the national discussion about the health workforce, particularly nursing, has focused primarily on supply strategies to address current and anticipated workforce shortages. However, from a quality improvement perspective, there is also an imperative to focus on the capacity of the health care workforce to function in redesigned care systems. The purpose of the health care system articulated earlier will not be attained without significant attention to determining and disseminating the requisite skills and knowledge across the health care workforce. *Health Professions Education: A Bridge to Quality*[8] delineated the needed transformation skills and knowledge of the various health professions. As with predecessor reports, the call for change is clear and direct, beginning with the statement, "Education for the health professions is in need of a major overhaul"[8] (p. 1). This assertion and the subsequent observations and recommendations apply to all health professions, including nursing.

The *Health Professions Education* report described the shortcomings of today's health professions education programs. Among these shortcomings was the need for individuals to work effectively in interdisciplinary teams—something for which they rarely receive training. That is, "patients and families commonly report that caregivers appear not to coordinate their work or even to know what each other is doing"[8] (p. 31). This concern is particularly disconcerting given the increase in chronic disease burden and the clear necessity for collaboration across settings and provider types to meet the needs of patient populations. Another all-too-common educational shortcoming is the lack of an educational foundation in informatics. Future clinical practice will occur in health information technology-rich environments, in spite of the current slow uptake of information technology.[8]

The vision advanced in *Health Professions Education* stated, "All health professionals should be educated to deliver patient-centered care as members of an interdisciplinary team, emphasizing evidence-based practice, quality improvement approaches, and informatics"[8] (p. 45). Yet gaps exist between the needs and expectations for the workforce in health care environments and the preparation of those professionals in academic environments. This disconnect is highly problematic because, "At the core of a redesigned health care system are health professionals"[8] (p. 37). Attention to the educational preparation of the health professions workforce is essential to the meaningful engagement of the entire quality agenda.

New Competencies for Health Professionals

The set of five competencies reflected in the vision statement are considered highly applicable to all health care disciplines, including nursing, although the manner in which they are operationalized by each discipline will vary. As with some of the rules for redesign presented in the *Quality Chasm* report, the evidence base underlying some of these competencies is incomplete and additional research is needed. Where research findings are limited, expert rationale for the competency is provided.

- **Competency 1—Provide patient-centered care**

The report noted that patient-centered care includes knowledge of shared responsibility between patients and caregivers; communication approaches that allow patient access to information and achieve patient understanding; consideration of patients' individuality, values, and needs; and focus on the use of related population-based strategies to improve appropriate use of health services. The *Health Professions Education* report cites research related to some of these characteristics. For example, findings indicated that patients who were involved in decision making about their care have higher functional status, better outcomes, and lower costs.[8]

Additionally, health systems need to be analyzed to determine the extent to which the systems facilitate or constrain the deployment of skills and knowledge associated with this competency.

- **Competency 2—Work in interdisciplinary teams**

Interdisciplinary teams have been shown to enhance quality and lower costs. Substantially more research is needed to determine characteristics that facilitate team effectiveness, as well as the development of successful academic models capable of teaching and testing these performance attributes. Challenging the development of interdisciplinary educational content and the use of this competency in practice is the absence of a common language across disciplines, politics, and turf battles among the professions. Berwick captured the essence of interdisciplinary practice in a statement he offered in the development of the *Health Professions Education* report when he said[8] (p. 56), "System-mindedness means cooperation…. It means asking yourself … not what are the parts of me, not what do I do, but what am I part of?" For health professions educators, including nursing faculty, a corollary may be how do we help students acquire knowledge about their chosen profession as well as knowledge about how to effectively function in interprofessional teams of which they are destined to become part? Questions for nurse educators include how well are we instilling this competency in students and, how do we know?

Interdisciplinary approaches to research on the set of five competencies may be viewed as too challenging to build in academic environments. Yet it may be in this confluence of ideas, philosophies, and approaches that nurse researchers and others are better able to understand, test, and design interdisciplinary practices. In fact, the hard work of interdisciplinary practice may best be modeled through interdisciplinary education and research efforts that begin in academic environments. The culture of many academic environments, however, does not yet value the production of interdisciplinary education or research partnerships.

- **Competency 3—Employ evidence-based practices**

The IOM describes evidence-based practice as the integration of research evidence, clinical expertise, and patient values in making decisions about the care of individual patients. Each of these sources may be contributing factors relevant to decision making regarding patient care. In terms of the implications of this competency for nurses, the report indicated that the following knowledge and skills were necessary: knowing how to find the best sources of evidence, formulating clear clinical questions, and determining when and how to integrate new findings into practice. This knowledge requires bridging content between traditional nursing research courses and clinical courses. The *Health Professions Education* report noted that the evidence base for nursing and other disciplines is markedly limited, and the availability of data that captures information around nursing interventions in administrative and clinical records for research purposes is minimal. Some nurse researchers and nursing organizations are playing pivotal roles in attempting to address this deficit.

- **Competency 4—Apply quality improvement**

The science of quality improvement is expanding rapidly, and the competency of nurses to apply this science is important. Through academic and continuing education opportunities, nurses need to be competent in measuring quality of care, assessing and benchmarking practices to identify improvement opportunities, designing and testing interventions, identifying hazards and errors in care, implementing safety design principles such as standardization and human factors training, and participating as a member of interdisciplinary teams[8] (p. 59). A major challenge is the lack of quality improvement content expertise across faculty. Deans, other administrators, and faculty leaders need to focus on acquiring this expertise for their faculty as well as incorporating it into nursing education curricula, including clinical coursework.

- **Competency 5—Utilize informatics**

Health care informatics relates to the application of information technology (IT) systems to problems in health care and includes an array of applications from order entry to decision support systems. Research findings indicate that IT applications can enhance patient safety by standardizing, flagging errors, and eliminating handwritten data, among other functions.[8] Utilizing informatics can influence knowledge management, communication, and decisionmaking. Educational programming to target facets of this competency have increased in health care environments as well as in academic programs. However, considerable work remains to be done to prepare nurses to fully harness informatics to ensure safety and enhance care quality. Not the least of this work is the analysis of environmental attributes that contribute to successful informatics applications.

Much work remains in terms of teaching the five competencies in nursing education programs, applying the competencies in nursing practice, and focusing on the competencies through nursing research.

The *Health Professions Education* report gives extensive consideration to the purposes and limitations of accreditation, certification, and licensure and the relationship of these oversight processes to clinician competence and patient outcomes. Currently, most of these oversight processes do not address nurses' knowledge of any of the five competency areas. As with other disciplines, actually demonstrating competency is generally not part of the ongoing oversight of individual nurses. This report suggested that hard work on the part of oversight bodies (e.g., developing assessment tools) must be done to assure the public that nurses maintain minimum levels of competence throughout their careers.[8]

There is tremendous pressure on academic programs to ensure that students acquire other essential core content, making the addition of expectations such as those expressed in *Health Professions Education* difficult to accommodate. Nevertheless, the case is made. The inadequacy of educational preparation is reflected in the lack of skills and knowledge applied in current nursing practice. This report asserts, "The extent to which health professionals are implementing these competency areas does not meet the health care needs of the American public"[8] (p. 67).

Quality Through Collaboration: The Future of Rural Health

The last IOM report presented in this section addressed the unique circumstances of rural health care—rural populations and characteristics that influence the quality of rural health care. Based on a review of research findings as well as expert opinion, a number of specific recommendations are offered that build on rural health strengths and address their challenges. The IOM's *Quality Through Collaboration: The Future of Rural Health* highlighted a conclusion

important to nurses and others: that is, there is a paucity of research available on the quality of rural health care. As with urban health care, the limited rural research that does exist indicates variability of care quality.[11] This circumstance underscores the need for nurses and others with interest and expertise in rural health to further expand knowledge in this largely ignored area. One particular area needing nursing inquiry is the extent to which rural health care delivery reflects activity and progress toward achieving the six aims for improvement.

A unique contribution of the *Future of Rural Health* report is the application of the six aims to improve not just care quality delivered in health care organizations, as has been discussed in earlier reports, but also to target efforts that can improve the quality of health in the general population. Nurses in rural communities can be pivotal in helping to build a local community focus on both the quality of health and the quality of health care. The report provides illustrative examples of the application of each of the six aims and community level interventions to achieve those aims. Much of the work of targeting efforts toward improving the quality of population health will involve nurses and other leaders in rural health care settings working with community leaders in local schools, government, and other sectors. How to effectively engage this collective focus to advance population health should be a priority research area.

As with most of the reports in the IOM Quality Chasm series, the theme of leadership emerged in *The Future of Rural Health*. In this case, particular attention is given to the need for rural health system leaders to embrace and drive quality improvement within their organizations as well as the need to engage larger issues of population health quality. An identified strength of many rural communities is the familiarity that people have with each other and the various local community sectors. Also, often typical of rural communities is the orientation and practice of engaging across sectors to achieve community-level outcomes. This characteristic can help to facilitate new efforts around building quality into population health.[11]

The *Future of Rural Health* report pivots from the major components of the *Crossing the Quality Chasm* report and frames the issues in a rural context. For example, priority issues such as information technology applications, quality improvement infrastructure components, workforce considerations, and the aims for improvement are all viewed through the prism of a rural context. In addition, *The Future of Rural Health* cited relevant rural examples of each of the six aims, considering them in the context of the community as well as the context of health care delivery. Measures of the safety aim included measuring community characteristics such as occupational accident rates in rural areas and toxic environmental exposure/risk from pesticides. Brief discussions focused on community-level strategies for improving safety, effectiveness in community health improvement, and community-centered care that reflects responsiveness to the aggregated needs, values, and other characteristics of the local community. Clearly, the broadened application of the six aims for improvement in a rural community context offers an area for research and reconfigured interdisciplinary efforts that include stakeholders outside of traditional health care settings. The community-level application of the six aims, revamped to consider unique characteristics of urban areas, also should be highly relevant to urban communities and populations.

Too frequently, research conducted on quality and safety interventions in urban health care settings has been directly generalized to the often very different environments, staffing mix, and patient populations found in rural health care settings. For example, deploying rapid response teams in rural areas needs to take into consideration the different staff mix available on site in rural settings. Relevant research on functions common to rural health care settings is extremely limited. For example, there is minimal nursing research on the processes involved in patient

stabilization and transfer. This is a set of activities common to rural hospitals but far less frequently performed in urban hospitals. Research on patient outcomes associated with these processes is virtually nonexistent. More efforts need to be directed toward developing and determining relevant rural knowledge and tools, appropriate performance measures, and the development of data feedback capabilities. To begin to fill knowledge gaps and improve health care quality and population health, access to the science of quality improvement and acquiring related expertise is pivotal. This includes acquiring competence in evaluating, adopting, and adapting this new knowledge area for application in rural environments.[18]

In addition to identifying gaps in research knowledge and new framing of aims for application to quality improvement in rural population health, the *Future of Rural Health* report also addressed internal and external drivers of quality improvement specific to rural health systems. For example, unlike most urban hospitals, which are reimbursed through the prospective payment system, a large subset of rural hospitals are designated as critical access hospitals. These hospitals receive cost-based reimbursement, and there are currently no requirements linking Medicare payment to reporting on quality indicators, as is the case with prospective payment system hospitals. The report states that no providers, rural or urban, should be excluded from public reporting. However, mechanisms for linking cost-based reimbursement to quality indicators and eventually patient outcomes need to be developed for rural health care facilities. Additionally, determining how best to report and assign meaning to data extracted from small numbers of patient encounters remains a challenge.

In terms of drivers internal to rural health care settings, the job design of nurse leaders typically requires them to manage multiple roles and expectations. For example, frequently, the nurse responsible for quality assurance and improvement in a facility carries many other responsibilities as well. Given the limited numbers of nurses and other personnel in rural communities, efficiently acquiring and applying quality improvement knowledge and related skills can be particularly challenging. Conversely, because health care providers tend to be relatively few in number, information and new care approaches are often rapidly diffused throughout small rural facilities.

The report devoted significant attention to characteristics essential to the rural health care workforce. Building on the *Health Professions Education* report, *The Future of Rural Health* noted that the five identified competencies are all relevant to rural health care, but the applications may be different. Interdisciplinary teams may consist of individuals geographically separated, but who share involvement in the ongoing care of individuals. Electronic intensive care units are an example. Under these circumstances, applying team concepts may have special ramifications for nurses and others. While research findings from some of these practices indicated markedly improved patient morbidity and mortality, there was virtually no research base on which to guide the configuration and deployment of these types of teams.

The Future of Rural Health also advocated for educational preparation that includes rural-relevant practice knowledge and rural clinical experience. The role of rural consumers in acquiring quality care is also discussed, with attention given to the fact that their role in managing their health may be operationalized differently compared to their urban counterparts given resource availability, etc. For example, access to certain clinicians, including home health nurses and diabetes nurse educators, may be enabled through Web and other technology applications. Yet minimal study of the quality of these encounters has been undertaken. Although technology offers the promise of linking sparsely populated areas to health care services, there is a digital divide between rural and urban areas across the country. To the extent

that electronic connectivity is essential for care continuity, special effort needs to be made to overcome these challenges. Public policy is and will continue to play a major role in bridging this divide, offering nurses another area to engage in issues concerning rural access to quality health care.

Future Directions

In summary, the Quality Chasm series of reports emphasized a number of key attributes of the architecture needed to build a safe, consistently high-performing health care system. Expressed throughout the reports were serious concerns about the status of contemporary health care. Essential features of high-quality care systems—such as workforce competencies, effective application of internal and external drivers, progress toward achieving the six identified aims for improvement, and the application of a set of rules to systems redesign—are far from where they should be. The Quality Chasm series called for leadership in education, practice, and research to drive needed change. The series called for major overhaul of not just the organizations in which health care providers work, but the education of health care providers themselves. The series made a special effort to recognize the unique needs of specific populations, such as those in rural communities or those with mental health problems, and recommended approaches to more effectively deliver quality care to those populations. Based on the challenges and recommendations set forth, it is clear that significant work remains to be done.

Specific to the nursing profession, nurse educators, clinicians, and researchers need to help build state-of-the-art and state-of-the-science approaches for redesigning nursing care processes, using information technology between nurses and patients and nurses and other clinicians; acquiring, managing, and appropriately applying new knowledge and skills; preparing nurses to function effectively in teams; and evaluating nurses' performance in this regard. Regardless of the settings in which nurses practice, much more effort must be devoted to care coordination for individuals with chronic conditions, while diligently measuring both performance and outcomes. Nurses have a substantive and essential role in helping to apply the quality framework articulated in the IOM Quality Chasm series. And nurses clearly have a role in developing additional approaches and new features to the quality agenda. Active engagement in patient safety and quality improvement efforts is relevant to all nurses. Unlike the minimal progress from Nightingale's time until now, hopefully future nurses will be able to reflect back to the beginning of the 21st century and determine that nursing made significant strides. They will see improvement in both the quality of health and health care quality due to an improved role of nurses in providing quality care.

Research Implications

Every report in the Quality Chasm series calls for specific, targeted research to further develop the evidence base related to quality care. Research targeting quality improvement has been supported and implemented by various stakeholders, ranging from health profession organizations to Federal agencies to health providers themselves. Findings and implications are being applied in a variety of ways, from changing internal drivers of quality such as work structure (e.g., rapid response teams) to altering external drivers of quality (e.g., paying providers for performance based on evidence-based quality indicators). While nurses have been part of many of the research activities, significant research remains to be done.

The following is a compilation of some of the exemplar areas of research derived from the four reports reviewed in this section. These research areas are both relevant to nursing and are areas for which nursing's contribution is important.

- The role of leaders in addressing errors and designing safety and quality into health care systems is a common thread throughout the IOM Quality Chasm report series. Currently, the work design of practice in clinical settings introduces significant potential for executing unsafe actions. This is particularly relevant to nursing, given that much of the care delivered in health systems is nursing care.

  Research Focus: Identify how to effectively lead, design, test, and change safety structures and processes in health systems, in addition to researching the safety of structures and processes themselves (e.g., effective strategies for teaching and achieving consistent application of the Situation-Background-Assessment-Recommendation [SBAR] model of communication.) Research is needed that continues the work of determining high-risk structures, functions, and processes in various types of health care delivery settings, focusing on ways to make unsafe nursing activity and practices extremely difficult to carry out (e.g., identify potentially unsafe work-arounds). Design research to test the effectiveness of simulated team approaches to care processes that move beyond established simulations, such as responding to cardiac arrest.

- Public, standardized reporting of serious medical errors is recommended, and a number of States have implemented error reporting systems. Recently, Federal legislation related to reporting errors has been enacted.

  Research Focus: Policy research should determine effective means for conveying public information in ways that facilitate consumer choice of care settings and drive quality improvement at the level of care delivery.

- Encourage health care consumers to actively participate in ensuring the delivery of safe care.

  Research Focus: Determine effective strategies to inform and engage consumers in ways that help ensure their receipt of safe, high-quality care. Nurses, working with other stakeholders such as insurers and employers, should test messages and delivery structures designed to ensure that consumers receive safe care; for example, develop strategies for consumers to use when (1) querying clinicians about self-care processes, (2) making informed choices about health care interventions, (3) designing Web-based support groups for geographically dispersed consumers with chronic conditions.

- Using external factors such as paying for quality performance can drive quality improvement. Examples exist of health systems that have tested the intervention of using payment incentives to improve performance (e.g., Premier demonstration project funded by the Centers for Medicare & Medicaid Services).

  Research Focus: Successful pay-for-performance models should be replicated. To facilitate this initiative, research that isolates nursing characteristics contributing to performance improvement will be useful to informing dissemination and efficient adoption of these models.

- Creating learning environments is a prerequisite to systemwide delivery and improvement of care quality.

  Research Focus: Test approaches to construct and sustain organizational cultures oriented toward safe and high-quality care. This focus includes altering power gradients in clinical settings to ensure free flow of information and testing approaches to educating teams of health profession students in academic settings to maximize communication, problem identification, and systemwide corrections.

- Even when evidence exists regarding effective approaches to care delivery, this information is not consistently applied.

Research Focus: Research is needed to determine communication approaches and incentives that encourage behavior change and the adoption of evidence-based approaches to nursing care.

- The Quality Chasm report series proposes a set of new rules to guide health care systems, including rules such as the need for transparency, anticipation of patient needs, and the patient as the source of control.

Research Focus: More research is needed to assist with effective application of each of the new rules. For example, nurse researchers could consider how to restructure care relationships and processes to determine how to move from a system that reacts to patient needs to one that anticipates patient needs.

- Population-centered care is a concept central to *The Future of Rural Health*: In this report the six aims for improvement discussed in many of the other IOM reports were considered in a population rather than a health care system context. However, an evidence base needs to be developed to better understand how to construct this concept for the purpose of improving health and health care.

Research Focus: Significant research is needed to understand possible benefits as well as clarify population-centered care as a means to improve population health. A key area of focus is to determine how to effectively engage rural stakeholders—community leaders, educational leaders, and representatives from other sectors—to achieve measurable improvements in population health. Additionally, inquiry regarding the extent to which rural health care delivery systems reflect progress toward achieving the six aims for improvement is very limited. For example, minimal research exists on the process of patient stabilization and transfer from rural hospital emergency rooms to other facilities, and yet this is a common function of many rural facilities.

- *The Future of Rural Health* discusses the importance of linking facilities and providers across geographic distances as a means to build efficient quality improvement infrastructure. Connecting clinicians using IT to provide access to locally unavailable care has been implemented in terms of telemental health, e-Intensive Care, and other IT-based services.

Research Focus: Patient outcomes associated with some technology-based interventions (e.g., e-intensive care units) have been evaluated, but very little is known about how to guide the configuration and deployment of these virtual teams, the members of which exist at geographic distance from each other. Access to home health nurses, diabetes nurse educators, and others may be enabled through the Web and other technology applications, but the associated costs, patient outcomes, etc., are not yet well established through a body of research. Fairly limited efforts have been undertaken to support these technology-based interventions through payment methods as opposed to time-limited grant funding.

- The *Health Professions Education* report advances five competencies considered essential to the ability of providers to deliver high-quality care.

Research Focus: Educational research is needed to determine how to facilitate learning and adequately assess each of the core competencies in health profession students across disciplines (e.g., utilize evidence-based practices).

Chapter 5. Understanding Adverse Events: A Human Factors Framework

Kerm Henriksen, Elizabeth Dayton, Margaret A. Keyes, Pascale Carayon, Ronda Hughes

Introduction

In addition to putting the spotlight on the staggering numbers of Americans that die each year as a result of preventable medical error, the Institute of Medicine's (IOM's) seminal report, *To Err is Human: Building a Safer Health System*, repeatedly underscored the message that the majority of the factors that give rise to preventable adverse events are systemic; that is, they are not the result of poorly performing individual nurses, physicians, or other providers.[1] Although it was not the intent of *To Err is Human* to treat systems thinking and human factors principles in great detail, it cited the work of many prominent human factors investigators and pointed out the impressive safety gains made in other high-risk industries such as aviation, chemical processing, and nuclear power. One of the beneficial consequences of the report is that it exposed a wide audience of health services researchers and practitioners to systems and human factors concepts to which they might not otherwise have been exposed. Similarly, the report brought to the attention of the human factors community serious health care problems that it could address. Today, both health care and human factors practitioners are venturing beyond their own traditional boundaries, working together in teams, and are benefiting from the sharing of new perspectives and clinical knowledge. The purpose of the present chapter is to further this collaboration between health care and human factors, especially as it is relevant to nursing, and continue the dialog on the interdependent system factors that underlie patient safety.

Human Factors—What Is It?

The study of human factors has traditionally focused on human beings and how we interact with products, devices, procedures, work spaces, and the environments encountered at work and in daily living.[2] Most individuals have encountered a product or piece of equipment or a work environment that leads to less than optimal human performance. If human strengths and limitations are not taken into account in the design process, devices can be confusing or difficult to use, unsafe, or inefficient. Work environments can be disruptive, stressful, and lead to unnecessary fatigue. For those who like comprehensive, formal definitions, consider the following, adapted from Chapanis and colleagues:[3]

> Human factors research discovers and applies information about human behavior, abilities, limitations, and other characteristics to the design of tools, machines, systems, tasks, and jobs, and environments for productive, safe, comfortable, and effective human use.

This definition can be simplified as follows:

> Human factors research applies knowledge about human strengths and limitations to the design of interactive systems of people, equipment, and their environment to ensure their effectiveness, safety, and ease of use.

Such a definition means that the tasks that nurses perform, the technology they are called upon to use, the work environment in which they function, and the organizational policies

that shape their activities may or may not be a good fit for their strengths and limitations. When these system factors and the sensory, behavioral, and cognitive characteristics of providers are poorly matched, substandard outcomes frequently occur with respect to effort expended, quality of care, job satisfaction, and perhaps most important, the safety of patients.

Many nursing work processes have evolved as a result of local practice or personal preference rather than through a systematic approach of designing a system that leads to fewer errors and greater efficiency. Far too often, providers and administrators have fallen into a "status quo trap," doing things simply because they always have been done that way. Human factors practitioners, on the other hand, take into account human strengths and weaknesses in the design of systems, emphasizing the importance of avoiding reliance on memory, vigilance, and followup intentions—areas where human performance is less reliable. Key processes can be simplified and standardized, which leads to less confusion, gains in efficiency, and fewer errors. When care processes become standardized, nurses have more time to attend to individual patients' specialized needs, which typically are not subject to standardization. When medical devices and new technology are designed with the end user in mind, ease of use and error detection or preventability are possible, in contrast to many current "opaque" computer-controlled devices that prevent the provider from understanding their full functionality.

The field of human factors does not focus solely on devices and technology. Although human factors research emerged during World War II as a result of equipment displays and controls that were not well suited to the visual and motor abilities of human operators, each subsequent decade of human factors work has witnessed a broadening of the human performance issues considered worthy of investigation. More recently, a number of human factors investigators with interests in health care quality and safety advocated addressing a more comprehensive range of sociotechnical system factors, including not only patients, providers, the tasks performed, and teamwork, but also work environments or microsystems, organizational and management issues, and socioeconomic factors external to the institution.[4–7] One of the lessons stemming from a systems approach is that significant improvements in quality and safety are likely to be best achieved by attending to and correcting the misalignments among these interdependent levels of care. Managing the system interdependencies of care, as evidenced by continued major breakdowns such as inadequate transitions of patient care, is a major challenge faced by providers and their human factors partners alike.

Understanding Systems

At a very basic level, a system is simply a set of interdependent components interacting to achieve a common specified goal. Systems are such a ubiquitous part of our lives that we often fail to recognize that we are active participants in many systems throughout the day. When we get up in the morning, we are dependent on our household systems (e.g., plumbing, lighting, ventilation) to function smoothly; when we send our children off to school, we are participants in the school system; and when we get on the highway and commute to work, we are participants (and sometimes victims) of our transportation system. At work, we find ourselves engaged simultaneously in several systems at different levels. We might report to work in a somewhat self-contained setting such as the intensive care unit (ICU) or operating room (OR)—what human factors practitioners refer to as microsystems—yet the larger system is the hospital itself, which, in turn, is likely to be just one facility in yet a larger health care system or network, which in itself is just one of the threads that make up the fabric of our broader and quite diffuse national health care system. The key point is that we need to recognize and understand the functioning of the many systems that we are part of and

how policies and actions in one part of the overall system can impact the safety, quality, and efficiency of other parts of the system.

Systems thinking has not come naturally to health care professionals.[8] Although health care providers work together, they are trained in separate disciplines where the primary emphasis is the mastery of the skills and knowledge to diagnose ailments and render care. In the pursuit of becoming as knowledgeable and skillful as possible in their individual disciplines, a challenge facing nursing, medicine, and the other care specialties is to be aware of the reality that they are but one component of a very intricate and fragmented web of interacting subsystems of care where no single person or entity is in charge. This is how the authors of *To Err is Human* defined our health system:[1]

> Health care is composed of a large set of interacting systems—paramedic, and emergency, ambulatory, impatient care, and home health care; testing imaging laboratories; pharmacies; and so forth—that are coupled in loosely connected but intricate network of individuals, teams, procedures, regulations, communications, equipment, and devices that function with diffused management in a variable and uncertain environment. Physicians in community practice may be so tenuously connected that they do not even view themselves as part of the system of care.

A well-known expression in patient safety is that *each system is perfectly designed to achieve exactly the results that it gets.* It was made popular by a highly respected physician, Donald Berwick of the Institute of Healthcare Improvement, who understands the nature of systems. If we reap what we sow, as the expression connotes, and given that one does not have to be a systems engineer to understand systems, it makes sense for all providers to understand the workings of the systems of which they are a part. It is unfortunate that today one can receive an otherwise superb nursing or medical education and still receive very little instruction on the nature of systems that will shape and influence every moment of a provider's working life.

Sociotechnical System Models

With a systems perspective, the focus is on the interactions or interdependencies among the components and not just the components themselves. Several investigators have proposed slightly different models of important interrelated system factors, but they all seem to start with individual tasks performed at the point of patient care and then progressively expand to encompass other factors at higher organizational levels. Table 1 shows the similarity among three of these models. In an examination of system factors in the radiation oncology therapy environment, Henriksen and colleagues[4] examined the role of individual characteristics of providers (e.g., skills, knowledge, experience); the nature of the work performed (e.g., competing tasks, procedures/practices, patient load, complexity of treatment); the physical environment (e.g., lighting, noise, temperature, workplace layout, distractions); the human-system interfaces (e.g., equipment location, controls and displays, software, patient charts); the organizational/social environment (e.g., organizational climate, group norms, morale, communication); and management (e.g., staffing, organization structure, production schedule, resource availability, and commitment to quality). Vincent and colleagues[5] also proposed a hierarchical framework of factors influencing clinical practice that included patient characteristics, task factors, individual (staff) factors, team factors, work environment, and organizational and management factors. Carayon and Smith[6] proposed a work system model that is a collection of interacting subsystems made up of people (disciplines) performing tasks using various tools and technology within a physical environment in pursuit of organizational goals that serve as inputs to care processes and ultimately to outcomes for patients, providers,

and the organization alike. The similarity among these independently derived models is quite striking, in that they are all sociotechnical system models involving technical, environmental, and social components.

Table 1. Sociotechnical System Models

Authors	Elements of Model
Henriksen, Kaye, Morisseau 1993[4]	• Individual characteristics • Nature of the work • Physical environment • Human-system interfaces • Organizational/social/environmental • Management
Vincent 1998[5]	• Patient characteristics • Task factors • Individual factors • Team factors • Work environment • Organizational and management factors
Carayon, Smith 2000[6]	• People (disciplines) • Tools and technology • Physical environment • Organizational goals • Care processes

Human Error—A Troublesome Term

While one frequently finds references to human error in the mass media, the term has actually fallen into disfavor among many patient safety researchers. The reasons are fairly straightforward. The term lacks explanatory power by not explaining anything other than a human was involved in the mishap. Too often the term 'human error' connotes blame and a search for the guilty culprits, suggesting some sort of human deficiency or lack of attentiveness. When human error is viewed as a cause rather than a consequence, it serves as a cloak for our ignorance. By serving as an end point rather than a starting point, it retards further understanding. It is essential to recognize that errors or preventable adverse events are simply the symptoms or indicators that there are defects elsewhere in the system and not the defects themselves. In other words, the error is just the tip of the iceberg; it's what lies underneath that we need to worry about. When serious investigations of preventable adverse events are undertaken, the error serves as simply the starting point for a more careful examination of the contributing system defects that led to the error. However, a very common but misdirected response to managing error is to "put out the fire," identify the individuals involved, determine their culpability, schedule them for retraining or disciplinary action, introduce new procedures or retrofixes, and issue proclamations for greater vigilance. An approach aimed at the individual is the equivalent of swatting individual mosquitoes rather than draining the swamp to address the source of the problem.

A disturbing quality in many investigations of preventable adverse events is the hidden role that human bias can play. Despite the best of intentions, humans do not always make fair and impartial assessments of events and other people. A good example is hindsight bias.[9–12] As noted by Reason,[10] the most significant psychological difference between

individuals who were involved in events leading up to a mishap and those who are called upon to investigate it after it has occurred is knowledge of the outcome. Investigators have the luxury of hindsight in knowing how things are going to turn out; nurses, physicians, and technicians at the sharp end do not. With knowledge of the outcome, hindsight bias is the exaggerated extent to which individuals indicate they could have predicted the event before it occurred. Given the advantage of a known outcome, what would have been a bewildering array of nonconvergent events becomes assimilated into a coherent causal framework for making sense out of what happened. If investigations of adverse events are to be fair and yield new knowledge, greater focus and attention need to be directed at the precursory and antecedent circumstances that existed for sharp end personnel before the mishap occurred. The point of investigating preventable adverse health care events is primarily to make sense of the factors that contribute to the omissions and misdirected actions when they occur.[11, 12] This in no way denies the fact that well-intended providers do things that inflict harm on patients, nor does it lessen individual accountability. Quite simply, one has to look closely at the factors contributing to the adverse event and not just the most immediate individual involved.

In addition to hindsight bias, investigations of accidents are also susceptible to what social psychologists have termed the attribution error.[13] Human observers or investigators tend to make a fundamental error when they set out to determine the causal factors of someone's mistake. Rather than giving careful consideration to the prevailing situational and organizational factors that are present when misfortune befalls someone else, the observer tends to make dispositional attributions and views the mishap as evidence of some inherent character flaw or defect in the individual. For example, a nurse who administers the wrong medication to an emergency department (ED) patient at the end of a 10-hour shift may be judged by peers and the public as negligent or incompetent. On the other hand, when misfortune befalls individuals themselves, they are more likely to attribute the cause to situational or contextual factors rather than dispositional ones. To continue with the example, the nurse who actually administered incorrect medication in the ED may attribute the cause to the stressful and hurried work environment, the physician's messily scribbled prescription, or fatigue after 10 intense hours of work.

Pragmatic and System Characteristics

Rasmussen[14] points out the arbitrary and somewhat pragmatic aspects of investigations of human error and system performance. When system performance is below some specified standard, an effort is made to back-track the chain of events and circumstances to find the causes. How far back to go or when to stop are open questions, the answers to which are likely to vary among different investigators. One could stop at the provider's actions and claim medical error, or one could seek to identify other reasons—poor communication, confusing equipment interfaces, lack of standardized procedures, interruptions in the care environment, diffusion of responsibility, management neglect—that may have served as contributing factors. Rasmussen notes that the search for causes will stop when one comes across one or more factors that are familiar (that will therefore serve as acceptable explanations) and for which there are available corrections or cures. Since there is no well-defined start point to which one is progressively working backward through the causal chain, how far back one is willing to search is likely to depend on pragmatic considerations such as resources, time constrains, and internal political ramifications. Rasmussen also observes that some human actions become classified as human error simply because they are performed in unkind work environments; that is, work environments where there is not much tolerance for individual experimentation and where it is not possible for individuals to correct

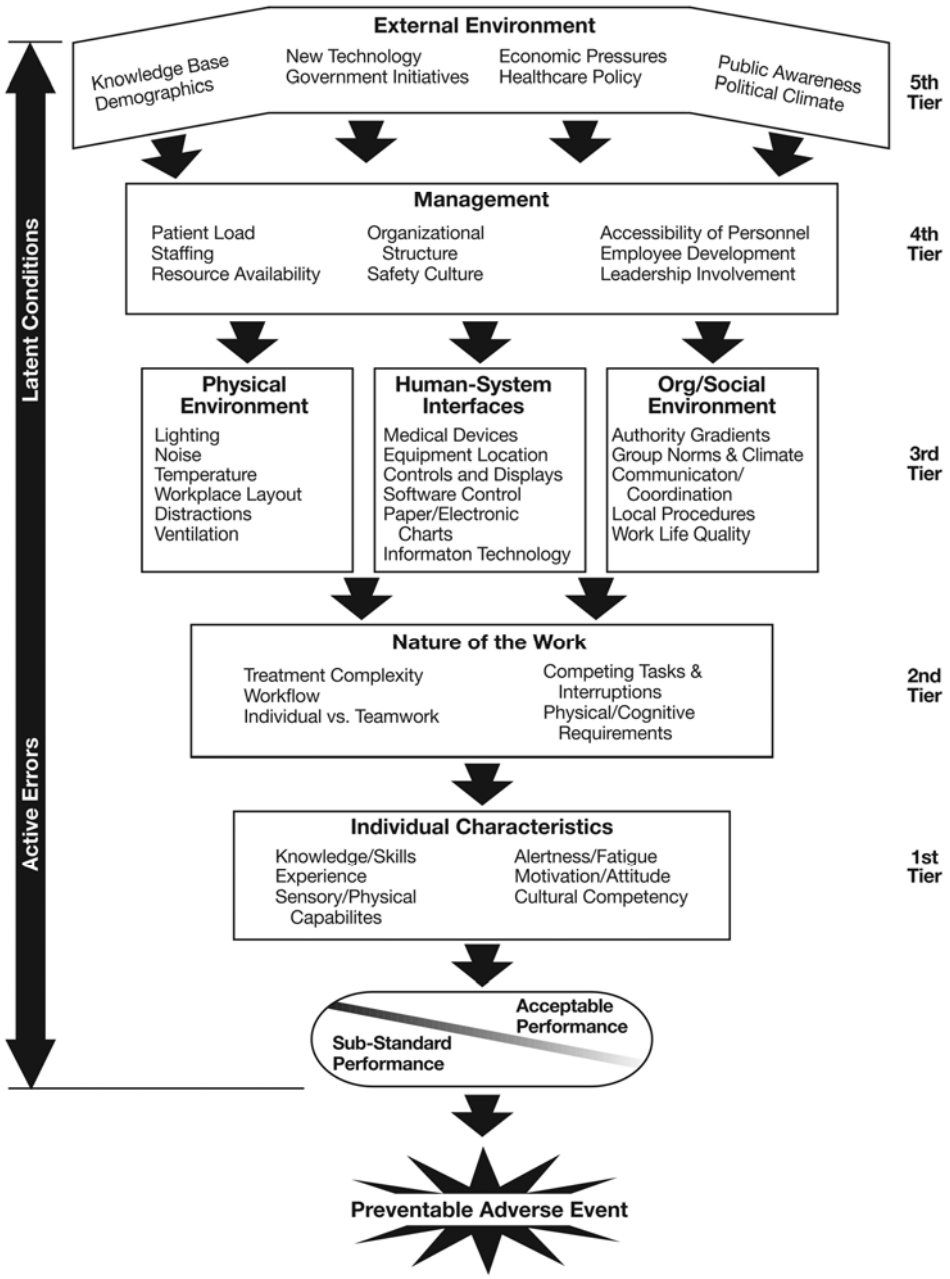
inappropriate actions before they lead to undesirable consequences. In some unkind environments, it may not be possible to reverse the inappropriate actions, while in others it may not be possible to foresee the undesirable consequences. Rasmussen's unkind work environment is quite similar to Perrow's notion of *tightness of coupling* in complex systems.[15]

Perrow's analysis of system disasters in high-risk industries shifts the burden of responsibility from the front-line operator of the system to actual properties of the system. Using the concepts of *tightness of coupling* and *interactive complexity*, Perrow focuses on the inherent characteristics of systems that make some industries more prone to accidents.[15] Tightness of coupling refers to dependencies among operational sequences that are relatively intolerant of delays and deviations, while interactive complexity refers to the number of ways system components (i.e., equipment, procedures, people) can interact, especially unexpectedly. It is the multiple and unexpected interactions of malfunctioning parts, inadequate procedures, and unanticipated actions—each innocuous by themselves—in tightly coupled systems that give rise to accidents. Such accidents are rare but inevitable, even "normal," to use Perrow's terminology. By understanding the special characteristics of high-risk systems, decisionmakers might be able to avoid blaming the wrong components of the system and also refrain from technological fixes that serve only to make the system riskier.

A Human Factors Framework

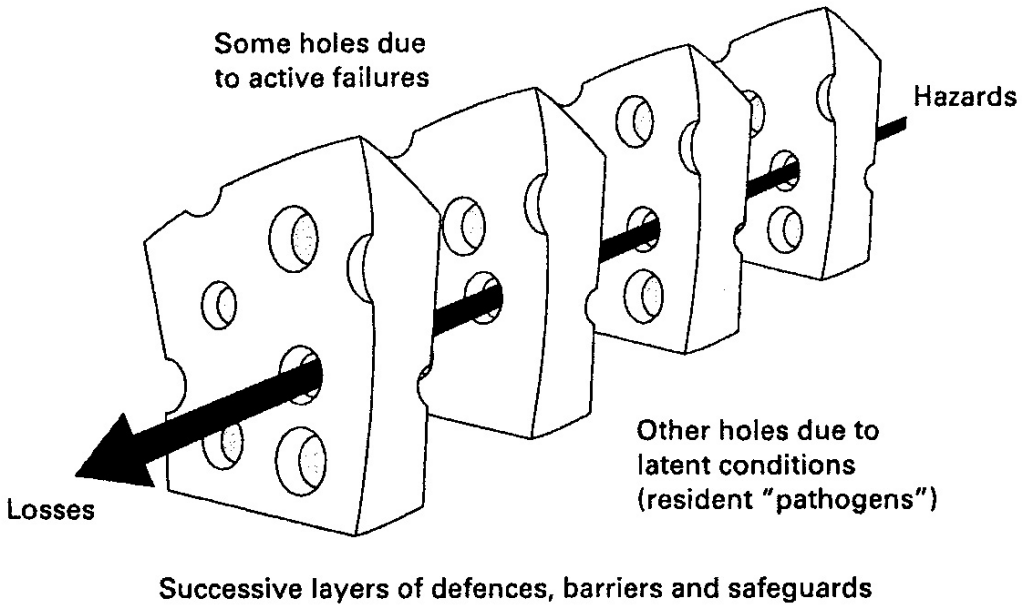
Figure 1 shows many of the components or major factors that need to be addressed to gain a better understanding of the nature of preventable adverse events. What the figure does not portray very well is the way in which these major factors can interact with one another. A basic tenet of any systems approach to adverse events is that changes in one part of the system will surely have repercussions on another part of the system. Hence, it is important to focus on the way these components can interact and influence one another and not just the components themselves. When these components are functioning well together, they serve collectively as a set of barriers or system of defenses to the occurrence of preventable adverse events. However, it is when weaknesses or vulnerabilities exist within these components and they interact or align themselves in such a way that the weaknesses overlap that preventable adverse events occur. This way of describing "holes" that exist in the successive components or layers of defenses has more light-heartedly been dubbed the "Swiss cheese" model of accident causation, made popular by James Reason, a prominent British psychologist who has dramatically influenced the way we think about patient safety.[16] Figure 2 shows the Swiss cheese model of accident causation and how the trajectory of hazards can result in losses or adverse events.

Figure 1. Contributing Factors to Adverse Events in Health Care



In brief, many adverse events result from this unique interaction or alignment of several necessary but singly insufficient factors. Weaknesses in these factors typically are present in the system long before the occurrence of an adverse event. All that is needed is for a sufficient number to become aligned for a serious adverse event to occur.

Figure 2. The "Swiss Cheese" Model of Accident Causation



Source: Reason J, Carthey J, deLeval M. Diagnosing "vulnerable system syndrome": An essential prerequisite to effective risk management. Qual Health Care, 2001; 10(Suppl. II):ii21-ii25. Reprinted with permission of the BMJ Publishing Group.

The distinction made by Reason between *latent conditions* and *active errors*, shown along the left margin of Figure 1, also is very important.[11, 17] In health care, active errors are committed by those providers (e.g., nurses, physicians, technicians) who are in the middle of the action, responding to patient needs at the *sharp end*.[18] Latent conditions are the potential contributing factors that are hidden and lie dormant in the health care delivery system, occurring upstream at the more remote tiers, far removed from the active end. These latent conditions—more organizational, contextual, and diffuse in nature or design related—have been dubbed the *blunt end*.[18] The distinction between latent conditions and active errors is important because it allows us to clearly see that nurses, who have the greatest degree of patient contact, are actually the last line of defense against medical error (and hence the most vulnerable). As such, nurses can inherit the less recognized sins of omission and commission of everyone else who has played a role in the design of the health care delivery system. Reason perhaps makes this point best:[10]

> Rather than being the main instigators of an accident, operators tend to be inheritors of system defects created by poor design, incorrect installation, faulty maintenance and bad management decisions. Their part is usually that of adding a final garnish to a lethal brew whose ingredients have already been long in the cooking.

The human factors framework outlined here allows us to examine a wide range of latent conditions that are part of the health care sociotechnical system in which providers reside.

Individual Characteristics

Figure 1 identifies *individual characteristics* as a first-tier factor that has a direct impact on provider performance and whether that performance is likely to be considered acceptable or substandard. Individual characteristics include all the qualities that individuals bring with them to the job—things such as knowledge, skill level, experience, intelligence, sensory capabilities, training and education, and even organismic and attitudinal states such as alertness, fatigue, and motivation, just to mention a few. The knowledge and skills that health

care providers develop prior to employment through accredited training programs is fundamental to their ability to perform their work. At the same time, organismic factors such as fatigue resulting from long hours and stress can influence the ability of providers to apply their specialized knowledge optimally. Communication ability and cultural competency skills should also be included at this level. Fortunately, few critics would argue that the skills and abilities mentioned here are unimportant in having an impact on optimal health care delivery and outcomes.

The Nature of the Work

The second-tier factor in Figure 1, *the nature of the work*, refers to characteristics of the work itself and includes the extent to which well-defined procedures are utilized, the nature of the workflow, peak and nonpeak patient loads, the presence or absence of teamwork, the complexity of treatments, equipment functioning and downtime, interruptions and competing tasks, and the physical/cognitive requirements for performing the work. Although empirical studies on the impact of these work-related factors in health care settings are not as plentiful as they are in the human factors literature, they indeed exist. For example, a review of the external beam radiation therapy literature[19] found fewer treatment administration errors when therapists worked in pairs[20]and greater numbers of treatment administration errors at the higher patient census levels.[21] If management becomes overly ambitious in directing a high volume of patients to be treated in a fixed period of time, the consequence for radiation therapists is a high-pressure work environment and an increase in the number of adverse events. With respect to the human factors literature, there is an abundance of research on the effects of work-related factors on human performance drawn largely from defense-related operations and that of other highly hazardous industries where proficient human performance plays a critical role.[22–25]

Human-System Interfaces

The *human-system interface* refers to the manner in which two subsystems— typically human and equipment—interact or communicate within the boundaries of the system. This is shown as a third-tier factor in Figure 1. Nurses use medical devices and equipment extensively and thus have plentiful first-hand experience with the poor fit that frequently exists between the design of the devices' controls and displays and the capabilities and knowledge of users. One approach for investigating the mismatches between devices and people is to recognize there is an expanding progression of interfaces in health care settings, each with their own vulnerabilities and opportunities for confusion.[26, 27] Starting at the very center with the patient, a *patient-device interface* needs to be recognized. Does the device or accessory attachment need to be fitted or adapted to the patient? What physical, cognitive, and affective characteristics of the patient need to be taken into account in the design and use of the device? What sort of understanding does the patient need to have of device operation and monitoring? With the increasing migration of sophisticated devices into the home as a result of strong economic pressures to move patients out of hospitals as soon as possible, safe home care device use becomes a serious challenge, especially with elderly patients with comorbidities who may be leaving the hospital sicker as a result of shorter stays, and where the suitability of the home environment may be called into question (e.g., home caregivers are also likely to be aged, and the immediate home environment layout may not be conducive to device use). In brief, the role of the patient in relation to the device and its immediate environment necessitates careful examination. At the same time, the migration of devices into the home nicely illustrates the convergence of several system factors—health care economics,

shifting demographics, acute and chronic needs of patients, competency of home caregivers, supportiveness of home environments for device use—that in their collective interactivity and complexity can bring about threats to patient safety and quality of care.

Providers of care are subject to a similar set of device use issues. Human factors practitioners who focus on the *provider (user)–device interface* are concerned about the provider's ability to operate, maintain, and understand the overall functionality of the device, as well as its connections and functionality in relation to other system components. In addition to controls and displays that need to be designed with human motor and sensory capabilities in mind, the device needs to be designed in a way that enables the nurse or physician to quickly determine the state of the device. Increasing miniaturization of computer-controlled devices has increased their quality but can leave providers with a limited understanding of the full functionality of the device. With a poor understanding of device functionality, providers are at a further loss when the device malfunctions and when swift decisive action may be critical for patient care. The design challenge is in creating provider-device interfaces that facilitate the formation of appropriate mental models of device functioning and that encourage meaningful dialogue and sharing of tasks between user and device. Providers also have a role in voicing their concerns regarding poorly designed devices to their managers, purchasing officers, and to manufacturers.

The next interface level in our progression of interfaces is the *microsystem-device interface*. At the microsystem level (i.e., contained organizational units such as EDs and ICUs), it is recognized that medical equipment and devices frequently do not exist in stand-alone form but are tied into and coupled with other components and accessories that collectively are intended to function as a seamless, integrated system. Providers, on the other hand, are quick to remind us that this is frequently not the case, given the amount of time they spend looking for appropriate cables, lines, connectors, and other accessories. In many ORs and ICUs, there is an eclectic mix of monitoring systems from different vendors that interface with various devices that increases the cognitive workload placed on provider personnel. Another microsystem interface problem, as evidenced by several alerts from health safety organizations, are medical gas mix-ups, where nitrogen and carbon dioxide have been mistakenly connected to the oxygen supply system. Gas system safeguards using incompatible connectors have been overridden with adapters and other retrofitted connections. The lesson for providers here is to be mindful that the very need for an adaptor is a warning signal that a connection is being sought that may not be intended by the device manufacturer and that may be incorrect and harmful.[28]

Yet other device-related concerns are sociotechnical in nature, and hence we refer to a *sociotechnical-device interface*. How well are the technical requirements for operating and maintaining the device supported by the physical and socio-organizational environment of the user? Are the facilities and workspaces where the device is used adequate? Are quality assurance procedures in place that ensure proper operation and maintenance of the device? What sort of training do providers receive in device operation before using the device with patients? Are chief operating officers and nurse managers committed to safe device use as an integral component of patient safety? As health information technology (HIT) plays an increasing role in efforts to improve patient safety and quality of care, greater scrutiny needs to be directed at discerning the optimal and less-than-optimal conditions in the sociotechnical environment for the intelligent and proper use of these devices and technologies.

The Physical Environment

The benefits of a *physical work environment* that is purposefully designed for the nature of the work that is performed have been well understood in other high-risk industries for a

number of years. More recently, the health care profession has begun to appreciate the relationship between the physical environment (e.g., design of jobs, equipment, and physical layout) and employee performance (e.g., efficiency, reduction of error, and job satisfaction). The third tier in Figure 1 also emphasizes the importance of the physical environment in health care delivery.

There is a growing evidence base from health care architecture, interior design, and environmental and human factors engineering that supports the assertion that safety and quality of care can be designed into the physical construction of facilities. An extensive review by Ulrich and colleagues[29] found more than 600 studies that demonstrated the impact of the design of the physical environment of hospitals on safety and quality outcomes for patients and staff. A diverse range of design improvements include better use of space for improved patient vigilance and reduced steps to the point of patient care; mistake proofing and forcing functions that preclude the initiation of potentially harmful actions; standardization of facility systems, equipment, and patient rooms; in-room placement of sinks for hand hygiene; single-bed rooms for reducing infections; better ventilation systems for pathogen control; improved patient handling, transport, and prevention of falls; HIT for quick and reliable access to patient information and enhanced medication safety; appropriate and adjustable lighting; noise reduction for lowering stress; simulation suites with sophisticated mannequins that enable performance mastery of critical skills; improved signage; use of affordances and natural mapping; and greater accommodation and sensitivity to the needs of families and visitors. Reiling and colleagues[30] described the design and building of a new community hospital that illustrates the deployment of patient safety-driven design principles.

A basic premise of sound design is that it starts with a thorough understanding of user requirements. A focus on the behavioral and performance requirements of a building's occupants has generally been accepted in architecture since the early 1970s.[31–33] Architects have devised methods—not dissimilar to function and task analysis techniques developed by human factors practitioners—that inventory all the activities that are performed by a building's occupants as well as visitors. Table 2 lists just a small sample of questions that need to be asked.[34, 35]

Table 2. Determining Activities Performed by Building Occupants and Visitors

• Who will be using the facility? • What are the characteristic activities of user groups? • What can be learned about the extent, time of occurrence, and duration of anticipated activities?
• What are the relationships and exchanges between building dwellers and visitors? • How many people will be moving about within the facility, for what purpose, and how frequently? • What are the demographics (e.g., age, gender) and special characteristics of building users?
• What user groups require special equipment, fixtures, furnishings, placement, signage, safety features, and security components?
• What spaces are needed to support user activities? • What special provisions are needed in these spaces to ensure safety and quality of the services rendered? • How can the spaces be designed to facilitate human performance on the required tasks?

• What are the recommended circulation patterns for facilitating information, equipment, and supply flow between spaces? • What are the design provisions for advances in health information technology? • What space adjacency requirements exist?
• What provisions with respect to user groups need to be made for temperature, humidity, ventilation, illumination, noise, distraction, hazards, and climatic conditions?

Given the vast amounts of time spent on hospital units and the number of repetitive tasks performed, nurses as an occupational group are especially sensitive to building and workplace layout features that have a direct bearing on the quality and safety of care provided. When designing workplaces in clinical settings, human capabilities and limitations need to be considered with respect to distances traveled, standing and seated positions, work surfaces, the lifting of patients, visual requirements for patient monitoring, and spaces for provider communication and coordination activities. Traveling unnecessary distances to retrieve needed supplies or information is a waste of valuable time. Repetitious motor activity facilitates fatigue. Information needed by several people can be made easily accessible electronically, communication and coordination among providers can be maximized by suitable spatial arrangements, and clear lines of sight where needed can be designed for monitoring tasks.

At the time of this chapter's writing, the U.S. hospital industry is in the midst of a major building boom for the next decade, with an estimated $200 billion earmarked for new construction. Nursing has an opportunity to play a key role in serving on design teams that seek to gain a better understanding of the tasks performed by provider personnel. By employing the accumulating evidence base, hospitals can be designed to be more effective, safe, efficient, and patient-centered. Or they can be designed in a way that repeats the mistakes of the past. Either way, the physical attributes that hospitals take will impact the quality and safety of health care delivery for years to come.

Organizational/Social Environment

As shown in the third tier of Figure 1, the organizational/social environment represents another set of latent conditions that can lie dormant for some time; yet when combined with other pathogens (to use Reason's metaphor[10]), can thwart the system's defenses and lead to error. Adverse events that have been influenced by organizational and social factors have been poorly understood due, in large part, to their delayed and dormant consequences. These are the omnipresent, but difficult to quantify factors—organizational climate, group norms, morale, authority gradients, local practices—that often go unrecognized by individuals because they are so deeply immersed in them. However, over time these factors are sure to have their impact.

In her analysis of the *Challenger* disaster, Vaughn[36] discovered a pattern of small, incremental erosions to safety and quality that over time became the norm. She referred to this organizational/social phenomenon as *normalization of deviance*. Disconfirming information (i.e., information that the launch mission was not going as well as it should) was minimized and brought into the realm of acceptable risk. This served to reduce any doubt or uneasy feelings about the status of the mission and preserved the original belief that their systems were essentially safe. A similar normalization of deviance seems to have happened in health care with the benign acceptance of shortages and adverse working conditions for nurses. If a hospital can get by with fewer and fewer nurses and other needed resources without the occurrence of serious adverse consequences, these unfavorable conditions may

continue to get stretched, creating thinner margins of safety, until a major adverse event occurs.

Another form of organizational fallibility is the *good provider fallacy*.[37, 38] Nurses as a group have well-deserved professional reputations as a result of their superb work ethic, commitment, and compassion. Many, no doubt, take pride in their individual competence, resourcefulness, and ability to solve problems on the run during the daily processes of care. Yet, as fine as these qualities are, there is a downside to them. In a study of hospital work process failures (e.g., missing supplies, malfunctioning equipment, incomplete/inaccurate information, unavailable personnel), Tucker and Edmondson[39] found that the failures elicited work-arounds and quick fixes by nurses 93 percent of the time, and reports of the failure to someone who might be able to do something about it 7 percent of the time. While this strategy for problem-solving satisfies the immediate patient care need, from a systems perspective it is sheer folly to focus only on the first-order problem and do nothing about the second-order problem—the contributing factors that create the first-order problem. By focusing only on first-order fixes or work-arounds and not the contributing factors, the problems simply reoccur on subsequent shifts as nurses repeat the cycle of trying to keep up with the crisis of the day. To change this shortsightedness, it is time for nurse managers and those who shape organizational climate to value some new qualities. Rather than simply valuing nurses who take the initiative, who roll with the punches while attempting quick fixes, and who otherwise "stay in their place," it is time to value nurses who ask penetrating questions, who present evidence contrary to the view that things are alright, and who step out of a traditionally compliant role and help solve the problem-behind-the-problem. Given the vast clinical expertise and know-how of nurses, it is a great loss when organizational and social norms in the clinical work setting create a culture of low expectations and inhibit those who can so clearly help the organization learn to deliver safer, higher quality, and more patient-centered care.

Management

Conditions of poor planning, indecision, or omission, associated with managers and those in decisionmaking positions, are termed latent because they occur further upstream in Figure 1 (tier four), far away from the sharp-end activities of nurses and other providers. Decisions are frequently made in a loose, diffuse, somewhat disorderly fashion. Because decisionmaking consequences accrue gradually, interact with other variables, and are not that easy to isolate and determine, those who make organizational policy, shape organizational culture, and implement managerial decisions are rarely held accountable for the consequences of their actions. Yet managerial dictum and organizational practices regarding staffing, communication, workload, patient scheduling, accessibility of personnel, insertion of new technology, and quality assurance procedures are sure to have their impact. As noted earlier, providers are actually the last line of defense, for it is the providers who ultimately must cope with the shortcomings of everyone else who has played a role in the design of the greater sociotechnical system. For example, the absence of a serious commitment to higher quality and safe care at the management level is a latent condition that may become apparent in terms of adverse consequences only when this "error of judgment" aligns itself with other system variables such as overworked personnel, excessive interruptions, poorly designed equipment interfaces, a culture of low expectations, and rapid-paced production schedules for treating patients.

Compared to providers, managers and decisionmakers are much better positioned to actually address the problems-behind-the-problem and be mindful of the interdependencies of care. Managers and decisionmakers have the opportunity to work across organizational units

of care and address the discontinuities. With perhaps a few exceptions, there is very little evidence that managers and leaders actually spend much time in attending to the complex interdependencies of care and areas of vulnerability in their institutions. While they may not have the same clinical know-how as sharp end personnel, they certainly have the corporate authority to involve those with clinical expertise in needed change efforts. Thus, a new role for health care leaders and managers is envisioned, placing a high value on understanding system complexity and focusing on the interdependencies—not just the components.[38] In this new role, leaders recognize that superb clinical knowledge and dedication of providers is no match for the toll that flawed and poorly performing interdependent systems of care can take. In brief, they aim to do something about the misalignments.

The External Environment

Lest it seem that the authors are being a bit harsh on management, it needs to be recognized that there are external forces exerting their influence at this level. From a systems perspective, one must not simply repeat the blame game and lay all the responsibility for health care delivery problems at the feet of management. Health care is an open system, and, as shown in Figure 1, each system level subsumes lower systems and gets subsumed by higher systems in return. Subsuming the management level and the more distal downstream levels is the external environment, which perhaps is best portrayed as a shifting mosaic of economic pressures, political climates and policies, scientific and technological advancements, and changing demographics. For those that toil at the sharp end, these diffuse, broad-based, and shifting forces may seem less relevant because of their more remote or indirect impact. While this is understandable, the impact of these forces is undeniable. The external environment influences patient safety and quality of care by shaping the context in which care is provided. A salient characteristic of our dynamic 21st-century society is that these external forces are stronger and change more frequently than ever before.[7] For providers and health care decisionmakers to stay ahead of these forces (rather than getting rolled over by them) and gain more proactive leverage to help shape the ensuing changes, it is first necessary to gain a better understanding of the external forces that are operating.

Not only is the scientific foundation of nursing and medicine expanding significantly (e.g., consider advances in genomics, neuroscience, immunology, and the epidemiology of disease), there is a corresponding need to master different procedures associated with new drug armamentariums, new imaging technologies, and new minimally invasive surgical interventions.[40] The groundwork is currently being laid for pay-for-performance to become a reality in the near future. Safety, efficiency, and high-quality care will serve as a basis for medical reimbursement, not just services rendered, as is currently the case. Two demographic trends are converging causing serious alarm. Nursing, as a profession, continues to experience shortages and discontent just as an aging baby boom population with a plethora of chronic and acute care needs starts to occupy a wide range of care settings. Medical practice has been steadily shifting from inpatient to outpatient settings. Economic incentives to move patients out of hospitals as soon as possible continue, and as noted earlier, there is a concurrent migration of sophisticated medical devices into the home despite fears that the home care environment may not be suitable for safe and effective medical device use. With continued cost-containment concerns and pressures on clinicians to be as productive as possible, the clinical setting becomes a less ideal place to acquire clinical skills from senior staff. Currently simulation techniques are receiving active investigation and may provide an alternative means of acquiring and maintaining clinical skills. At the same time, with a growing proportion of the population composed of minorities, greater sensitivity and tailored approaches directed toward those less well served by the health system will be needed.

Unlike other sectors of the economy, health care remained untouched for too long by advances in information technology (except, perhaps, for billing purposes). That is no longer the case, given the recent implementation of electronic health records, computer physician order entry systems, barcoding systems, and other technologies by early adopters. However, lofty expectations that usher in new technology are quickly dampened by unintended consequences.[41, 42] One of the early lessons learned is that successful implementation involves more than just technical considerations—the nature of clinical work, the design of well-conceived interfaces, workflow considerations, user acceptance and adoption issues, training, and other organizational support requirements all need to be taken into account. Still another external development that will likely have an impact on clinical practice in the years to come is the passage of the Patient Safety and Quality Improvement Act of 2005. It provides confidentiality protections and encourages providers to contract with patient safety organizations (PSOs) for the purpose of collecting and analyzing data on patient safety events so that information can be fed back to providers to help reduce harm to patients. With the confidentiality protections mandated by the act, providers should be able to report patient safety events freely without fear of reprisal or litigation. Finally, given the availability of numerous medical Web sites and a national press network sensitized to instances of substandard clinical care and medical error, today's patients are better informed and a bit less trusting with respect to their encounters with the health system.

What Can Nurses Do?

Considering all the system factors (and we have only identified some of them), a normal reaction probably is to feel a bit overwhelmed by the demanding and complex clinical environment in which nurses find themselves. Given the hierarchical and complex nature of system factors identified and the unanticipated ways they can interact, a reasonable question is, “What can nurses do?” The answer, in part, comes from learning to manage the unexpected[1]—a quality of high-reliability organizations (HROs) that many health care organizations are currently learning to adopt. In brief, HROs are those organizations that have sustained very impressive safety records while operating in very complex and unkind environments (e.g., aircraft carriers, nuclear power, firefighting crews), where the risk of injury to people and damage to expensive equipment or the environment is high. A key characteristic on the part of workers in HROs is that of *mindfulness*—a set of cognitive processes that allows individuals to be highly attuned to the many ways things can go wrong in unkind environments and ways to recover from them. Workers in HROs are qualitatively different and continuously mindful of different things compared to workers in less reliable organizations. Table 3 describes the five mindfulness processes that define the core components of HROs and the implications for nursing. For a fuller account of HROs, interested readers are encouraged to access the original source.[43]

Table 3. A State of Mindfulness for Nurses

Core process	Explanation/Implication for Nursing
Preoccupation with failure	Adverse events are rare in HROs, yet these organizations focus incessantly on ways the system can fail them. Rather than letting success breed complacency, they worry about success and know that adverse events will indeed occur. They treat close calls as a sign of danger lurking in the system. Hence, it is a good thing when nurses are preoccupied with the many ways things can go wrong and when they share that "inner voice of concern" with others.

Core process	Explanation/Implication for Nursing
Reluctance to simplify interpretations	When things go wrong, less reliable organizations find convenient ways to circumscribe and limit the scope of the problem. They simplify and do not spend much energy on investigating all the contributing factors. Conversely, HROs resist simplified interpretations, do not accept conventional explanations that are readily available, and seek out information that can disconfirm hunches and popular stereotypes. Nurses who develop good interpersonal, teamwork, and critical-thinking skills will enhance their organization's ability to accept disruptive information that disconfirms preconceived ideas.
Sensitivity to operations	Workers in HROs do an excellent job of maintaining a big picture of current and projected operations. Jet fighter pilots call it *situational awareness*; surface Navy personnel call it *maintaining the bubble*. By integrating information about operations and the actions of others into a coherent picture, they are able to stay ahead of the action and can respond appropriately to minor deviations before they result in major threats to safety and quality. Nurses also demonstrate excellent sensitivity to operations when they process information regarding clinical procedures beyond their own jobs and stay ahead of the action rather than trying to catch up to it.
Commitment to resilience	Given that errors are always going to occur, HROs commit equal resources to being mindful about errors that have already occurred and to correct them before they worsen. Here the idea is to reduce or mitigate the adverse consequences of untoward events. Nursing already shows resilience by putting supplies and recovery equipment in places that can be quickly accessed when patient conditions go awry. Since foresight always lags hindsight, nursing resilience can be honed by creating simulations of care processes that start to unravel (e.g., failure to rescue).
Deference to expertise	In managing the unexpected, HROs allow decisions to migrate to those with the expertise to make them. Decisions that have to be made quickly are made by knowledgeable front-line personnel who are closest to the problem. Less reliable organizations show misplaced deference to authority figures. While nurses, no doubt, can cite many examples of misplaced deference to physicians, there are instances where physicians have assumed that nurses have the authority to make decisions and act, resulting in a diffusion of responsibility. When it comes to decisions that need to be made quickly, implicit assumptions need to be made explicit; rules of engagement need to be clearly established; and deference must be given to those with the expertise, resources, and availability to help the patient.

It should be noted that not everyone in health care has been receptive to comparisons between health care delivery and the activities that take place in other high-risk industries such as aircraft carrier operations or nuclear power. Health care is not aviation; it is more complex and qualitatively different. While all of this may be true, it probably also is true that health care is the most poorly managed of all the high-risk industries and very late in coming to recognize the importance of system factors that underlie adverse events. The one thing that the other high-risk industries clearly have in common with health care is the human component. Sailors that work the decks of aircraft carriers have the same physiologies as those who work the hospital floor. They get fatigued from excessive hours of operation in the same way as those who occupy the nurses' station. When the technology and equipment they

use is poorly designed and confusing to use, they get frustrated and make similar types of mistakes as those in health care who have to use poorly designed medical devices. When the pace of operations pick up and they are bombarded with interruptions, short-term memory fails them in exactly the same way that it fails those who work in hectic EDs and ICUs. They respond to variations in the physical environment (e.g., lighting, noise, workplace layout) and to social/organizational pressures (e.g., group norms, culture, authority gradients) in a very similar fashion to those in health care who are exposed to the same set of factors. While the nature of the work may be dramatically different, the types of system factors that influence human performance are indeed very similar. The take-home message of all this is that the human factors studies that have been conducted in the other high-risk industries are very relevant to health care, and nursing in particular, as we continue to learn to improve the skills, processes, and system alignments that are needed for higher quality and safer care.

Conclusion

The complex and demanding clinical environment of nurses can be made a bit more understandable and easier in which to deliver care by accounting for a wide range of human factors concerns that directly and indirectly impact human performance. Human factors is the application of scientific knowledge about human strengths and limitations to the design of systems in the work environment to ensure safe and satisfying performance. A human factors framework such as that portrayed in Figure 1 helps us become aware of the salient components and their relationships that shape and influence the quality of care that is provided to patients. The concept of human error is a somewhat loaded term. Rather than falling into the trap of uncritically focusing on human error and searching for individuals to blame, a systems approach attempts to identify the contributing factors to substandard performance and find ways to better detect, recover from, or preclude problems that could result in harm to patients. Starting with the individual characteristics of providers such as their knowledge, skills, and sensory/physical capabilities, we examined a hierarchy of system factors, including the nature of the work performed, the physical environment, human-system interfaces, the organizational/social environment, management, and external factors. In our current fragmented health care system, where no single individual or entity is in charge, these multiple factors seem to be continuously misaligned and interact in a manner that leads to substandard care. These are the proverbial accidents in the system waiting to happen. Nurses serve in a critical role at the point of patient care; they are in an excellent position to not only identify the problems, but to help identify the problems-behind-the-problems. Nurses can actively practice the tenets of high-reliability organizations. It is recognized, of course, that nursing cannot address the system problems all on its own. Everyone who has a potential impact on patient care, no matter how remote (e.g., device manufacturers, administrators, nurse managers), needs to be mindful of the interdependent system factors that they play a role in shaping. Without a clear and strong nursing voice and an organizational climate that is conducive to candidly addressing system problems, efforts to improve patient safety and quality will fall short of their potential.

Chapter 6. Clinical Reasoning, Decisionmaking, and Action: Thinking Critically and Clinically

Patricia Benner, Ronda G. Hughes, Molly Sutphen

Background

This chapter examines multiple thinking strategies that are needed for high-quality clinical practice. Clinical reasoning and judgment are examined in relation to other modes of thinking used by clinical nurses in providing quality health care to patients that avoids adverse events and patient harm. The clinician's ability to provide safe, high-quality care can be dependent upon their ability to reason, think, and judge, which can be limited by lack of experience. The expert performance of nurses is dependent upon continual learning and evaluation of performance.

Critical Thinking

Nursing education has emphasized critical thinking as an essential nursing skill for more than 50 years.[1] The definitions of critical thinking have evolved over the years. There are several key definitions for critical thinking to consider. The American Philosophical Association (APA) defined critical thinking as purposeful, self-regulatory judgment that uses cognitive tools such as interpretation, analysis, evaluation, inference, and explanation of the evidential, conceptual, methodological, criteriological, or contextual considerations on which judgment is based.[2] A more expansive general definition of critical thinking is

> . . . in short, self-directed, self-disciplined, self-monitored, and self-corrective thinking. It presupposes assent to rigorous standards of excellence and mindful command of their use. It entails effective communication and problem solving abilities and a commitment to overcome our native egocentrism and sociocentrism. Every clinician must develop rigorous habits of critical thinking, but they cannot escape completely the situatedness and structures of the clinical traditions and practices in which they must make decisions and act quickly in specific clinical situations.[3]

There are three key definitions for nursing, which differ slightly. Bittner and Tobin defined critical thinking as being "influenced by knowledge and experience, using strategies such as reflective thinking as a part of learning to identify the issues and opportunities, and holistically synthesize the information in nursing practice"[4] (p. 268). Scheffer and Rubenfeld[5] expanded on the APA definition for nurses through a consensus process, resulting in the following definition:

> Critical thinking in nursing is an essential component of professional accountability and quality nursing care. Critical thinkers in nursing exhibit these habits of the mind: confidence, contextual perspective, creativity, flexibility, inquisitiveness, intellectual integrity, intuition, openmindedness, perseverance, and reflection. Critical thinkers in nursing practice the cognitive skills of analyzing, applying standards, discriminating, information seeking, logical reasoning, predicting, and transforming knowledge[6] (Scheffer & Rubenfeld, p. 357).

The National League for Nursing Accreditation Commission (NLNAC) defined critical thinking as:

> the deliberate nonlinear process of collecting, interpreting, analyzing, drawing conclusions about, presenting, and evaluating information that is both factually and belief based. This is demonstrated in nursing by clinical judgment, which includes ethical, diagnostic, and therapeutic dimensions and research[7] (p. 8).

These concepts are furthered by the American Association of Colleges of Nurses' definition of critical thinking in their *Essentials of Baccalaureate Nursing*:

> Critical thinking underlies independent and interdependent decision making. Critical thinking includes questioning, analysis, synthesis, interpretation, inference, inductive and deductive reasoning, intuition, application, and creativity[8] (p. 9).
>
> Course work or ethical experiences should provide the graduate with the knowledge and skills to:
>
> - Use nursing and other appropriate theories and models, and an appropriate ethical framework;
> - Apply research-based knowledge from nursing and the sciences as the basis for practice;
> - Use clinical judgment and decision-making skills;
> - Engage in self-reflective and collegial dialogue about professional practice;
> - Evaluate nursing care outcomes through the acquisition of data and the questioning of inconsistencies, allowing for the revision of actions and goals;
> - Engage in creative problem solving[8] (p. 10).

Taken together, these definitions of critical thinking set forth the scope and key elements of thought processes involved in providing clinical care. Exactly how critical thinking is defined will influence how it is taught and to what standard of care nurses will be held accountable.

Professional and regulatory bodies in nursing education have required that critical thinking be central to all nursing curricula, but they have not adequately distinguished critical reflection from ethical, clinical, or even creative thinking for decisionmaking or actions required by the clinician. Other essential modes of thought such as clinical reasoning, evaluation of evidence, creative thinking, or the application of well-established standards of practice—all distinct from critical reflection—have been subsumed under the rubric of critical thinking. In the nursing education literature, clinical reasoning and judgment are often conflated with critical thinking. The accrediting bodies and nursing scholars have included decisionmaking and action-oriented, practical, ethical, and clinical reasoning in the rubric of critical reflection and thinking. One might say that this harmless semantic confusion is corrected by actual practices, except that students need to understand the distinctions between critical reflection and clinical reasoning, and they need to learn to discern when each is better suited, just as students need to also engage in applying standards, evidence-based practices, and creative thinking.

The growing body of research, patient acuity, and complexity of care demand higher-order thinking skills. Critical thinking involves the application of knowledge and experience to identify patient problems and to direct clinical judgments and actions that result in positive patient outcomes. These skills can be cultivated by educators who display the virtues of critical thinking, including independence of thought, intellectual curiosity, courage, humility, empathy, integrity, perseverance, and fair-mindedness.[9]

The process of critical thinking is stimulated by integrating the essential knowledge, experiences, and clinical reasoning that support professional practice. The emerging paradigm for clinical thinking and cognition is that it is social and dialogical rather than monological and individual.[10–12] Clinicians pool their wisdom and multiple perspectives, yet some clinical knowledge can be demonstrated only in the situation (e.g., how to suction an extremely fragile patient whose oxygen saturations sink too low). Early warnings of problematic situations are made possible by clinicians comparing their observations to that of other providers. Clinicians form practice communities that create styles of practice, including ways of doing things, communication styles and mechanisms, and shared expectations about performance and expertise of team members.

By holding up critical thinking as a large umbrella for different modes of thinking, students can easily misconstrue the logic and purposes of different modes of thinking. Clinicians and scientists alike need multiple thinking strategies, such as critical thinking, clinical judgment, diagnostic reasoning, deliberative rationality, scientific reasoning, dialogue, argument, creative thinking, and so on. In particular, clinicians need forethought and an ongoing grasp of a patient's health status and care needs trajectory, which requires an assessment of their own clarity and understanding of the situation at hand, critical reflection, critical reasoning, and clinical judgment.

Critical Reflection, Critical Reasoning, and Judgment

Critical reflection requires that the thinker examine the underlying assumptions and radically question or doubt the validity of arguments, assertions, and even facts of the case. Critical reflective skills are essential for clinicians; however, these skills are not sufficient for the clinician who must decide how to act in particular situations and avoid patient injury. For example, in everyday practice, clinicians cannot afford to critically reflect on the well-established tenets of "normal" or "typical" human circulatory systems when trying to figure out a particular patient's alterations from that typical, well-grounded understanding that has existed since Harvey's work in 1628.[13] Yet critical reflection can generate new scientifically based ideas. For example, there is a lack of adequate research on the differences between women's and men's circulatory systems and the typical pathophysiology related to heart attacks. Available research is based upon multiple, taken-for-granted starting points about the general nature of the circulatory system. As such, critical reflection may not provide what is needed for a clinician to act in a situation. This idea can be considered reasonable since critical reflective thinking is not sufficient for good clinical reasoning and judgment. The clinician's development of skillful critical reflection depends upon being taught what to pay attention to, and thus gaining a sense of salience that informs the powers of perceptual grasp. The powers of noticing or perceptual grasp depend upon noticing what is salient and the capacity to respond to the situation.

Critical reflection is a crucial professional skill, but it is not the only reasoning skill or logic clinicians require. The ability to think critically uses reflection, induction, deduction, analysis, challenging assumptions, and evaluation of data and information to guide decisionmaking.[9, 14, 15] Critical reasoning is a process whereby knowledge and experience are applied in considering multiple possibilities to achieve the desired goals,[16] while considering the patient's situation.[14] It is a process where both inductive and deductive cognitive skills are used.[17] Sometimes clinical reasoning is presented as a form of evaluating scientific knowledge, sometimes even as a form of scientific reasoning. Critical thinking is inherent in making sound clinical reasoning.[18]

An essential point of tension and confusion exists in practice traditions such as nursing and medicine when clinical reasoning and critical reflection become entangled, because the clinician must have some established bases that are not questioned when engaging in clinical decisions and actions, such as standing orders. The clinician must act in the particular situation and time with the best clinical and scientific knowledge available. The clinician cannot afford to indulge in either ritualistic unexamined knowledge or diagnostic or therapeutic nihilism caused by radical doubt, as in critical reflection, because they must find an intelligent and effective way to think and act in particular clinical situations. Critical reflection skills are essential to assist practitioners to rethink outmoded or even wrong-headed approaches to health care, health promotion, and prevention of illness and complications, especially when new evidence is available. Breakdowns in practice, high failure rates in particular therapies, new diseases, new scientific discoveries, and societal changes call for critical reflection about past assumptions and no-longer-tenable beliefs.

Clinical reasoning stands out as a situated, practice-based form of reasoning that requires a background of scientific and technological research-based knowledge about general cases, more so than any particular instance. It also requires practical ability to discern the relevance of the evidence behind general scientific and technical knowledge and how it applies to a particular patient. In dong so, the clinician considers the patient's particular clinical trajectory, their concerns and preferences, and their particular vulnerabilities (e.g., having multiple comorbidities) and sensitivities to care interventions (e.g., known drug allergies, other conflicting comorbid conditions, incompatible therapies, and past responses to therapies) when forming clinical decisions or conclusions.

Situated in a practice setting, clinical reasoning occurs within social relationships or situations involving patient, family, community, and a team of health care providers. The expert clinician situates themselves within a nexus of relationships, with concerns that are bounded by the situation. Expert clinical reasoning is socially engaged with the relationships and concerns of those who are affected by the caregiving situation, and when certain circumstances are present, the adverse event. Halpern[19] has called excellent clinical ethical reasoning "emotional reasoning" in that the clinicians have emotional access to the patient/family concerns and their understanding of the particular care needs. Expert clinicians also seek an optimal perceptual grasp, one based on understanding and as undistorted as possible, based on an attuned emotional engagement and expert clinical knowledge.[19, 20]

Clergy educators[21] and nursing and medical educators have begun to recognize the wisdom of broadening their narrow vision of rationality beyond simple rational calculation (exemplified by cost-benefit analysis) to reconsider the need for character development—including emotional engagement, perception, habits of thought, and skill acquisition—as essential to the development of expert clinical reasoning, judgment, and action.[10, 22–24] Practitioners of engineering, law, medicine, and nursing, like the clergy, have to develop a place to stand in their discipline's tradition of knowledge and science in order to recognize and evaluate salient evidence in the moment. Diagnostic confusion and disciplinary nihilism are both threats to the clinician's ability to act in particular situations. However, the practice and practitioners will not be self-improving and vital if they cannot engage in critical reflection on what is not of value, what is outmoded, and what does not work. As evidence evolves and expands, so too must clinical thought.

Clinical judgment requires clinical reasoning across time about the particular, and because of the relevance of this immediate historical unfolding, clinical reasoning can be very different from the scientific reasoning used to formulate, conduct, and assess clinical experiments. While

scientific reasoning is also socially embedded in a nexus of social relationships and concerns, the goal of detached, critical objectivity used to conduct scientific experiments minimizes the interactive influence of the research on the experiment once it has begun. Scientific research in the natural and clinical sciences typically uses formal criteria to develop "yes" and "no" judgments at prespecified times. The scientist is always situated in past and immediate scientific history, preferring to evaluate static and predetermined points in time (e.g., snapshot reasoning), in contrast to a clinician who must always reason about transitions over time.[25, 26]

Techne and Phronesis

Distinctions between the mere scientific making of things and practice was first explored by Aristotle as distinctions between techne and phronesis.[27] Learning to be a good practitioner requires developing the requisite moral imagination for good practice. If, for example, patients exercise their rights and refuse treatments, practitioners are required to have the moral imagination to understand the probable basis for the patient's refusal. For example, was the refusal based upon catastrophic thinking, unrealistic fears, misunderstanding, or even clinical depression?

Techne, as defined by Aristotle, encompasses the notion of formation of character and habitus[28] as embodied beings. In Aristotle's terms, techne refers to the making of things or producing outcomes.[11] Joseph Dunne defines techne as "the activity of producing outcomes," and it "is governed by a means-ends rationality where the *maker or producer* governs the thing or outcomes produced or made through gaining mastery over the means of producing the outcomes, to the point of being able to separate means and ends"[11] (p. 54). While some aspects of medical and nursing practice fall into the category of techne, much of nursing and medical practice falls outside means-ends rationality and must be governed by concern for doing good or what is best for the patient in particular circumstances, where being in a relationship and discerning particular human concerns at stake guide action.

Phronesis, in contrast to techne, includes reasoning about the particular, across time, through changes or transitions in the patient's and/or the clinician's understanding. As noted by Dunne, phronesis is "characterized at least as much by a perceptiveness with regard to concrete particulars as by a knowledge of universal principles"[11] (p. 273). This type of practical reasoning often takes the form of puzzle solving or the evaluation of immediate past "hot" history of the patient's situation. Such a particular clinical situation is necessarily particular, even though many commonalities and similarities with other disease syndromes can be recognized through signs and symptoms and laboratory tests.[11, 29, 30] Pointing to knowledge embedded in a practice makes no claim for infallibility or "correctness." Individual practitioners can be mistaken in their judgments because practices such as medicine and nursing are inherently underdetermined.[31]

While phronetic knowledge must remain open to correction and improvement, real events, and consequences, it cannot consistently transcend the institutional setting's capacities and supports for good practice. Phronesis is also dependent on ongoing experiential learning of the practitioner, where knowledge is refined, corrected, or refuted. The Western tradition, with the notable exception of Aristotle, valued knowledge that could be made universal and devalued practical know-how and experiential learning. Descartes codified this preference for formal logic and rational calculation.

Aristotle recognized that when knowledge is underdetermined, changeable, and particular, it cannot be turned into the universal or standardized. It must be perceived, discerned, and judged, all of which require experiential learning. In nursing and medicine, perceptual acuity in physical

assessment and clinical judgment (i.e., reasoning across time about changes in the particular patient or the clinician's understanding of the patient's condition) fall into the Greek Aristotelian category of phronesis. Dewey[32] sought to rescue knowledge gained by practical activity in the world. He identified three flaws in the understanding of experience in Greek philosophy: (1) empirical knowing is the opposite of experience with science; (2) practice is reduced to techne or the application of rational thought or technique; and (3) action and skilled know-how are considered temporary and capricious as compared to reason, which the Greeks considered as ultimate reality.

In practice, nursing and medicine require both techne and phronesis. The clinician standardizes and routinizes what can be standardized and routinized, as exemplified by standardized blood pressure measurements, diagnoses, and even charting about the patient's condition and treatment.[27] Procedural and scientific knowledge can often be formalized and standardized (e.g., practice guidelines), or at least made explicit and certain in practice, except for the necessary timing and adjustments made for particular patients.[11, 22]

Rational calculations available to techne—population trends and statistics, algorithms—are created as decision support structures and can improve accuracy when used as a stance of inquiry in making clinical judgments about particular patients. Aggregated evidence from clinical trials and ongoing working knowledge of pathophysiology, biochemistry, and genomics are essential. In addition, the skills of phronesis (clinical judgment that reasons across time, taking into account the transitions of the particular patient/family/community and transitions in the clinician's understanding of the clinical situation) will be required for nursing, medicine, or any helping profession.

Thinking Critically

Being able to think critically enables nurses to meet the needs of patients within their context and considering their preferences; meet the needs of patients within the context of uncertainty; consider alternatives, resulting in higher-quality care;[33] and think reflectively, rather than simply accepting statements and performing tasks without significant understanding and evaluation.[34] Skillful practitioners can think critically because they have the following cognitive skills: information seeking, discriminating, analyzing, transforming knowledge, predicating, applying standards, and logical reasoning.[5] One's ability to think critically can be affected by age, length of education (e.g., an associate vs. a baccalaureate decree in nursing), and completion of philosophy or logic subjects.[35–37] The skillful practitioner can think critically because of having the following characteristics: motivation, perseverance, fair-mindedness, and deliberate and careful attention to thinking.[5, 9]

Thinking critically implies that one has a knowledge base from which to reason and the ability to analyze and evaluate evidence.[38] Knowledge can be manifest by the logic and rational implications of decisionmaking. Clinical decisionmaking is particularly influenced by interpersonal relationships with colleagues,[39] patient conditions, availability of resources,[40] knowledge, and experience.[41] Of these, experience has been shown to enhance nurses' abilities to make quick decisions[42] and fewer decision errors,[43] support the identification of salient cues, and foster the recognition and action on patterns of information.[44, 45]

Clinicians must develop the character and relational skills that enable them to perceive and understand their patient's needs and concerns. This requires accurate interpretation of patient data that is relevant to the specific patient and situation. In nursing, this formation of moral agency focuses on learning to be responsible in particular ways demanded by the practice, and to

pay attention and intelligently discern changes in patients' concerns and/or clinical condition that require action on the part of the nurse or other health care workers to avert potential compromises to quality care.

Formation of the clinician's character, skills, and habits are developed in schools and particular practice communities within a larger practice tradition. As Dunne notes,

> A practice is not just a surface on which one can display instant virtuosity. It grounds one in a tradition that has been formed through an elaborate development and that exists at any juncture only in the dispositions (slowly and perhaps painfully acquired) of its recognized practitioners. The question may of course be asked whether there are *any* such practices in the contemporary world, whether the wholesale encroachment of Technique has not obliterated them—and whether this is not the whole point of MacIntyre's recipe of withdrawal, as well as of the post-modern story of dispossession[11] (p. 378).

Clearly Dunne is engaging in critical reflection about the conditions for developing character, skills, and habits for skillful and ethical comportment of practitioners, as well as to act as moral agents for patients so that they and their families receive safe, effective, and compassionate care.

Professional socialization or professional values, while necessary, do not adequately address character and skill formation that transform the way the practitioner exists in his or her world, what the practitioner is capable of noticing and responding to, based upon well-established patterns of emotional responses, skills, dispositions to act, and the skills to respond, decide, and act.[46] The need for character and skill formation of the clinician is what makes a practice stand out from a mere technical, repetitious manufacturing process.[11, 30, 47]

In nursing and medicine, many have questioned whether current health care institutions are designed to promote or hinder enlightened, compassionate practice, or whether they have deteriorated into commercial institutional models that focus primarily on efficiency and profit. MacIntyre points out the links between the ongoing development and improvement of practice traditions and the institutions that house them:

> Lack of justice, lack of truthfulness, lack of courage, lack of the relevant intellectual virtues—these corrupt traditions, just as they do those institutions and practices which derive their life from the traditions of which they are the contemporary embodiments. To recognize this is of course also to recognize the existence of an additional virtue, one whose importance is perhaps most obvious when it is least present, the virtue of having an adequate sense of the traditions to which one belongs or which confront one. This virtue is not to be confused with any form of conservative antiquarianism; I am not praising those who choose the conventional conservative role of *laudator temporis acti.* It is rather the case that an adequate sense of tradition manifests itself in a grasp of those future possibilities which the past has made available to the present. Living traditions, just because they continue a not-yet-completed narrative, confront a future whose determinate and determinable character, so far as it possesses any, derives from the past[30] (p. 207).

It would be impossible to capture all the situated and distributed knowledge outside of actual practice situations and particular patients. Simulations are powerful as teaching tools to enable nurses' ability to think critically because they give students the opportunity to practice in a simplified environment. However, students can be limited in their inability to convey underdetermined situations where much of the information is based on perceptions of many

aspects of the patient and changes that have occurred over time. Simulations cannot have the sub-cultures formed in practice settings that set the social mood of trust, distrust, competency, limited resources, or other forms of situated possibilities.

Experience

One of the hallmark studies in nursing providing keen insight into understanding the influence of experience was a qualitative study of adult, pediatric, and neonatal intensive care unit (ICU) nurses, where the nurses were clustered into advanced beginner, intermediate, and expert level of practice categories. The advanced beginner (having up to 6 months of work experience) used procedures and protocols to determine which clinical actions were needed. When confronted with a complex patient situation, the advanced beginner felt their practice was unsafe because of a knowledge deficit or because of a knowledge application confusion. The transition from advanced beginners to competent practitioners began when they first had experience with actual clinical situations and could benefit from the knowledge gained from the mistakes of their colleagues. Competent nurses continuously questioned what they saw and heard, feeling an obligation to know more about clinical situations. In doing do, they moved from only using care plans and following the physicians' orders to analyzing and interpreting patient situations. Beyond that, the proficient nurse acknowledged the changing relevance of clinical situations requiring action beyond what was planned or anticipated. The proficient nurse learned to acknowledge the changing needs of patient care and situation, and could organize interventions "by the situation as it unfolds rather than by preset goals[48] (p. 24). Both competent and proficient nurses (that is, intermediate level of practice) had at least two years of ICU experience.[48] Finally, the expert nurse had a more fully developed grasp of a clinical situation, a sense of confidence in what is known about the situation, and could differentiate the precise clinical problem in little time.[48]

Expertise is acquired through professional experience and is indicative of a nurse who has moved beyond mere proficiency. As Gadamer[29] points out, experience involves a turning around of preconceived notions, preunderstandings, and extends or adds nuances to understanding. Dewey[49] notes that experience requires a prepared "creature" and an enriched environment. The opportunity to reflect and narrate one's experiential learning can clarify, extend, or even refute experiential learning.

Experiential learning requires time and nurturing, but time alone does not ensure experiential learning. Aristotle linked experiential learning to the development of character and moral sensitivities of a person learning a practice.[50] New nurses/new graduates have limited work experience and must experience continuing learning until they have reached an acceptable level of performance.[51] After that, further improvements are not predictable, and years of experience are an inadequate predictor of expertise.[52]

The most effective knower and developer of practical knowledge creates an ongoing dialogue and connection between lessons of the day and experiential learning over time. Gadamer, in a late life interview, highlighted the open-endedness and ongoing nature of experiential learning in the following interview response:

> Being experienced does not mean that one now knows something once and for all and becomes rigid in this knowledge; rather, one becomes more open to new experiences. A person who is experienced is undogmatic. Experience has the effect of freeing one to be open to new experience … In our experience we bring

> nothing to a close; we are constantly learning new things from our experience … this I call the interminability of all experience[32] (p. 403).

Practical endeavor, supported by scientific knowledge, requires experiential learning, the development of skilled know-how, and perceptual acuity in order to make the scientific knowledge relevant to the situation. Clinical perceptual and skilled know-how helps the practitioner discern when particular scientific findings might be relevant.[53]

Often experience and knowledge, confirmed by experimentation, are treated as oppositions, an either-or choice. However, in practice it is readily acknowledged that experiential knowledge fuels scientific investigation, and scientific investigation fuels further experiential learning. Experiential learning from particular clinical cases can help the clinician recognize future similar cases and fuel new scientific questions and study. For example, less experienced nurses—and it could be argued experienced as well—can use nursing diagnoses practice guidelines as part of their professional advancement. Guidelines are used to reflect their interpretation of patients' needs, responses, and situation,[54] a process that requires critical thinking and decisionmaking.[55, 56] Using guidelines also reflects one's problem identification and problem-solving abilities.[56] Conversely, the ability to proficiently conduct a series of tasks without nursing diagnoses is the hallmark of expertise.[39, 57]

Experience precedes expertise. As expertise develops from experience and gaining knowledge and transitions to the proficiency stage, the nurses' thinking moves from steps and procedures (i.e., task-oriented care) toward "chunks" or patterns[39] (i.e., patient-specific care). In doing so, the nurse thinks reflectively, rather than merely accepting statements and performing procedures without significant understanding and evaluation.[34] Expert nurses do not rely on rules and logical thought processes in problem-solving and decisionmaking.[39] Instead, they use abstract principles, can see the situation as a complex whole, perceive situations comprehensively, and can be fully involved in the situation.[48] Expert nurses can perform high-level care without conscious awareness of the knowledge they are using,[39, 58] and they are able to provide that care with flexibility and speed. Through a combination of knowledge and skills gained from a range of theoretical and experiential sources, expert nurses also provide holistic care.[39] Thus, the best care comes from the combination of theoretical, tacit, and experiential knowledge.[59, 60]

Experts are thought to eventually develop the ability to intuitively know what to do and to quickly recognize critical aspects of the situation.[22] Some have proposed that expert nurses provide high-quality patient care,[61, 62] but that is not consistently documented—particularly in consideration of patient outcomes—and a full understanding between the differential impact of care rendered by an "expert" nurse is not fully understood. In fact, several studies have found that length of professional experience is often unrelated and even negatively related to performance measures and outcomes.[63, 64]

In a review of the literature on expertise in nursing, Ericsson and colleagues[65] found that focusing on challenging, less-frequent situations would reveal individual performance differences on tasks that require speed and flexibility, such as that experienced during a code or an adverse event. Superior performance was associated with extensive training and immediate feedback about outcomes, which can be obtained through continual training, simulation, and processes such as root-cause analysis following an adverse event. Therefore, efforts to improve performance benefited from continual monitoring, planning, and retrospective evaluation. Even then, the nurse's ability to perform as an expert is dependent upon their ability to use intuition or insights gained through interactions with patients.[39]

Intuition and Perception

Intuition is the instant understanding of knowledge without evidence of sensible thought.[66] According to Young,[67] intuition in clinical practice is a process whereby the nurse recognizes something about a patient that is difficult to verbalize. Intuition is characterized by factual knowledge, "immediate possession of knowledge, and knowledge independent of the linear reasoning process"[68] (p. 23). When intuition is used, one filters information initially triggered by the imagination, leading to the integration of all knowledge and information to problem solve.[69] Clinicians use their interactions with patients and intuition, drawing on tacit or experiential knowledge,[70, 71] to apply the correct knowledge to make the correct decisions to address patient needs. Yet there is a "conflated belief in the nurses' ability to know what is best for the patient"[72] (p. 251) because the nurses' and patients' identification of the patients' needs can vary.[73]

A review of research and rhetoric involving intuition by King and Appleton[62] found that all nurses, including students, used intuition (i.e., gut feelings). They found evidence, predominately in critical care units, that intuition was triggered in response to knowledge and as a trigger for action and/or reflection with a direct bearing on the analytical process involved in patient care. The challenge for nurses was that rigid adherence to checklists, guidelines, and standardized documentation,[62] ignored the benefits of intuition. This view was furthered by Rew and Barrow[68, 74] in their reviews of the literature, where they found that intuition was imperative to complex decisionmaking,[68] difficult to measure and assess in a quantitative manner, and was not linked to physiologic measures.[74]

Intuition is a way of explaining professional expertise.[75] Expert nurses rely on their intuitive judgment that has been developed over time.[39, 76] Intuition is an informal, nonanalytically based, unstructured, deliberate calculation that facilitates problem solving,[77] a process of arriving at salient conclusions based on relatively small amounts of knowledge and/or information.[78] Experts can have rapid insight into a situation by using intuition to recognize patterns and similarities, achieve commonsense understanding, and sense the salient information combined with deliberative rationality.[10] Intuitive recognition of similarities and commonalities between patients are often the first diagnostic clue or early warning, which must then be followed up with critical evaluation of evidence among the competing conditions. This situation calls for intuitive judgment that can distinguish "expert human judgment from the decisions" made by a novice[79] (p. 23).

Shaw[80] equates intuition with direct perception. Direct perception is dependent upon being able to detect complex patterns and relationships that one has learned through experience are important. Recognizing these patterns and relationships generally occurs rapidly and is complex, making it difficult to articulate or describe. Perceptual skills, like those of the expert nurse, are essential to recognizing current and changing clinical conditions. Perception requires attentiveness and the development of a sense of what is salient. Often in nursing and medicine, means and ends are fused, as is the case for a "good enough" birth experience and a peaceful death.

Applying Practice Evidence

Research continues to find that using evidence-based guidelines in practice, informed through research evidence, improves patients' outcomes.[81–83] Research-based guidelines are

intended to provide guidance for specific areas of health care delivery.[84] The clinician—both the novice and expert—is expected to use the best available evidence for the most efficacious therapies and interventions in particular instances, to ensure the highest-quality care, especially when deviations from the evidence-based norm may heighten risks to patient safety. Otherwise, if nursing and medicine were exact sciences, or consisted only of techne, then a 1:1 relationship could be established between results of aggregated evidence-based research and the best path for all patients.

Evaluating Evidence

Before research should be used in practice, it must be evaluated. There are many complexities and nuances in evaluating the research evidence for clinical practice. Evaluation of research behind evidence-based medicine requires critical thinking and good clinical judgment. Sometimes the research findings are mixed or even conflicting. As such, the validity, reliability, and generalizability of available research are fundamental to evaluating whether evidence can be applied in practice. To do so, clinicians must select the best scientific evidence relevant to particular patients—a complex process that involves intuition to apply the evidence. Critical thinking is required for evaluating the best available scientific evidence for the treatment and care of a particular patient.

Good clinical judgment is required to select the most relevant research evidence. The best clinical judgment, that is, reasoning across time about the particular patient through changes in the patient's concerns and condition and/or the clinician's understanding, are also required. This type of judgment requires clinicians to make careful observations and evaluations of the patient over time, as well as know the patient's concerns and social circumstances. To evolve to this level of judgment, additional education beyond clinical preparation if often required.

Sources of Evidence

Evidence that can be used in clinical practice has different sources and can be derived from research, patient's preferences, and work-related experience.[85, 86] Nurses have been found to obtain evidence from experienced colleagues believed to have clinical expertise and research-based knowledge[87] as well as other sources.

For many years now, randomized controlled trials (RCTs) have often been considered the best standard for evaluating clinical practice. Yet, unless the common threats to the validity (e.g., representativeness of the study population) and reliability (e.g., consistency in interventions and responses of study participants) of RCTs are addressed, the meaningfulness and generalizability of the study outcomes are very limited. Relevant patient populations may be excluded, such as women, children, minorities, the elderly, and patients with multiple chronic illnesses. The dropout rate of the trial may confound the results. And it is easier to get positive results published than it is to get negative results published. Thus, RCTs are generalizable (i.e., applicable) only to the population studied—which may not reflect the needs of the patient under the clinicians care. In instances such as these, clinicians need to also consider applied research using prospective or retrospective populations with case control to guide decisionmaking, yet this too requires critical thinking and good clinical judgment.

Another source of available evidence may come from the gold standard of aggregated systematic evaluation of clinical trial outcomes for the therapy and clinical condition in question, be generated by basic and clinical science relevant to the patient's particular pathophysiology or

care need situation, or stem from personal clinical experience. The clinician then takes all of the available evidence and considers the particular patient's known clinical responses to past therapies, their clinical condition and history, the progression or stages of the patient's illness and recovery, and available resources.

In clinical practice, the particular is examined in relation to the established generalizations of science. With readily available summaries of scientific evidence (e.g., systematic reviews and practice guidelines) available to nurses and physicians, one might wonder whether deep background understanding is still advantageous. Might it not be expendable, since it is likely to be out of date given the current scientific evidence? But this assumption is a false opposition and false choice because without a deep background understanding, the clinician does not know how to best find and evaluate scientific evidence for the particular case in hand. The clinician's sense of salience in any given situation depends on past clinical experience and current scientific evidence.

Evidence-Based Practice

The concept of evidence-based practice is dependent upon synthesizing evidence from the variety of sources and applying it appropriately to the care needs of populations and individuals. This implies that evidence-based practice, indicative of expertise in practice, appropriately applies evidence to the specific situations and unique needs of patients.[88, 89] Unfortunately, even though providing evidence-based care is an essential component of health care quality, it is well known that evidence-based practices are not used consistently.

Conceptually, evidence used in practice advances clinical knowledge, and that knowledge supports independent clinical decisions in the best interest of the patient.[90, 91] Decisions must prudently consider the factors not necessarily addressed in the guideline, such as the patient's lifestyle, drug sensitivities and allergies, and comorbidities. Nurses who want to improve the quality and safety of care can do so though improving the consistency of data and information interpretation inherent in evidence-based practice.

Initially, before evidence-based practice can begin, there needs to be an accurate clinical judgment of patient responses and needs. In the course of providing care, with careful consideration of patient safety and quality care, clinicians must give attention to the patient's condition, their responses to health care interventions, and potential adverse reactions or events that could harm the patient. Nonetheless, there is wide variation in the ability of nurses to accurately interpret patient responses[92] and their risks.[93] Even though variance in interpretation is expected, nurses are obligated to continually improve their skills to ensure that patients receive quality care safely.[94] Patients are vulnerable to the actions and experience of their clinicians, which are inextricably linked to the quality of care patients have access to and subsequently receive.

The judgment of the patient's condition determines subsequent interventions and patient outcomes. Attaining accurate and consistent interpretations of patient data and information is difficult because each piece can have different meanings, and interpretations are influenced by previous experiences.[95] Nurses use knowledge from clinical experience[96, 97] and—although infrequently—research.[98–100]

Once a problem has been identified, using a process that utilizes critical thinking to recognize the problem, the clinician then searches for and evaluates the research evidence[101] and evaluates potential discrepancies. The process of using evidence in practice involves "a problem-solving approach that incorporates the best available scientific evidence, clinicians' expertise, and

patient's preferences and values"[102] (p. 28). Yet many nurses do not perceive that they have the education, tools, or resources to use evidence appropriately in practice.[103]

Reported barriers to using research in practice have included difficulty in understanding the applicability and the complexity of research findings, failure of researchers to put findings into the clinical context, lack of skills in how to use research in practice,[104, 105] amount of time required to access information and determine practice implications,[105–107] lack of organizational support to make changes and/or use in practice,[104, 97, 105, 107] and lack of confidence in one's ability to critically evaluate clinical evidence.[108]

When Evidence Is Missing

In many clinical situations, there may be no clear guidelines and few or even no relevant clinical trials to guide decisionmaking. In these cases, the latest basic science about cellular and genomic functioning may be the most relevant science, or by default, guestimation. Consequently, good patient care requires more than a straightforward, unequivocal application of scientific evidence. The clinician must be able to draw on a good understanding of basic sciences, as well as guidelines derived from aggregated data and information from research investigations.

Practical knowledge is shaped by one's practice discipline and the science and technology relevant to the situation at hand. But scientific, formal, discipline-specific knowledge are not sufficient for good clinical practice, whether the discipline be law, medicine, nursing, teaching, or social work. Practitioners still have to learn how to discern generalizable scientific knowledge, know how to use scientific knowledge in practical situations, discern what scientific evidence/knowledge is relevant, assess how the particular patient's situation differs from the general scientific understanding, and recognize the complexity of care delivery—a process that is complex, ongoing, and changing, as new evidence can overturn old.

Practice communities like individual practitioners may also be mistaken, as is illustrated by variability in practice styles and practice outcomes across hospitals and regions in the United States. This variability in practice is why practitioners must learn to critically evaluate their practice and continually improve their practice over time. The goal is to create a living self-improving tradition.

Within health care, students, scientists, and practitioners are challenged to learn and use different modes of thinking when they are conflated under one term or rubric, using the best-suited thinking strategies for taking into consideration the purposes and the ends of the reasoning. Learning to be an effective, safe nurse or physician requires not only technical expertise, but also the ability to form helping relationships and engage in practical ethical and clinical reasoning.[50] Good ethical comportment requires that both the clinician and the scientist take into account the notions of good inherent in clinical and scientific practices. The notions of good clinical practice must include the relevant significance and the human concerns involved in decisionmaking in particular situations, centered on clinical grasp and clinical forethought.

The Three Apprenticeships of Professional Education

We have much to learn in comparing the pedagogies of formation across the professions, such as is being done currently by the Carnegie Foundation for the Advancement of Teaching. The Carnegie Foundation's broad research program on the educational preparation of the profession focuses on three essential apprenticeships:

> To capture the full range of crucial dimensions in professional education, we developed the idea of a three-fold apprenticeship: (1) intellectual training to learn the academic knowledge base and the capacity to think in ways important to the profession; (2) a skill-based apprenticeship of practice; and (3) an apprenticeship to the ethical standards, social roles, and responsibilities of the profession, through which the novice is introduced to the meaning of an integrated practice of all dimensions of the profession, grounded in the profession's fundamental purposes.[109]

This framework has allowed the investigators to describe tensions and shortfalls as well as strengths of widespread teaching practices, especially at articulation points among these dimensions of professional training.

Research has demonstrated that these three apprenticeships are taught best when they are integrated so that the intellectual training includes skilled know-how, clinical judgment, and ethical comportment. In the study of nursing, exemplary classroom and clinical teachers were found who do integrate the three apprenticeships in all of their teaching, as exemplified by the following anonymous student's comments:

> With that as well, I enjoyed the class just because I do have clinical experience in my background and I enjoyed it because it took those practical applications and the knowledge from pathophysiology and pharmacology, and all the other classes, and it tied it into the actual aspects of like what is going to happen at work. For example, I work in the emergency room and question: Why am I doing this procedure for this particular patient? Beforehand, when I was just a tech and I wasn't going to school, I'd be doing it because I was told to be doing it—or I'd be doing CPR because, you know, the doc said, start CPR. I really enjoy the Care and Illness because now I know the process, the pathophysiological process of why I'm doing it and the clinical reasons of why they're making the decisions, and the prioritization that goes on behind it. I think that's the biggest point. Clinical experience is good, but not everybody has it. Yet when these students transition from school and clinicals to their job as a nurse, they will understand what's going on and why.

The three apprenticeships are equally relevant and intertwined. In the Carnegie *National Study of Nursing Education* and the companion study on medical education as well as in cross-professional comparisons, teaching that gives an integrated access to professional practice is being examined. Once the three apprenticeships are separated, it is difficult to reintegrate them. The investigators are encouraged by teaching strategies that integrate the latest scientific knowledge and relevant clinical evidence with clinical reasoning about particular patients in unfolding rather than static cases, while keeping the patient and family experience and concerns relevant to clinical concerns and reasoning.

Clinical judgment or phronesis is required to evaluate and integrate techne and scientific evidence.

Within nursing, professional practice is wise and effective usually to the extent that the professional creates relational and communication contexts where clients/patients can be open and trusting. Effectiveness depends upon mutual influence between patient and practitioner, student and learner. This is another way in which clinical knowledge is dialogical and socially distributed. The following articulation of practical reasoning in nursing illustrates the social,

dialogical nature of clinical reasoning and addresses the centrality of perception and understanding to good clinical reasoning, judgment and intervention.

Clinical Grasp*

Clinical grasp describes clinical inquiry in action. Clinical grasp begins with perception and includes problem identification and clinical judgment across time about the particular transitions of particular patients. Garrett Chan[20] described the clinician's attempt at finding an "optimal grasp" or vantage point of understanding. Four aspects of clinical grasp, which are described in the following paragraphs, include (1) making qualitative distinctions, (2) engaging in detective work, (3) recognizing changing relevance, and (4) developing clinical knowledge in specific patient populations.

Making Qualitative Distinctions

Qualitative distinctions refer to those distinctions that can be made only in a particular contextual or historical situation. The context and sequence of events are essential for making qualitative distinctions; therefore, the clinician must pay attention to transitions in the situation and judgment. Many qualitative distinctions can be made only by observing differences through touch, sound, or sight, such as the qualities of a wound, skin turgor, color, capillary refill, or the engagement and energy level of the patient. Another example is assessing whether the patient was more fatigued after ambulating to the bathroom or from lack of sleep. Likewise the quality of the clinician's touch is distinct as in offering reassurance, putting pressure on a bleeding wound, and so on.[110]

Engaging in Detective Work, Modus Operandi Thinking, and Clinical Puzzle Solving

Clinical situations are open ended and underdetermined. Modus operandi thinking keeps track of the particular patient, the way the illness unfolds, the meanings of the patient's responses as they have occurred in the particular time sequence. Modus operandi thinking requires keeping track of what has been tried and what has or has not worked with the patient. In this kind of reasoning-in-transition, gains and losses of understanding are noticed and adjustments in the problem approach are made.

We found that teachers in a medical surgical unit at the University of Washington deliberately teach their students to engage in "detective work." Students are given the daily clinical assignment of "sleuthing" for undetected drug incompatibilities, questionable drug dosages, and unnoticed signs and symptoms. For example, one student noted that an unusual dosage of a heart medication was being given to a patient who did not have heart disease. The student first asked her teacher about the unusually high dosage. The teacher, in turn, asked the

---

student whether she had asked the nurse or the patient about the dosage. Upon the student's questioning, the nurse did not know why the patient was receiving the high dosage and assumed the drug was for heart disease. The patient's staff nurse had not questioned the order. When the student asked the patient, the student found that the medication was being given for tremors and that the patient and the doctor had titrated the dosage for control of the tremors. This deliberate approach to teaching detective work, or modus operandi thinking, has characteristics of "critical reflection," but stays situated and engaged, ferreting out the immediate history and unfolding of events.

Recognizing Changing Clinical Relevance

The meanings of signs and symptoms are changed by sequencing and history. The patient's mental status, color, or pain level may continue to deteriorate or get better. The direction, implication, and consequences for the changes alter the relevance of the particular facts in the situation. The changing relevance entailed in a patient transitioning from primarily curative care to primarily palliative care is a dramatic example, where symptoms literally take on new meanings and require new treatments.

Developing Clinical Knowledge in Specific Patient Populations

Extensive experience with a specific patient population or patients with particular injuries or diseases allows the clinician to develop comparisons, distinctions, and nuanced differences within the population. The comparisons between many specific patients create a matrix of comparisons for clinicians, as well as a tacit, background set of expectations that create population- and patient-specific detective work if a patient does not meet the usual, predictable transitions in recovery. What is in the background and foreground of the clinician's attention shifts as predictable changes in the patient's condition occurs, such as is seen in recovering from heart surgery or progressing through the predictable stages of labor and delivery. Over time, the clinician develops a deep background understanding that allows for expert diagnostic and interventions skills.

Clinical Forethought

Clinical forethought is intertwined with clinical grasp, but it is much more deliberate and even routinized than clinical grasp. Clinical forethought is a pervasive habit of thought and action in nursing practice, and also in medicine, as clinicians think about disease and recovery trajectories and the implications of these changes for treatment. Clinical forethought plays a role in clinical grasp because it structures the practical logic of clinicians. At least four habits of thought and action are evident in what we are calling clinical forethought: (1) future think, (2) clinical forethought about specific patient populations, (3) anticipation of risks for particular patients, and (4) seeing the unexpected.

Future think. Future think is the broadest category of this logic of practice. Anticipating likely immediate futures helps the clinician make good plans and decisions about preparing the environment so that responding rapidly to changes in the patient is possible. Without a sense of salience about anticipated signs and symptoms and preparing the environment, essential clinical judgments and timely interventions would be impossible in the typically fast pace of acute and intensive patient care. Future think governs the style and content of the nurse's attentiveness to

the patient. Whether in a fast-paced care environment or a slower-paced rehabilitation setting, thinking and acting with anticipated futures guide clinical thinking and judgment. Future think captures the way judgment is suspended in a predictive net of anticipation and preparing oneself and the environment for a range of potential events.

Clinical forethought about specific diagnoses and injuries. This habit of thought and action is so second nature to the experienced nurse that the new or inexperienced nurse may have difficulty finding out about what seems to other colleagues as "obvious" preparation for particular patients and situations. Clinical forethought involves much local specific knowledge about who is a good resource and how to marshal support services and equipment for particular patients.

Examples of preparing for specific patient populations are pervasive, such as anticipating the need for a pacemaker during surgery and having the equipment assembled ready for use to save essential time. Another example includes forecasting an accident victim's potential injuries, and recognizing that intubation might be needed.

Anticipation of crises, risks, and vulnerabilities for particular patients. This aspect of clinical forethought is central to knowing the particular patient, family, or community. Nurses situate the patient's problems almost like a topography of possibilities. This vital clinical knowledge needs to be communicated to other caregivers and across care borders. Clinical teaching could be improved by enriching curricula with narrative examples from actual practice, and by helping students recognize commonly occurring clinical situations in the simulation and clinical setting. For example, if a patient is hemodynamically unstable, then managing life-sustaining physiologic functions will be a main orienting goal. If the patient is agitated and uncomfortable, then attending to comfort needs in relation to hemodynamics will be a priority. Providing comfort measures turns out to be a central background practice for making clinical judgments and contains within it much judgment and experiential learning.

When clinical teaching is too removed from typical contingencies and strong clinical situations in practice, students will lack practice in active thinking-in-action in ambiguous clinical situations. In the following example, an anonymous student recounted her experiences of meeting a patient:

> I was used to different equipment and didn't know how things went, didn't know their routine, really. You can explain all you want in class, this is how it's going to be, but when you get there … . Kim was my first instructor and my patient that she assigned me to—I walked into the room and he had every tube imaginable. And so I was a little overwhelmed. It's not necessarily even that he was that critical … . She asked what tubes here have you seen? Well, I know peripheral lines. You taught me PICC [peripherally inserted central catheter] lines, and we just had that, but I don't really feel comfortable doing it by myself, without you watching to make sure that I'm flushing it right and how to assess it. He had a chest tube and I had seen chest tubes, but never really knew the depth of what you had to assess and how you make sure that it's all kosher and whatever. So she went through the chest tube and explained, it's just bubbling a little bit and that's okay. The site, check the site. The site looked okay and that she'd say if it wasn't okay, this is what it might look like … . He had a feeding tube. I had done feeding tubes but that was like a long time ago in my LPN experiences schooling. So I hadn't really done too much with the feeding stuff either … . He had a [nasogastric] tube, and knew pretty much about that and I think at the time it was

> clamped. So there were no issues with the suction or whatever. He had a Foley catheter. He had a feeding tube, a chest tube. I can't even remember but there were a lot.

As noted earlier, a central characteristic of a practice discipline is that a self-improving practice requires ongoing experiential learning. One way nurse educators can enhance clinical inquiry is by increasing pedagogies of experiential learning. Current pedagogies for experiential learning in nursing include extensive preclinical study, care planning, and shared postclinical debriefings where students share their experiential learning with their classmates. Experiential learning requires open learning climates where students can discuss and examine transitions in understanding, including their false starts, or their misconceptions in actual clinical situations. Nursing educators typically develop open and interactive clinical learning communities, so that students seem committed to helping their classmates learn from their experiences that may have been difficult or even unsafe. One anonymous nurse educator described how students extend their experiential learning to their classmates during a postclinical conference:

> So for example, the patient had difficulty breathing and the student wanted to give the meds instead of addressing the difficulty of breathing. Well, while we were sharing information about their patients, what they did that day, I didn't tell the student to say this, but she said, 'I just want to tell you what I did today in clinical so you don't do the same thing, and here's what happened.' Everybody's listening very attentively and they were asking her some questions. But she shared that. She didn't have to. I didn't tell her, you must share that in postconference or anything like that, but she just went ahead and shared that, I guess, to reinforce what she had learned that day but also to benefit her fellow students in case that thing comes up with them.

The teacher's response to this student's honesty and generosity exemplifies her own approach to developing an open community of learning. Focusing *only* on performance and on "being correct" prevents learning from breakdown or error and can dampen students' curiosity and courage to learn experientially.

Seeing the unexpected. One of the keys to becoming an expert practitioner lies in how the person holds past experiential learning and background habitual skills and practices. This is a skill of foregrounding attention accurately and effectively in response to the nature of situational demands. Bourdieu[29] calls the recognition of the situation central to practical reasoning. If nothing is routinized as a habitual response pattern, then practitioners will not function effectively in emergencies. Unexpected occurrences may be overlooked. However, if expectations are held rigidly, then subtle changes from the usual will be missed, and habitual, rote responses will inappropriately rule. The clinician must be flexible in shifting between what is in background and foreground. This is accomplished by staying curious and open. The clinical "certainty" associated with perceptual grasp is distinct from the kind of "certainty" achievable in scientific experiments and through measurements. Recognition of similar or paradigmatic clinical situations is similar to "face recognition" or recognition of "family resemblances." This concept is subject to faulty memory, false associative memories, and mistaken identities; therefore, such perceptual grasp is the beginning of curiosity and inquiry and not the end. Assessment and validation are required. In rapidly moving clinical situations, perceptual grasp is the starting point for clarification, confirmation, and action. Having the clinician say out loud how he or she is understanding the situation gives an opportunity for confirmation and disconfirmation from other clinicians present.[111] The relationship between foreground and

background of attention needs to be fluid, so that missed expectations allow the nurse to *see* the unexpected. For example, when the background rhythm of a cardiac monitor changes, the nurse notices, and what had been background tacit awareness becomes the foreground of attention. A hallmark of expertise is the ability to notice the unexpected.[20] Background expectations of usual patient trajectories form with experience. Tacit expectations for patient trajectories form that enable the nurse to notice subtle failed expectations and pay attention to early signs of unexpected changes in the patient's condition. Clinical expectations gained from caring for similar patient populations form a tacit clinical forethought that enable the experienced clinician to notice missed expectations. Alterations from implicit or explicit expectations set the stage for experiential learning, depending on the openness of the learner.

Conclusion

Learning to provide safe and quality health care requires technical expertise, the ability to think critically, experience, and clinical judgment. The high-performance expectation of nurses is dependent upon the nurses' continual learning, professional accountability, independent and interdependent decisionmaking, and creative problem-solving abilities.

Chapter 7. The Evidence for Evidence-Based Practice Implementation

Marita G. Titler

Background

Overview of Evidence-Based Practice

Evidence-based health care practices are available for a number of conditions such as asthma, heart failure, and diabetes. However, these practices are not always implemented in care delivery, and variation in practices abound.[1–4] Traditionally, patient safety research has focused on data analyses to identify patient safety issues and to demonstrate that a new practice will lead to improved quality and patient safety.[5] Much less research attention has been paid to how to implement practices. Yet, only by putting into practice what is learned from research will care be made safer.[5] Implementing evidence-based safety practices are difficult and need strategies that address the complexity of systems of care, individual practitioners, senior leadership, and—ultimately—changing health care cultures to be evidence-based safety practice environments.[5]

Nursing has a rich history of using research in practice, pioneered by Florence Nightingale.[6–9] Although during the early and mid-1900s, few nurses contributed to this foundation initiated by Nightingale,[10] the nursing profession has more recently provided major leadership for improving care through application of research findings in practice.[11]

Evidence-based practice (EBP) is the conscientious and judicious use of current best evidence in conjunction with clinical expertise and patient values to guide health care decisions.[12–15] Best evidence includes empirical evidence from randomized controlled trials; evidence from other scientific methods such as descriptive and qualitative research; as well as use of information from case reports, scientific principles, and expert opinion. When enough research evidence is available, the practice should be guided by research evidence in conjunction with clinical expertise and patient values. In some cases, however, a sufficient research base may not be available, and health care decisionmaking is derived principally from nonresearch evidence sources such as expert opinion and scientific principles.[16] As more research is done in a specific area, the research evidence must be incorporated into the EBP.[15]

Models of Evidence-Based Practice

Multiple models of EBP are available and have been used in a variety of clinical settings.[16–36] Although review of these models is beyond the scope of this chapter, common elements of these models are selecting a practice topic (e.g., discharge instructions for individuals with heart failure), critique and syntheses of evidence, implementation, evaluation of the impact on patient care and provider performance, and consideration of the context/setting in which the practice is implemented.[15, 17] The learning that occurs during the process of translating research into practice is valuable information to capture and feed back into the process, so that others can adapt the evidence-based guideline and/or the implementation strategies.

A recent conceptual framework for maximizing and accelerating the transfer of research results from the Agency for Healthcare Research and Quality (AHRQ) patient safety research portfolio to health care delivery was developed by the dissemination subcommittee of the AHRQ Patient Safety Research Coordinating Committee.[37] This model is a synthesis of concepts from scientific information on knowledge transfer, social marketing, social and organizational innovation, and behavior change (see Figure 1).[37] Although the framework is portrayed as a series of stages, the authors of this framework do not believe that the knowledge transfer process is linear; rather, activities occur simultaneously or in different sequences, with implementation of EBPs being a multifaceted process with many actors and systems.

Steps of Evidence-Based Practice

Steps of promoting adoption of EBPs can be viewed from the perspective of those who conduct research or generate knowledge,[23, 37] those who use the evidence-based information in practice,[16, 31] and those who serve as boundary spanners to link knowledge generators with knowledge users.[19]

Steps of knowledge transfer in the AHRQ model[37] represent three major stages: (1) knowledge creation and distillation, (2) diffusion and dissemination, and (3) organizational adoption and implementation. These stages of knowledge transfer are viewed through the lens of researchers/creators of new knowledge and begin with determining what findings from the patient safety portfolio or individual research projects ought to be disseminated.

Knowledge creation and distillation is conducting research (with expected variation in readiness for use in health care delivery systems) and then packaging relevant research findings into products that can be put into action—such as specific practice recommendations—thereby increasing the likelihood that research evidence will find its way into practice.[37] It is essential that the knowledge distillation process be informed and guided by end users for research findings to be implemented in care delivery. The criteria used in knowledge distillation should include perspectives of the end users (e.g., transportability to the real-world health care setting, feasibility, volume of evidence needed by health care organizations and clinicians), as well as traditional knowledge generation considerations (e.g., strength of the evidence, generalizability).

Diffusion and dissemination involves partnering with professional opinion leaders and health care organizations to disseminate knowledge that can form the basis of action (e.g., essential elements for discharge teaching for hospitalized patient with heart failure) to potential users. Dissemination partnerships link researchers with intermediaries that can function as knowledge brokers and connectors to the practitioners and health care delivery organizations. Intermediaries can be professional organizations such as the National Patient Safety Foundation or multidisciplinary knowledge transfer teams such as those that are effective in disseminating research-based cancer prevention programs. In this model, dissemination partnerships provide an authoritative seal of approval for new knowledge and help identify influential groups and communities that can create a demand for application of the evidence in practice. Both mass communication and targeted dissemination are used to reach audiences with the anticipation that early users will influence the latter adopters of the new usable, evidence-based research findings. Targeted dissemination efforts must use multifaceted dissemination strategies, with an emphasis on channels and media that are most effective for particular user segments (e.g., nurses, physicians, pharmacists).

End user adoption, implementation, and institutionalization is the final stage of the knowledge transfer process.[37] This stage focuses on getting organizations, teams, and individuals

to adopt and consistently use evidence-based research findings and innovations in everyday practice. Implementing and sustaining EBPs in health care settings involves complex interrelationships among the EBP topic (e.g., reduction of medication errors), the organizational social system characteristics (such as operational structures and values, the external health care environment), and the individual clinicians.[35, 37–39] A variety of strategies for implementation include using a change champion in the organization who can address potential implementation challenges, piloting/trying the change in a particular patient care area of the organization, and using multidisciplinary implementation teams to assist in the practical aspects of embedding innovations into ongoing organizational processes.[35, 37] Changing practice takes considerable effort at both the individual and organizational level to apply evidence-based information and products in a particular context.[22] When improvements in care are demonstrated in the pilot studies and communicated to other relevant units in the organization, key personnel may then agree to fully adopt and sustain the change in practice. Once the EBP change is incorporated into the structure of the organization, the change is no longer considered an innovation but a standard of care.[22, 37]

In comparison, other models of EBP (e.g., Iowa Model of Evidence-based Practice to Promote Quality of Care[16]) view the steps of the EBP process from the perspective of clinicians and/or organizational/clinical contexts of care delivery. When viewing steps of the EBP process through the lens of an end user, the process begins with selecting an area for improving care based on evidence (rather than asking what findings ought to be disseminated); determining the priority of the potential topic for the organization; formulating an EBP team composed of key stakeholders; finding, critiquing, and synthesizing the evidence; setting forth EBP recommendations, with the type and strength of evidence used to support each clearly documented; determining if the evidence findings are appropriate for use in practice; writing an EBP standard specific to the organization; piloting the change in practice; implementing changes in practice in other relevant practice areas (depending on the outcome of the pilot); evaluating the EBP changes; and transitioning ongoing quality improvement (QI) monitoring, staff education, and competency review of the EBP topic to appropriate organizational groups as defined by the organizational structure.[15, 40] The work of EBP implementation from the perspective of the end user is greatly facilitated by efforts of AHRQ, professional nursing organizations (e.g., Oncology Nursing Society), and others that distill and package research findings into useful products and tools for use at the point of care delivery.

When the clinical questions of end users can be addressed through use of existing evidence that is packaged with end users in mind, steps of the EBP process take less time and more effort can be directed toward the implementation, evaluation, and sustainability components of the process. For example, finding, critiquing, and synthesizing the evidence; setting forth EBP recommendations with documentation of the type and strength of evidence for each recommendation; and determining appropriateness of the evidence for use in practice are accelerated when the knowledge-based information is readily available. Some distilled research findings also include quick reference guides that can be used at the point of care and/or integrated into health care information systems, which also helps with implementation.[41, 42]

Translation Science: An Overview

Translation science is the investigation of methods, interventions, and variables that influence adoption by individuals and organizations of EBPs to improve clinical and operational decisionmaking in health care.[35, 43–46] This includes testing the effect of interventions on

promoting and sustaining adoption of EBPs. Examples of translation studies include describing facilitators and barriers to knowledge uptake and use, organizational predictors of adherence to EBP guidelines, attitudes toward EBPs, and defining the structure of the scientific field.[11, 47–49]

Translation science must be guided by a conceptual model that organizes the strategies being tested, elucidates the extraneous variables (e.g., behaviors and facilitators) that may influence adoption of EBPs (e.g., organizational size, characteristics of users), and builds a scientific knowledge base for this field of inquiry.[15, 50] Conceptual models used in the translating-research-into-practice studies funded by AHRQ were adult learning, health education, social influence, marketing, and organizational and behavior theories.[51] Investigators have used Rogers's Diffusion of Innovation model,[35, 39, 52–55] the Promoting Action on Research Implementation in Health Services (PARIHS) model,[29] the push/pull framework,[23, 56, 57] the decisionmaking framework,[58] and the Institute for Healthcare Improvement (IHI) model[59] in translation science.

Study findings regarding evidence-based practices in a diversity of health care settings are building an empirical foundation of translation science.[19, 43, 51, 60–83] These investigations and others[18, 84–86] provide initial scientific knowledge to guide us in how to best promote use of evidence in practice. To advance knowledge about promoting and sustaining adoption of EBPs in health care, translation science needs more studies that test translating research into practice (TRIP) interventions: studies that investigate what TRIP interventions work, for whom, in what circumstances, in what types of settings; and studies that explain the underlying mechanisms of effective TRIP interventions.[35, 49, 79, 87] Partnership models, which encourage ongoing interaction between researchers and practitioners, may be the way forward to carry out such studies.[56] Challenges, issues, methods, and instruments used in translation research are described elsewhere.[11, 19, 49, 78, 88–97]

Research Evidence

What Is Known About Implementing Evidence-Based Practices?

Multifaceted implementation strategies are needed to promote use of research evidence in clinical and administrative health care decisionmaking.[15, 22, 37, 45, 64, 72, 77, 79, 98, 99] Although Grimshaw and colleagues[65] suggest that multifaceted interventions are no more effective than single interventions, context (site of care delivery) was not incorporated in the synthesis methodology. As noted by others, the same TRIP intervention may meet with varying degrees of effectiveness when applied in different contexts.[35, 49, 79, 80, 87, 100, 101] Implementation strategies also need to address *both* the individual practitioner and organizational perspective.[15, 22, 37, 64, 72, 77, 79, 98] When practitioners decide individually what evidence to use in practice, considerable variability in practice patterns result,[71] potentially resulting in adverse patient outcomes.

For example, an "individual" perspective of EBP would leave the decision about use of evidence-based endotracheal suctioning techniques to each nurse and respiratory therapist. Some individuals may be familiar with the research findings for endotracheal suctioning while others may not. This is likely to result in different and conflicting practices being used as people change shifts every 8 to 12 hours. From an organizational perspective, endotracheal suctioning policies and procedures based on research are written, the evidence-based information is integrated into the clinical information systems, and adoption of these practices by nurses and other practitioners is systematically promoted in the organization. This includes assuring that practitioners have the

necessary knowledge, skills, and equipment to carry out the evidence-based endotracheal suctioning practice. The organizational governance supports use of these practices through various councils and committees such as the Practice Committee, Staff Education Committee, and interdisciplinary EBP work groups.

The Translation Research Model,[35] built on Rogers's seminal work on diffusion of innovations,[39] provides a guiding framework for testing and selecting strategies to promote adoption of EBPs. According to the Translation Research Model, adoption of innovations such as EBPs are influenced by the nature of the innovation (e.g., the type and strength of evidence, the clinical topic) and the manner in which it is communicated (disseminated) to members (nurses) of a social system (organization, nursing profession).[35] Strategies for promoting adoption of EBPs must address these four areas (nature of the EBP topic; users of the evidence; communication; social system) within a context of participative change (see Figure 2)**.** This model provided the framework for a multisite study that tested the effectiveness of a multifaceted TRIP intervention designed to promote adoption of evidence-based acute pain management practices for hospitalized older adults. The intervention improved the quality of acute pain management practices and reduced costs.[81] The model is currently being used to test the effectiveness of a multifaceted TRIP intervention to promote evidence-based cancer pain management of older adults in home hospice settings.[*] This guiding framework is used herein to overview what is known about implementation interventions to promote use of EBPs in health care systems (see Evidence Table).

Nature of the Innovation or Evidence-Based Practice

Characteristics of an innovation or EBP topic that affect adoption include the relative advantage of the EBP (e.g., effectiveness, relevance to the task, social prestige); the compatibility with values, norms, work, and perceived needs of users; and complexity of the EBP topic.[39] For example, EBP topics that are perceived by users as relatively simple (e.g., influenza vaccines for older adults) are more easily adopted in less time than those that are more complex (acute pain management for hospitalized older adults). Strategies to promote adoption of EBPs related to characteristics of the topic include practitioner review and "reinvention" of the EBP guideline to fit the local context, use of quick reference guides and decision aids, and use of clinical reminders.[53, 59, 60, 65, 74, 82, 102–107] An important principle to remember when planning implementation of an EBP is that the attributes of the EBP topic as perceived by users and stakeholders (e.g., ease of use, valued part of practice) are neither stable features nor sure determinants of their adoption. Rather it is the interaction among the characteristics of the EBP topic, the intended users, and a particular context of practice that determines the rate and extent of adoption.[22, 35, 39]

Studies suggest that clinical systems, computerized decision support, and prompts that support practice (e.g., decisionmaking algorithms, paper reminders) have a positive effect on aligning practices with the evidence base.[15, 51, 65, 74, 80, 82, 102, 104, 107–110] Computerized knowledge management has consistently demonstrated significant improvements in provider performance and patient outcomes.[82] Feldman and colleagues, using a just-in-time e-mail reminder in home health care, have demonstrated (1) improvements in evidence-based care and outcomes for patients with heart failure,[64, 77] and (2) reduced pain intensity for cancer patients.[75] Clinical information systems should deploy the evidence base to the point of care and incorporate

[*] Principal Investigator: Keela Herr (R01 grant no. CA115363-01; National Cancer Institute (NCI))

computer decision-support software that integrates evidence for use in clinical decisionmaking about individual patients.[40, 104, 111–114] There is still much to learn about the "best" manner of deploying evidence-based information through electronic clinical information systems to support evidence-based care.[115]

Methods of Communication

Interpersonal communication channels, methods of communication, and influence among social networks of users affect adoption of EBPs.[39] Use of mass media, opinion leaders, change champions, and consultation by experts along with education are among strategies tested to promote use of EBPs. Education is necessary but not sufficient to change practice, and didactic continuing education alone does little to change practice behavior.[61, 116] There is little evidence that interprofessional education as compared to discipline-specific education improves EBP.[117] Interactive education, used in combination with other practice-reinforcing strategies, has more positive effects on improving EBP than didactic education alone.[66, 68, 71, 74, 118, 119] There is evidence that mass media messages (e.g., television, radio, newspapers, leaflets, posters and pamphlets), targeted at the health care consumer population, have some effect on use of health services for the targeted behavior (e.g., colorectal cancer screening). However, little empirical evidence is available to guide framing of messages communicated through planned mass media campaigns to achieve the intended change.[120]

Several studies have demonstrated that opinion leaders are effective in changing behaviors of health care practitioners,[22, 68, 79, 100, 116, 121–123] especially in combination with educational outreach or performance feedback. Opinion leaders are from the local peer group, viewed as a respected source of influence, considered by associates as technically competent, and trusted to judge the fit between the innovation and the local situation.[39, 116, 121, 124–127] With their wide sphere of influence across several microsystems/units, opinion leaders' use of the innovation influences peers and alters group norms.[39,128] The key characteristic of an opinion leader is that he or she is trusted to evaluate new information in the context of group norms. Opinion leadership is multifaceted and complex, with role functions varying by the circumstances, but few successful projects to implement innovations in organizations have managed without the input of identifiable opinion leaders.[22, 35, 39, 81, 96] Social interactions such as "hallway chats," one-on-one discussions, and addressing questions are important, yet often overlooked components of translation.[39, 59] Thus, having local opinion leaders discuss the EBPs with members of their peer group is necessary to translate research into practice. If the EBP that is being implemented is interdisciplinary in nature, discipline-specific opinion leaders should be used to promote the change in practice.[39]

Change champions are also helpful for implementing innovations.[39, 49, 81, 129–131] They are practitioners within the local group setting (e.g., clinic, patient care unit) who are expert clinicians, passionate about the innovation, committed to improving quality of care, and have a positive working relationship with other health care professionals.[39, 125, 131, 132] They circulate information, encourage peers to adopt the innovation, arrange demonstrations, and orient staff to the innovation.[49, 130] The change champion believes in an idea; will not take "no" for an answer; is undaunted by insults and rebuffs; and, above all, persists.[133] Because nurses prefer interpersonal contact and communication with colleagues rather than Internet or traditional sources of practice knowledge,[134–137] it is imperative that one or two change champions be identified for each patient care unit or clinic where the change is being made for EBPs to be enacted by direct care providers.[81, 138] Conferencing with opinion leaders and change champions

periodically during implementation is helpful to address questions and provide guidance as needed.[35, 66, 81, 106]

Because nurses' preferred information source is through peers and social interactions,[134–137, 139, 140] using a core group in conjunction with change champions is also helpful for implementing the practice change.[16, 110, 141] A core group is a select group of practitioners with the mutual goal of disseminating information regarding a practice change and facilitating the change by other staff in their unit/microsystem.[142] Core group members represent various shifts and days of the week and become knowledgeable about the scientific basis for the practice; the change champion educates and assists them in using practices that are aligned with the evidence. Each member of the core group, in turn, takes the responsibility for imparting evidence-based information and effecting practice change with two or three of their peers. Members assist the change champion and opinion leader with disseminating the EBP information to other staff, reinforce the practice change on a daily basis, and provide positive feedback to those who align their practice with the evidence base.[15] Using a core-group approach in conjunction with a change champion results in a critical mass of practitioners promoting adoption of the EBP.[39]

Educational outreach, also known as academic detailing, promotes positive changes in practice behaviors of nurses and physicians.[22, 64, 66, 71, 74, 75, 77, 81, 119, 143] Academic detailing is done by a topic expert, knowledgeable of the research base (e.g., cancer pain management), who may be external to the practice setting; he or she meets one-on-one with practitioners in their setting to provide information about the EBP topic. These individuals are able to explain the research base for the EBPs to others and are able to respond convincingly to challenges and debates.[22] This strategy may include providing feedback on provider or team performance with respect to selected EBP indicators (e.g., frequency of pain assessment).[66, 81, 119]

Users of the Innovation or Evidence-Based Practice

Members of a social system (e.g., nurses, physicians, clerical staff) influence how quickly and widely EBPs are adopted.[39] Audit and feedback, performance gap assessment (PGA), and trying the EBP are strategies that have been tested.[15, 22, 65, 66, 70–72, 81, 98, 124, 144] PGA and audit and feedback have consistently shown a positive effect on changing practice behavior of providers.[65, 66, 70, 72, 81, 98, 124, 144, 145] PGA (baseline practice performance) informs members, at the *beginning* of change, about a practice performance and opportunities for improvement. Specific practice indicators selected for PGA are related to the practices that are the focus of evidence-based practice change, such as every-4-hour pain assessment for acute pain management.[15, 66, 81]

Auditing and feedback are ongoing processes of using and assessing performance indicators (e.g., every-4-hour pain assessment), aggregating data into reports, and discussing the findings with practitioners *during* the practice change.[22, 49, 66, 70, 72, 81, 98, 145] This strategy helps staff know and see how their efforts to improve care and patient outcomes are progressing throughout the implementation process. Although there is no clear empirical evidence for how to provide audit and feedback,[70, 146] effects may be larger when clinicians are active participants in implementing change and discuss the data rather than being passive recipients of feedback reports.[67, 70] Qualitative studies provide some insight into use of audit and feedback.[60, 67] One study on use of data feedback for improving treatment of acute myocardial infarction found that (1) feedback data must be perceived by physicians as important and valid, (2) the data source and timeliness of data feedback are critical to perceived validity, (3) time is required to establish credibility of data within a hospital, (4) benchmarking improves the validity of the data feedback, and (5) physician leaders can enhance the effectiveness of data feedback. Data feedback that profiles an

individual physician's practices can be effective but may be perceived as punitive; data feedback must persist to sustain improved performance; and effectiveness of data feedback is intertwined with the organizational context, including physician leadership and organizational culture.[60] Hysong and colleagues[67] found that high-performing institutions provided timely, individualized, nonpunitive feedback to providers, whereas low performers were more variable in their timeliness and nonpunitiveness and relied more on standardized, facility-level reports. The concept of useful feedback emerged as the core concept around which timeliness, individualization, nonpunitiveness, and customizability are important.

Users of an innovation usually try it for a period of time before adopting it in their practice.[22, 39, 147] When "trying an EBP" (piloting the change) is incorporated as part of the implementation process, users have an opportunity to use it for a period of time, provide feedback to those in charge of implementation, and modify the practice if necessary.[148] Piloting the EBP as part of implementation has a positive influence on the extent of adoption of the new practice.[22, 39, 148]

Characteristics of users such as educational preparation, practice specialty, and views on innovativeness may influence adoption of an EBP, although findings are equivocal.[27, 39, 130, 149–153] Nurses' disposition to critical thinking is, however, positively correlated with research use,[154] and those in clinical educator roles are more likely to use research than staff nurses or nurse managers.[155]

Social System

Clearly, the social system or context of care delivery matters when implementing EBPs.[2, 30, 33, 39, 60, 84, 85, 91, 92, 101, 156–163] For example, investigators demonstrated the effectiveness of a prompted voiding intervention for urinary incontinence in nursing homes, but sustaining the intervention in day-to-day practice was limited when the responsibility of carrying out the intervention was shifted to nursing home staff (rather than the investigative team) and required staffing levels in excess of a majority of nursing home settings.[164] This illustrates the importance of embedding interventions into ongoing processes of care.

Several organizational factors affect adoption of EBPs.[22, 39, 79, 134, 165–167] Vaughn and colleagues[101] demonstrated that organizational resources, physician full-time employees (FTEs) per 1,000 patient visits, organizational size, and whether the facility was located in or near a city affected use of evidence in the health care system of the Department of Veterans Affairs (VA). Large, mature, functionally differentiated organizations (e.g., divided into semiautonomous departments and units) that are specialized, with a focus of professional knowledge, slack resources to channel into new projects, decentralized decisionmaking, and low levels of formalization will more readily adopt innovations such as new practices based on evidence. Larger organizations are generally more innovative because size increases the likelihood that other predictors of innovation adoption—such as slack financial and human resources and differentiation—will be present. However, these organizational determinants account for only about 15 percent of the variation in innovation adoption between comparable organizations.[22] Adler and colleagues[168] hypothesize that while more structurally complex organizations may be more innovative and hence adopt EBPs relatively early, less structurally complex organizations may be able to diffuse EBPs more effectively. Establishing semiautonomous teams is associated with successful implementation of EBPs, and thus should be considered in managing organizational units.[168–170]

As part of the work of implementing EBPs, it is important that the social system—unit, service line, or clinic—ensures that policies, procedures, standards, clinical pathways, and documentation systems support the use of the EBPs.[49, 68, 72, 73, 103, 140, 171] Documentation forms or clinical information systems may need revision to support changes in practice; documentation systems that fail to readily support the new practice thwart change.[82]

Absorptive capacity for new knowledge is another social system factor that affects adoption of EBPs. Absorptive capacity is the knowledge and skills to enact the EBPs; the strength of evidence alone will not promote adoption. An organization that is able to systematically identify, capture, interpret, share, reframe, and recodify new knowledge, and put it to appropriate use, will be better able to assimilate EBPs.[82, 103, 172, 173] A learning organizational culture and proactive leadership that promotes knowledge sharing are important components of building absorptive capacity for new knowledge.[66, 139, 142, 174] Components of a receptive context for EBP include strong leadership, clear strategic vision, good managerial relations, visionary staff in key positions, a climate conducive to experimentation and risk taking, and effective data capture systems. Leadership is critical in encouraging organizational members to break out of the convergent thinking and routines that are the norm in large, well-established organizations.[4, 22, 39, 122, 148, 163, 175]

An organization may be generally amenable to innovations but not ready or willing to assimilate a particular EBP. Elements of system readiness include tension for change, EBP-system fit, assessment of implications, support and advocacy for the EBP, dedicated time and resources, and capacity to evaluate the impact of the EBP during and following implementation. If there is tension around specific work or clinical issues and staff perceive that the situation is intolerable, a potential EBP is likely to be assimilated if it can successfully address the issues, and thereby reduce the tension.[22, 175]

Assessing and structuring workflow to fit with a potential EBP is an important component of fostering adoption. If implications of the EBP are fully assessed, anticipated, and planned for, the practice is more likely to be adopted.[148, 162, 176] If supporters for a specific EBP outnumber and are more strategically placed within the organizational power base than opponents, the EBP is more likely to be adopted by the organization.[60, 175] Organizations that have the capacity to evaluate the impact of the EBP change are more likely to assimilate it. Effective implementation needs both a receptive climate and a good fit between the EBP and intended adopters' needs and values.[22, 60, 140, 175, 177]

Leadership support is critical for promoting use of EBPs.[33, 59, 72, 85, 98, 122, 178–181] This support, which is expressed verbally, provides necessary resources, materials, and time to fulfill assigned responsibilities.[148, 171, 182, 183] Senior leaders need to create an organizational mission, vision, and strategic plan that incorporate EBP; implement performance expectations for staff that include EBP work; integrate the work of EBP into the governance structure of the health care system; demonstrate the value of EBPs through administrative behaviors; and establish explicit expectations that nurse leaders will create microsystems that value and support clinical inquiry.[122, 183, 184]

A recent review of organizational interventions to implement EBPs for improving patient care examined five major aspects of patient care. The review suggests that revision of professional roles (changing responsibilities and work of health professionals such as expanding roles of nurses and pharmacists) improved processes of care, but it was less clear about the effect on improvement of patient outcomes. Multidisciplinary teams (collaborative practice teams of physicians, nurses, and allied health professionals) treating mostly patients with prevalent

chronic diseases resulted in improved patient outcomes. Integrated care services (e.g., disease management and case management) resulted in improved patient outcomes and cost savings. Interventions aimed at knowledge management (principally via use of technology to support patient care) resulted in improved adherence to EBPs and patient outcomes. The last aspect, quality management, had the fewest reviews available, with the results uncertain. A number of organizational interventions were not included in this review (e.g., leadership, process redesign, organizational learning), and the authors note that the lack of a widely accepted taxonomy of organizational interventions is a problem in examining effectiveness across studies.[82]

An organizational intervention that is receiving increasing attention is tailored interventions to overcome barriers to change.[162, 175, 185] This type of intervention focuses on first assessing needs in terms of what is causing the gap between current practice and EBP for a specified topic, what behaviors and/or mechanism need to change, what organizational units and persons should be involved, and identification of ways to facilitate the changes. This information is then used in tailoring an intervention for the setting that will promote use of the specified EBP. Based on a recent systematic review, effectiveness of tailored implementation interventions remains uncertain.[185]

In summary, making an evidence-based change in practice involves a series of action steps and a complex, nonlinear process. Implementing the change will take several weeks to months, depending on the nature of the practice change. Increasing staff knowledge about a specific EBP and passive dissemination strategies are not likely to work, particularly in complex health care settings. Strategies that seem to have a positive effect on promoting use of EBPs include audit and feedback, use of clinical reminders and practice prompts, opinion leaders, change champions, interactive education, mass media, educational outreach/academic detailing, and characteristics of the context of care delivery (e.g., leadership, learning, questioning). It is important that senior leadership and those leading EBP improvements are aware of change as a process and continue to encourage and teach peers about the change in practice. The new practice must be continually reinforced and sustained or the practice change will be intermittent and soon fade, allowing more traditional methods of care to return.[15]

Practice Implications From Translation Science

Principles of Evidence-Based Practice for Patient Safety

Several translation science principles are informative for implementing patient safety initiatives:

- First, consider the context and engage health care personnel who are at the point of care in selecting and prioritizing patient safety initiatives, clearly communicating the evidence base (strength and type) for the patient safety practice topic(s) and the conditions or setting to which it applies. These communication messages need to be carefully designed and targeted to each stakeholder user group.
- Second, illustrate, through qualitative or quantitative data (e.g., near misses, sentinel events, adverse events, injuries from adverse events), the reason the organization and individuals within the organization should commit to an evidence-based safety practice topic. Clinicians tend to be more engaged in adopting patient safety initiatives when they understand the evidence base of the practice, in contrast to administrators saying, "We must do this because it is an external regulatory requirement." For example, it is critical

to converse with busy clinicians about the evidence-based rationale for doing fall-risk assessment, and to help them understand that fall-risk assessment is an external regulatory agency expectation because the strength of the evidence supports this patient safety practice.

- Third, didactic education alone is never enough to change practice; one-time education on a specific safety initiative is not enough. Simply improving knowledge does not necessarily improve practice. Rather, organizations must invest in the tools and skills needed to create a culture of evidence-based patient safety practices where questions are encouraged and systems are created to make it easy to do the right thing.
- Fourth, the context of EBP improvements in patient safety need to be addressed at each step of the implementation process; piloting the change in practice is essential to determine the fit between the EBP patient safety information/innovation and the setting of care delivery. There is no one way to implement, and what works in one agency may need modification to fit the organizational culture of another context.
- Finally, it is important to evaluate the processes and outcomes of implementation. Users and stakeholders need to know that the efforts to improve patient safety have a positive impact on quality of care. For example, if a new barcoding system is being used to administer blood products, it is imperative to know that the steps in the process are being followed (process indicators) and that the change in practice is resulting in fewer blood product transfusion errors (outcome indicators).

Research Implications

Translation science is young, and although there is a growing body of knowledge in this area, we have, to date, many unanswered questions. These include the type of audit and feedback (e.g., frequency, content, format) strategies that are most effective, the characteristics of opinion leaders that are critical for success, the role of specific context variables, and the combination of strategies that are most effective. We also know very little about use of tailored implementation interventions, or the key context attributes to assess and use in developing and testing tailored interventions. The types of clinical reminders that are most effective for making EBP knowledge available at the point of care require further empirical explanation. We also know very little about the intensity and intervention dose of single and multifaceted strategies that are effective for promoting and sustaining use of EBPs or how the effectiveness differs by type of topic (e.g., simple versus complex). Only recently has the context of care delivery been acknowledged as affecting use of evidence, and further empirical work is needed in this area to understand how complex adaptive systems of practice incorporate knowledge acquisition and use. Lastly, we do not know what strategies or combination of strategies work for whom, in what context, why they work in some settings or cases and not others, and what is the mechanism by which these strategies or combination of strategies work.

This is an exciting area of investigation that has a direct impact on implementing patient safety practices. In planning investigations, researchers must use a conceptual model to guide the research and add to the empirical and theoretical understanding of this field of inquiry. Additionally, funding is needed for implementation studies that focus on evidence-based patient safety practices as the topic of concern. To generalize empirical findings from patient safety implementation studies, we must have a better understanding of what implementation strategies work, with whom, and in what types of settings, and we must investigate the underlying

mechanisms of these strategies. This is likely to require mixed methods, a better understanding of complexity science, and greater appreciation for nontraditional methods and realistic inquiry.[87]

Conclusion

Although the science of translating research into practice is fairly new, there is some guiding evidence of what implementation interventions to use in promoting patient safety practices. However, there is no magic bullet for translating what is known from research into practice. To move evidence-based interventions into practice, several strategies may be needed. Additionally, what works in one context of care may or may not work in another setting, thereby suggesting that context variables matter in implementation.[80]

Titler, Ph.D., R.N., F.A.A.N., University of Iowa Hospitals and Clinics, Department of Nursing Services and Patient Care, 200 Hawkins Drive RM T10 GH, Iowa City, IA 52242-1009; e-mail: Marita-titler@uiowa.edu.

Search Strategy

Several electronic databases were searched (MEDLINE®, CINAHL®, PubMed®) using terms of evidence-based practice research, implementation research, and patient safety. (The terms "quality improvement" or "quality improvement intervention research" were not used.) The Cochrane Collaboration–Cochrane Reviews was also searched to look for systematic reviews of specific implementation strategies, and the *Journal of Implementation Science* was also reviewed. I also requested the final reports of the TRIP I and TRIP II studies funded by AHRQ. Classic articles known to the author were also included in this chapter (e.g., Locock et al.[123]).

Evidence Table. Evidence-Based Practice in Nursing

Source	Issue Related to EBP	Design Type*	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Findings
Berner 2003[121]	Local opinion leaders.	Group randomized controlled trial (RCT). Evidence level 2.	RCT 3 study arms: no intervention, traditional health care QI; opinion leader (OL) plus QI (level 2). Outcomes = 6 evidence-based quality indicators for 1994 unstable angina guidelines (level 2).	Hospitals in Alabama. Patients admitted to an Alabama hospital during 1997–98 (baseline) and 1999–2000 (followup) with ICD-9 CM codes of unstable angina, angina pectoris, coronary artery disease, and chest pain unspecified. Mean age of patients was >70 years of age.	Peer nominated opinion leader added to a Centers for Medicare and Medicaid Services (CMS) QI intervention.	OL treatment effects (over QI group) found for antiplatelet medication within 24 hours and heparin use (2 of 5 indicators).

Bootsmiller 2004[103]	Assess the implementation methods for 4 clinical practice guidelines (CPGs) in the VA health care system.	Retrospective cohort study. Evidence level 5.	Survey methods with questionnaire sent to 416 quality managers, primary care administrators, or others involved with guideline implementation in primary care at 143 VA medical centers with primary care clinics (level 9). Modified Dillman method was used. Outcomes: methods used to implement guidelines (level 4).	Primary care clinics of VA medical centers. Study population is individual responsible for guideline implementation. 242 surveys returned from 130 hospitals. CPGs were chronic obstructive pulmonary disease (COPD), diabetes, heart failure, and major depressive disorder.	Total number of interventions used were counted and type of interventions used to implement CPGs were categorized as consistently effective, variably effective, and minimally effective, based on Bero's categories: Consistently effective: - Forms created/revised - Computer interactive education - Internet discussion groups - Responsibilities of nonphysicians changed academic detailing Variably effective: - CPG workgroup - Clinical meetings to discuss CPG Minimally effective: - Providers receive brief summary - Providers receive CPG - Providers receive pocket guide - Storyboards - Instructional tape of CPG - Grand rounds	Commonly used approaches were clinical meetings to discuss guidelines (variably effective/Bero's classification), provider receipt of brief summary (minimally effective classification), forms created or revised (consistently effective classification), responsibilities of nonphysicians revised (consistently effective classification). Most facilities used 4–7 approaches. Consistently and minimally effective approaches were used most frequently. Strategies used together almost always included one consistently effective approach.

Bradley 2004[60]	Describe the implementation process for the Hospital Elder Life Program (HELP)—an evidence-based program for improving care of older patients.	Descriptive prospective study.	Qualitative analyses of implementation process at the beginning of implementation and every 6 months for up to 18 months.	8 hospitals implementing HELP. In-depth, open-ended interviews were conducted by telephone with physicians, nurses, volunteers, and administrative staff involved in the HELP implementation.		Major themes in implementing the HELP program were (1) gain internal support for the program, recognizing diverse requirements and goals; (2) ensure effective clinical leadership in multiple roles; (3) integrate with existing geriatric programs to foster coordination rather than competition; (4) balance program fidelity with hospital-specific circumstances; (5) document and publicize positive outcomes; (6) maintain momentum while changing practice and shifting organizational culture.

Source	Issue Related to EBP	Design Type*	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Findings
Bradley 2004[177]	Identify key themes about effective approaches for data feedback as well as pitfalls to avoid in using data feedback to support performance improvement efforts.	Retrospective cohort study. Evidence level 5.	Qualitative study with open-ended interviews of clinical and administrative staff at 8 hospitals representing a range of sizes, geographical regions, and beta-blocker use rate after AMI (level 9). Outcomes = key themes in use of data feedback.	8 hospitals. Interviewed physicians (n = 14), nurses (n = 15), quality management (n = 11), and administrative (n = 5) staff who were identified as key in improving care of patients with AMI.	Data feedback for improving performance of beta-blocker use after AMI.	7 major themes: Data must be perceived by physicians as valid to motivate change. It takes time to develop credibility of data within a hospital. The source and timeliness of the data are critical to perceived validity. Benchmarking improves the validity of the data feedback. Physician leaders can enhance the effectiveness of data feedback. Data feedback that profiles an individual physician's practices can be effective but may be perceived as punitive. Data feedback must persist to sustain improved performance. Effectiveness of data feedback might be intertwined with the organizational context, including physician leadership and organizational culture.

Carter 2005[61]	Evaluation of the relationship between physicians' knowledge of hypertension guidelines and blood pressure (BP) control in their patients.	Cross-sectional study	Cross-sectional study of physicians' knowledge about Joint National Committee (JNC) 7 hypertension guidelines (level 4). Outcomes were BP values of patients each physician treated.	Study setting was two academic primary care clinics located in the same academic medical center. The sample was 32 primary care physicians and 613 patients they treated. Mean age of physicians was 41 years (Standard Deviation [SD]. = 10.9), majority were men (66%).	Association between physician knowledge and BP control. Covariates of presence of diabetes, patient age.	There was a strong inverse relationship between BP control rates and correct responses by physicians on the knowledge test (r = -0.524; *p* = .002). Strong correlation was also found between correct responses on the knowledge survey and a higher mean systolic BP (r = 0.453; *p* = .009). When the covariates of patient age and diabetes were added to the model, there was no longer a significant association between physician knowledge and BP control. However, the correlation (in the multivariate model) was still in the same direction; for every 5 points better on the knowledge test, there was a 16% decrease in the rate of BP control (*p* = .13), and for every 10 years increase in patient age, there was a 16% decrease in BP control (*p* = .04).

Chin 2004[62, 186]	To determine the additive effect of additional support for organizational change techniques and chronic care management as they are added to the Health Disparities Collaborative initiatives to improve diabetes care in community health centers.	RCT	34 centers were randomized to a standardized intensity arm (Health Disparities Collaborative initiatives) or high intensity arm. (level 2). Outcomes included process of care measures; laboratory values based on American Diabetes Association (ADA) recommendations; and patient surveys of satisfaction with provider's communication style and overall care, attitudes about interacting with providers, knowledge of ADA recommendations, and provider performance of key processes of care (levels 1 and 2).	34 community health centers from the Midwest or West Central clusters that participated in the 1998–99 or 1999–2000 Diabetes Collaborative of the Bureau of Primary Health Care in Improving Diabetes Care Collaboratively in the Community. These centers care for the medically underserved. In the standard arm, there were 843 patients at baseline and 665 in the followup standard intensity group. 993 patients were in the high intensity arm at baseline and 818 postinterventions high intensity group. Mean age of subjects ranged from 56 to 58, a majority were female, and white.	All 34 centers were community health centers that are overseen by the Bureau of Primary Health Care and had participated in the Health Disparities Collaborative to improve diabetes care. Interventions included forming a QI team, adoption of the Plan-Do-Study-Act (PDSA) cycle for QI, learning sessions, data feedback, monthly teleconferences, and regional meetings over a year. The centers randomized to the standard intensity arm continued to receive quarterly data-feedback reports, conference calls with other centers, and a yearly in-person meeting with other health centers. The high intensity sites received the standard intensity interventions plus additional support in organizational change strategies, chronic care management, and strategies to engage patients in behavioral change designed to get them to be more active in their care.	Centers in the high intensity arm showed higher rates of Hgb A1c and urine microalbumin assessment, eye exam, foot exam, dental referral, and increased prescription of home glucose monitoring postintervention as compared to the standard intensity arm. No significant differences by treatment arm were noted for patient survey data.

Davey 2005[187]	To estimate the effectiveness of persuasive interventions, restrictive interventions, and structural interventions (alone or in combination) in promoting prudent antibiotic prescribing to hospital inpatients.	Systematic literature review. Evidence level 1. (Table 3.1)	RCTs, quasi-randomized controlled trials, controlled before and after studies, and interrupted time series studies (levels 2 and 3). Outcomes were appropriate antibiotic prescribing and patient outcomes, including length of stay, inpatient mortality, and 28-day mortality (levels 1 and 2).	66 studies (43 interrupted time series studies, 13 RCTs, 6 controlled before/after studies, 2 controlled clinical trials, 1 cluster clinical trial, 1 cluster randomized trial. The majority of studies (42) were from the United States. Study participants were health care professionals who prescribe antibiotics to hospitalized inpatients receiving acute care.	Interventions were categorized as persuasive interventions (distribution of educational materials; local consensus process; educational outreach visits; local opinion leaders; reminders provided verbally, on paper, or via the computer; audit and feedback), restrictive interventions (formulary restrictions, prior authorization requirements, therapeutic substations, automatic stop orders and antibiotic policy changes), and structural (changing from paper to computerized records, introduction of quality monitoring mechanisms).	A wide variety of interventions has been shown to be effective in changing antibiotic prescribing for hospitalized patients. Restrictive interventions have a greater immediate impact than persuasive interventions, although their impact on clinical outcomes and long-term effects are uncertain.

Estabrooks 2004[20]	To map research utilization as a field of study in nursing and identify the structure of this scientific community, including the current network of researchers.	Systematic literature review.	Bibliometric analysis to map the development and structure of the field. Outcomes were journal patterns of publication, country patterns of publication, author patterns of publication, references per article, co-occurrence of words, citation patterns, interdisciplinary flow of information, within field diffusion of information.	630 articles (350 opinion articles, 65 conceptual articles, 112 research utilization studies, 103 research articles) published in 194 different journals.	Article location and data abstraction up to 2001/2002.	On the basis of co-citation, scholars at the core of the field are Horsley, Stetler, Fun, Titler, and Goode. The field has attained a critical mass of nurse scholars and scholarly works as demonstrated by more than 60% of the references in articles are to research by nurses. Emergence of interdisciplinary collaborative groups in this field is yet evolving.
Feldman 2005[64] Murtaugh 2005[77]	Tested a basic and an augmented e-mail reminder to improve evidence-based care of individuals with heart failure (HF) in home health care settings.	RCT. Evidence level 2 (Table 3.1)	Prospective randomized trail with 3 groups (control, basic e-mail reminder, augmented e-mail reminder). Outcome measures were nursing practices and patient outcomes. Level 1 outcomes.	Older adults with heart failure (n = 628; $\bar{x}$ age = 72) and nurses (n = 354; $\bar{x}$ age = 43.6; 93% female) caring for those patients. Home health care agency in a large urban setting.	Basic e-mail reminder upon patient admission to the nurses' care that highlighted 6 HF-specific clinical practices for improving patient outcomes. Augmented intervention included basic e-mail reminder plus package of material for care of HF patient (medication management, prompter card for improving communication with physicians, self-care guide for patients) and followup outreach by a clinical nurse specialist (CNS) who served as an expert peer.	Basic and augmented intervention significantly improved delivery of evidence-based care over control group; augmented intervention improved care more than basic intervention.

Foxcroft and Cole 2000[188]	Organizational infrastructures to promote evidence-based nursing practice.	Systematic literature review.	RCT, controlled clinical trial, and interrupted time series (levels 2, 3, 7). Unit of intervention was organizational, comprising nurses or groups of professionals including nurses. Outcomes = objective measures of evidence-based practice (levels 1 and 2).	121 papers were identified as potentially relevant, but no studies met the inclusion criteria. After relaxing the criteria, 7 studies were included and all used a retrospective case study design (15).	Entire or identified component of an organizational infrastructure to promote effective nursing interventions.	No high-quality studies that reported the effectiveness of organizational infrastructure interventions to promote evidence-based nursing practice were identified. Conceptual models that were assessed positively against criteria are briefly included in this review.
Greenhalgh 2005[22]	Diffusion, spread, and sustainability of innovations in the organization and delivery of health services.	Systematic literature review. Evidence level 1 (Table 3.1).	Metanarrative review.	Comprehensive report of factors and strategies to promote use of innovations in health care services.	7 key topic areas addressed: characteristics of the innovation, adoption by individuals, assimilation by organizations, diffusion and dissemination, the inner context, the outer context, implementation and routinization.	Complex process requiring multiple strategies. Excellent resource of scholarly work in knowledge transfer and innovation adoption.

Source	Issue Related to EBP	Design Type*	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Findings
Grilli 2002[120]	Assess the effect of mass media on use of health services.	Systematic literature review. Evidence level 1 (Table 3.1).	RCTs, controlled clinical trials, controlled before-and-after studies, and interrupted time series analysis (levels 2, 3, 4). Outcomes were objective measures of health services (drugs, medical or surgical procedures, diagnostic tests) by professionals, patients, or the public.	26 papers reporting 20 time series and on controlled before-and-after study met the inclusion criteria.	All studies relied on a variety of media, including radio, TV, newspapers, posters, and leaflets. To meet inclusion criteria, studies had to use mass media, be targeted at the population level, and aimed to promote/discourage use of evidence-based health care interventions or change public lifestyle.	Mass media campaigns have a positive influence upon the manner in which health services are used. Mass media have an important role in influencing use of health care interventions. Mass media campaign is one of the tools that may encourage use of effective services and discourage those of unproven effectiveness.

Grimshaw 2004[144] Grimshaw 2006[65]	Assessment of the effectiveness of guideline dissemination and implementation strategies.	Systematic literature review. Evidence level 1 (Table 3.1).	RCTs, controlled clinical trials, controlled before-and-after studies, interrupted time series from 1966 to 1998 (levels 2, 3, 4). Outcomes were objective measures of provider behavior and/or patient outcomes (levels 1, 2).	Studies of guidelines aimed at medically qualified professionals. (Studies on guidelines aimed at multiple professionals were included only if results for medical professionals were reported separately or if medical professionals represented more than 50% of the targeted population.) The review included 110 clustered RCTs, 29 patient RCTs, 7 clustered controlled clinical trials, 10 patient controlled clinical trials, 40 controlled before-and-after studies, and 39 interrupted time series designs. The most common setting was primary care (39%) followed by inpatient settings (19%) and generalist ambulatory settings (19%). Other studies addressed settings across sites of care or were in a variety of other types of settings (e.g., nursing homes).	Interventions were educational materials, educational meetings, educational outreach, consensus, opinion leaders, patient-directed interventions, audit and feedback, reminders, other professional (marketing, mass media), financial interventions, organizational interventions, structural interventions, and regulatory interventions. Studies compared single interventions to no intervention, multifaceted interventions to no intervention, or a control receiving one or more single intervention. This systematic review compared findings from studies with a single intervention against a “no-intervention” control group; single interventions against an “intervention” control group; multifaceted interventions against “no-intervention” control group (7 different types of comparisons); multifaceted interventions against intervention controls (4 different types of comparisons). A total of 309 comparisons were done. This systematic review also includes economic evaluations and cost analysis.	This is a comprehensive review of implementation strategies. The reader is referred to the technology report, as a comprehensive summary of findings is beyond the scope of this chapter. Overall findings include: the overall quality of studies were poor; the majority of comparisons (86.6%) observed improvements in care; reminders are a potentially effective intervention and are likely to result in moderate improvements in care processes; educational outreach may result in modest improvements in processes of care; educational materials and audit and feedback appeared to result in modest improvements in care; multifaceted interventions did not appear to be more effective than single interventions; multifaceted interventions did not appear to increase with the number of

Horbar 2004[66]	To evaluate a coordinated, multifaceted implementation intervention designed to promote evidence-based surfactant therapy.	Clustered randomized trial.	Cluster randomized trial with randomization at the hospital level (level 2). Outcomes were proportion of infants receiving their first dose of surfactant in the delivery room, proportion of infants treated with surfactant who received their fist dose more than 2 hours after birth, and time after birth at which the first dose of surfactant was administered; proportion of all infants who developed a pneumothorax, and proportion of all infants who died prior to discharge (levels 1 and 2).	114 hospitals with membership in the Vermont Oxford Network, not participating in a formal quality improvement collaborative, with the majority of infants born in the hospital rather than transferred in and born in 1998 and 1999; received the first dose of surfactant within 15 minutes after birth. Subjects were high-risk preterm infants 23 to 29 weeks gestational age. The intervention group had 3,313 neonates and 2,726 in the comparison group.	The multifaceted 18-month intervention included quarterly audit and feedback of data, evidence reviews, an interactive 3-day training workshop, and ongoing support to participants via conference calls and e-mail discussion.	The proportion of infants 23 to 29 weeks gestational age receiving surfactant in the delivery room was significantly higher in the intervention than the control group for all infants (OR = 5.38). Those who received surfactant more than 2 hours after birth was significantly lower in the intervention than control group (OR = 0.35). There were no significant differences in rates of mortality or pneumothorax between groups. Infants in the intervention group received their first dose of surfactant significantly sooner after birth with a median time of 21 minutes as compared to 78 minutes in the control group ($p <$ .001).

Source	Issue Related to EBP	Design Type*	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Findings
Hysong 2006[67]	Exploratory study of how high-performing facilities and low-performing facilities differ in the way they use clinical data for feedback purposes.	Cross-sectional study.	Descriptive, qualitative, cross-sectional study. Subjects were interviewed using a semistructured interview format (level 4). Outcomes were participant responses to questions asking how CPGs were currently implemented at their facility, including strategies, barriers, and facilitators.	Study setting was 6 VA medical settings (from a pool of 15) ranked as high performing (n = 3) and low performing (n = 3) organizations with respect to 20 indicators for 6 chronic conditions treated in outpatient settings. 102 employees across 6 facilities were the subjects. Within each facility, facility leadership (n = 25), middle management (n = 34), and outpatient clinic personnel (n = 33) were interviewed.	No study intervention, but transcripts were analyzed using grounded theory, and passages that specifically addressed feedback of data were included in the analyses.	High-performing institutions provided timely, individualized, nonpunitive feedback to providers, whereas low performers were more variable in their timeliness and nonpunitiveness and relied more on standardized, facility-level reports. The concept of actionable feedback emerged as the core concept around which timeliness, individualization, nonpunitiveness, and customizability are important.

Source	Issue Related to EBP	Design Type*	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Findings
Irwin & Ozer 2004[68] Ozer 2005[189]	To determine if a systems intervention for primary care providers resulted in increased preventive screening and counseling of adolescent patients compared to usual care.	Controlled trial.	2 intervention outpatient pediatric clinics and 2 comparison outpatient pediatric clinics in the same health system were used to test the intervention. Level 3. Outcomes were adolescent reports of whether their provider screened and counseled them for risky behavior (tobacco, alcohol, drugs, sexual behavior, and safety—helmet and seatbelt use). Level 2.	4 outpatient pediatric clinics within Kaiser Permanente, Northern California. 76 clinicians were in the study (37 in each treatment arm). Adolescent reports of provider behavior—across all phases of the study, the intervention sample size was 1,717, and the comparison sample size was 911. Mean age of adolescents was 14.8 years (SD = 1.34). Data were collected from adolescents at baseline, following training, and following forms implementation.	The intervention was 2 phases. First phase was an 8-hour clinician training in adolescent preventative services based on social cognitive theory, including didactic education, discussions, demonstration role plays, and interactive role-plays at each intervention site (4 months). Second phase was implementation of screening and chart forms customized for this study (4 months). All clinicians participated in the training and the tools were implemented on a clinic-wide basis. Local opinion leaders were integrally involved in the intervention.	Average baseline screening rates in the intervention group ranged from 42% for helmet use to 71% for tobacco use. Following training, screening rates increased significantly across all 6 target areas, ranging from 70% for helmet use to 85% for tobacco use, and remained constant during the posttools implementation phase. Counseling rates followed a similar pattern. By comparison, screening and counseling rates in the comparison group tended to remain stable across all 3 data collection points. Screening and counseling rates were significantly higher in the intervention group than the comparison group after the full implementation of the intervention; screening and counseling rates were significantly higher in the intervention than the comparison group after the training component of the intervention; screening and counseling rates

Jacobson 2005[69]	Assessment of the effectiveness of patient reminder and patient recall systems in improving immunization rates.	Systematic literature review. Evidence level 1 (Table 3.1).	RCTs, controlled before-and-after studies, and interrupted time series (levels 2 and 3). Outcomes were immunization rates or the proportion of the target population up to date on recommended immunizations.	43 studies. Approximately three-fourths of the studies were conducted in the United States. The majority of the studies were RCTs. Studies included children and adults and a variety of settings.	Reminder methods and recall systems included letters to patients, postcards, person-to-person telephone calls, autodialer, postcard and phone combination, and tracking and outreach.	Patients receiving patient reminder and recall interventions were more likely to have been immunized or up to date on immunizations (OR = 1.70). All types of reminders and recall were found to be effective, with increases in immunization rates on the order of 5%–20%. Person-to-person telephone reminders were the most effective single approach (OR = 1.92). Letter reminders were similar to phone reminders in effectiveness (OR = 1.89). Reminder and recall interventions were effective for children and adults in all types of settings.

Source	Issue Related to EBP	Design Type*	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Findings
Jamtvedt 2006[70]	Use of audit and feedback to improve professional practice.	Systematic literature review. Metaregression along with visual and qualitative analyses. Evidence level 1 (Table 3.1).	Randomized trails (level 2). Outcome measures = noncompliance with guideline recommendations (level 2).	85 studies. 53 trials in North America, 16 in Europe, 8 in Australia, 2 in Thailand, 1 in Uganda. In most trials, the professionals were physicians; in 2 studies the providers were nurses, and 5 involved mixed providers.	Audit and feedback defined as any summary of clinical performance of health care over a specified period of time, delivered in written, electronic, or verbal format.	Audit and feedback can be effective in improving professional practice with effects generally moderate. Absolute effects of audit and feedback are more likely to be larger when baseline adherence to recommended practice is low. Audit and feedback should be targeted where it is likely to effect change.
Jones 2004[71]	Improvement of pain practices in nursing homes.	Clustered RCT. Evidence level 2 (Table 3.1).	An intervention study to improve pain practices (RCT). The intervention was implemented in 6 nursing homes (level 2). Outcomes = pain knowledge and attitudes of staff; pain assessment and treatment decisions based on 2 short case studies; barriers to effective pain management. Outcomes measured from questionnaires distributed to nurses and nursing assistants (level 3).	12 long-term care sites in Colorado—6 in urban sites and 6 in rural sites. Nursing homes ranged in size from 65 to 150 beds.	Education for staff; resident educational video; designation of a 3-member internal pain team; pain vital sign; site visits with discussion of feedback reports; pain rounds and consultations. Implementation phase lasted 9 months.	No significant treatment effect for staff knowledge or staff attitudes; staff in the treatment group were 2.5 times more likely to chose an aggressive pain management strategy than those in the control group (p = .002); no significant treatment effect for decreasing barriers to pain management.

Katz 2004[72,98]	Testing an intervention to improve use of EBP smoking cessation guidelines.	RCT with randomization at the clinic level. Evidence level 2 (Table 3.1).	Prospective randomized trial of 8 primary care clinics in southern Wisconsin (level 2). Outcomes included staff performance and patient quit rates (levels 1 and 2).	8 community-based clinics (6 family practice, 2 internal medicine).	Multimodality intervention (5 components—didactic and interactive education of staff, modified vital signs stamp imprinted on each encounter form, offering nicotine patches and telephone counseling, group and confidential individual feedback to providers on whether clinicians had assessed smoking status and provided cessation counseling as needed) to implement AHRQ smoking cessation guideline.	Quit rates higher in experimental (E) sites at 2 and 6 months. Percentage of patients advised to quit smoking higher at E sites than control (C) sites.
Levine 2004[73]	Test a nurse-administered, protocol-driven model for comprehensive preventive services in a low-income outpatient setting. Focus was on preventive services as recommended by the U.S. Preventive Services Task Force (USPSTF).	Controlled trial.	Controlled comparison using a convenience sample of patients within a single practice (n = 987) and a usual care group (n = 666) obtained from a random sample of households from the postal zip codes served by the same practice (level 3). Outcomes were percentage of preventive services initiated in the treatment arm versus the comparison arm (level 1).	Primary care single practice with internal medicine, family medicine, and pediatric clinics. Patients receiving care in this clinic between January and September 2001. Children = 514 (about 170 in each of 3 age groups: 0–2, 3–7, 8–17; 63% African American). Adults = 473 (about 170 in each age group 18–49 and 50–64; 130 in 65 or older; 76% African American).	Offer all identified preventive services that are needed using a nursing model under the guidance of a protocol agreed upon by the medical staff.	Use of a nursing protocol for USPSTF recommendations was associated with a significantly higher percentage of preventive services initiated (99.6%) in the experimental arm as compared to usual care group (18.6%) ($p < .001$).

Locock 2001[123]	Role of opinion leader in innovation and change.	Systematic literature review.	Case studies using principally qualitative methods. Outcomes = effectiveness of opinion leaders in promoting change/adoption of evidence-based practices (level 2.)	Variety of acute care and primary care settings. Evaluation of PACE project[100] and Welsh Clinical National Demonstration Project.	Local opinion leaders defined as those perceived as having particular influence on the beliefs and actions of their colleagues, either positive or negative.	Both expert and peer opinion leaders have important and distinct roles to play in promoting adoption of EBPs. Opinion leadership is part of a wider process that cannot be understood in isolation of other contextual variables with which it may interact. The value of the expert opinion leader is in the initial stages of getting an idea rolling, endorsing the evidence, and translating it into a form that is acceptable to practitioners and takes account of their local experience. Peer opinion leader influence seems to be important in mainstream implementation, providing a role model for fellow practitioners and building their confidence. The local context may modify or magnify the opinion leader influence.

Loeb 2004[74]	To test the effect of a multifaceted implementation intervention for safely reducing antimicrobial prescriptions for suspected urinary tract infections in nursing home residents.	Cluster RCT.	The study design was randomization of 24 nursing homes to an intervention group or a usual care group (level 2). Main outcome measures were antimicrobials prescribed for urinary infections, total antimicrobials, hospitalizations, and deaths (level 1).	Free standing, community-based nursing homes with 100 or more beds in Hamilton, Ontario, region and Boise, Idaho, region were sites for the study. The numbers of residents were 2,156 in the intervention arm and 2,061 in the comparison arm.	Implementation of algorithms for diagnostic testing and antibiotic prescribing developed from research findings. Implementation strategies included interactive education with nurses, one-on-one meeting with physicians that see more than 80% of the patients, written materials, real-time paper reminders, and quarterly outreach visits targeted to nurses and physicians.	The rate of antimicrobial use for suspected urinary infections was significantly lower in the treatment arm (1.17 courses of antimicrobials per 1,000 resident days) as compared to the comparison arm (1.59 per 1,000 patient days) (*P* = .03). The proportion of antimicrobials prescribed for suspected urinary infections were lower in the intervention arm than the comparison arm (*P* = .02). There was no significant difference for total antimicrobial use, rate of urine cultures obtained, overall hospitalization, or mortality.

Lozano 2004[174]	To test the effectiveness of 2 implementation interventions in reducing asthma symptom days as compared to usual care.	Cluster RCT.	RTC. Outcomes were annualized asthma symptom days, asthma-specific functional health status, and frequency of brief oral steroid bursts (level 1).	42 primary care practices in 3 locales and targeted 3–17-year-old children with mild to moderate persistent asthma enrolled in practices affiliated with man-aged care organizations. Among the 638 patient subjects, the mean age was 9.4 years (SD = 3.5); the majority were white (66%) and boys (60%).	3 treatment arms were usual care, provider (MD, PA, NP) oriented strategy of targeted education through an on-site peer leader, and an organizational approach that combined the provider education with a nurse-run intervention (planned care arm) to better organize chronic asthma care in the primary care practice.	Children in the planned care arm had 13.3 fewer symptoms annually (P = .02) and 39% lower oral steroid burst rate per year relative to usual care (P = .01). Those in the peer leader arm showed a 36% decrease in annualized steroid bursts per year as compared to usual care (P = .008). Improvements in asthma-specific functional status were also found for both the peer leader and planned care arm as compared to usual care.
McDonald 2005[75]	Testing of 2 computer-based reminder interventions designed to promote evidence-based pain management practices among home care nurses.	RCT. Evidence level 2 (Table 3.1).	Nurses were randomly assigned to one of 3 treatment groups (control, basic e-mail reminder, augmented e-mail reminder). Outcomes = pain management practices of nurses and patient's pain (levels 1 and 2).	Home health care. Nurses were mostly female (> 90%) with an average age of 43.3 years.	Basic e-mail reminder that focused on 6 key practices (2 treatment arms) was sent to nurse every time an eligible cancer patient with pain was admitted to his/her care. Nurses in the augmented intervention group also received provider prompts, patient education material, and CNS outreach.	Nursing pain management practices did not differ significantly among the groups (P < .05), but pain levels were lower in the 2 treatment groups as compared to the control group. Patients treated by nurses in the augmented group had a 25% reduction in the probability of hospitalization.

O'Brien 1997[119]	Assess the effect of outreach visits on improving professional practice or patient outcomes.	Systematic literature review. Evidence level 1 (Table 3.1).	Randomized trials (level 2). Outcomes of provider performance (level 2).	18 trials. Providers were mainly primary care physicians practicing in community settings. In 13 trials the behaviors were prescribing practices. 10 trials in North America, 4 in Europe, 2 in Indonesia, and 2 in Australia.	Outreach visits defined as use of a trained person who meets with providers in their practice settings to provide information with the intent of changing provider's performance. The information may include feedback about performance.	Positive effects on practice were observed in all studies. Only 1 study measured a patient outcome. Educational outreach visits, particularly when combined with social marketing, appear to be a promising approach to modifying health professional behavior, especially prescribing. Further research is needed to identify key characteristics of outreach visits important to success.
O'Brien 1999[116]	Assessment of the use of local opinion leaders on the practice of health professionals or patient outcomes.	Systematic literature review. Evidence level 1 (Table 3.1).	RCTs (level 2). Outcomes were objectively measured provider performance in a health care setting or health outcomes (levels 1 and 2).	Focus was on health care providers responsible for patient care.	Use of providers nominated by their colleagues as educationally influential. 8 studies met inclusion criteria. A variety of patient problems were targeted.	In 3 trials that measured patient outcomes, 1 achieved an impact on practice. Only 2 trials provided strong evidence for improving performance of health care providers. Local opinion leaders may be important change agents for some problems.

O'Brien 2001[118]	Assess the effects of educational meetings on professional practice and health care outcomes.	Systematic literature review. Evidence level 1 (Table 3.1).	Randomized trials and well-designed quasi-experimental studies (levels 2 and 3). Outcomes were objectively measured health professional practice behaviors or patient outcomes in a setting where health care was provided (levels 1, 2, 3).	32 studies met inclusion criteria with 30 RCTs. 24 studies were in North America, 2 in the United Kingdom, and 1 each in Australia, Brazil, France, Indonesia, Sri Lanka, and Zambia. Most of the study participants were physicians; 4 included nurses, and 3 other health professionals.	The intervention was defined as continuing education: meetings, conferences, lectures, workshops, seminars, symposia, and courses that occurred off-site from the practice setting. Education was defined as didactic (predominately lectures with Q and A), or interactive (sessions that involved some type of interaction in small, moderate, or large groups). 7 studies were didactic and 25 were interactive. Duration and frequency of the intervention varied widely.	The few studies that compared didactic education to no intervention did not show an effect on professional practice. Studies that used interactive education were more likely to be effective in improving practice. Studies did not include information to determine what makes some interactive educational sessions more effective than others. Interactive workshops can result in moderately large changes in professional practice. Didactic education alone is unlikely to change professional practice.

Redfern 2003[79]	Evaluation of the South Thames Evidence-based Practice (STEP) project.	Pretest and posttest.	Each of the 9 projects followed a pretest/posttest design within a clinical audit framework over a period of 27 months (level 6). Outcomes = intermediate outcomes of uptake of change by staff and patient outcomes (levels 1 and 2).	9 projects that focused on improving evidence-based nursing practices. UK sites included acute care wards, community nursing services, and long-term care. Topics were leg ulcer management, breast-feeding, pressure ulcer care, nutrition in stroke patients (n = 2), Use of functional independence measure (FIM) assessment tool, assessment of continence, assessment and transfer of older adults on discharge from hospital, family therapy in schizophrenia.	A 2-week training program followed by 3 monthly seminars, staff training program, active support in the practice setting.	Intermediate outcomes improved in most projects; leaders' ratings of staff adherence were moderate or better in the majority of the projects; patient outcomes improved in most projects. Organizational factors were found to have a major impact on achieving successful change in practice. Having enough staff of the right skill mix, strong leadership, supportive managers and colleagues, and organizational stability are important to successful change. Project leaders and a credible change agent who works with practitioners face-to-face to encourage enthusiastic involvement are also important.

Shaw 2005[185]	Tailored interventions to address specific identified barriers to change in professional performance.	Systematic literature review with metaregression. Evidence level 1 (Table 3.1).	RCTs (level 2). Outcomes = professional performance, patient outcomes, or both (levels 1 and 2).	15 RCTs. 7 in primary care or community settings and health care professionals responsible for patient care. 10 in North America, 2 in the United Kingdom, 2 in Indonesia, and 1 in Norway.	An intervention was defined as tailored if it was chosen after identification of barriers and to overcome those barriers.	Results were mixed with variation in the direction and size of effect. The effectiveness of tailored interventions remains uncertain, and more rigorous trials including process evaluations are needed.
Titler 2006[81]	Testing a TRIP intervention for promoting adoption of evidence-based acute pain management practices for care of older adults hospitalized with hip fracture.	RCT with randomization at the clinic level. Evidence level 2 (Table 3.1).	Prospective randomized trial of 12 acute care hospitals in the Midwest United States (level 2). Outcomes included nurse and physician performance, patient pain levels, and cost effectiveness (levels 1 and 2).	12 large (n = 2), medium (n = 6), and small hospitals (n = 4) in the Midwest.	Multifaceted intervention that addressed the characteristics of the EBP, the users, the social context of care, and communication, based on Rogers' diffusion of innovation framework.	Acute pain management strategies improved more in the experimental than comparison group, and the TRIP intervention saved health care dollars.

Wensing 2006[82]	Organizational strategies for improving professional performance, patient outcomes, and costs.	Systematic literature review. Evidence level 1.	A review of reviews that included RCTs, interrupted time series, controlled before/after studies, and prospective comparative observational studies (levels 2, 5, 6, 7). Outcomes = professional practice and patient outcomes (levels 1 and 2).	36 reviews were included. A taxonomy of organizational strategies to improve patient care was developed to organize findings.	Revision of professional roles, multidisciplinary teams, integrated care services, knowledge management, quality management.	Revision of professional roles can improve professional performance, while positive effects on patient outcomes remain uncertain. Multidisciplinary teams can improve patient outcomes but have primarily been tested in highly prevalent chronic diseases. Integrated care systems can improve patient outcomes and save costs; they have been extensively tested in highly prevalent chronic conditions. Professional performance and patient outcomes can be improved by implementation of computers in clinical practice settings (knowledge management). Effects of quality management on professional performance and patient outcomes remain uncertain. There is growing evidence of rigorous evaluations of organizational strategies, but the evidence underlying some strategies is limited; for no strategy can

Chapter 8. Health Services Research: Scope and Significance

Donald M. Steinwachs, Ronda G. Hughes

Background

The provision of high-quality, affordable, health care services is an increasingly difficult challenge. Due to the complexities of health care services and systems, investigating and interpreting the use, costs, quality, accessibility, delivery, organization, financing, and outcomes of health care services is key to informing government officials, insurers, providers, consumers, and others making decisions about health-related issues. Health services researchers examine the access to care, health care costs and processes, and the outcomes of health services for individuals and populations.

The field of health services research (HSR) is relied on by decisionmakers and the public to be the primary source of information on how well health systems in the United States and other countries are meeting this challenge. The "goal of HSR is to provide information that will eventually lead to improvements in the health of the citizenry."[1] Drawing on theories, knowledge, and methods from a range of disciplines,[2] HSR is a multidisciplinary field that moves beyond basic and applied research, drawing on all the health professions and on many academic disciplines, including biostatistics, epidemiology, health economics, medicine, nursing, operations research, psychology, and sociology.[3]

In 1979, the Institute of Medicine defined HSR as "inquiry to produce knowledge about the structure, processes, or effects of personal health services"[4] (p. 14). This was expanded upon in 2002 by AcademyHealth, the professional organization of the HSR field, with the following definition, which broadly describes the scope of HSR:

> Health services research is the multidisciplinary field of scientific investigation that studies how social factors, financing systems, organizational structures and processes, health technologies, and personal behaviors affect access to health care, the quality and cost of health care, and ultimately our health and well-being. Its research domains are individuals, families, organizations, institutions, communities, and populations.[5]

More specifically, HSR informs and evaluates innovations in health policy. These include changes in Medicare and Medicaid coverage, disparities in access and utilization of care, innovations in private health insurance (e.g., consumer-directed health plans), and trends among those without health insurance.[6–10] The health care industry continues to change, and HSR examines the impact of organizational changes on access to care, quality, and efficiency (e.g., growth in for-profit hospital systems). As new diagnostic and treatment technologies are introduced, HSR examines their impact on patient outcomes of care and health care costs.

The definition of HSR also highlights the importance of examining the contribution of services to the health of individuals and broader populations. HSR applied at the population level is particularly important in understanding health system performance and the impact of health policy on the public's health. In the United States, the *National Healthcare Quality Report*,[11] *National Healthcare Disparities Report*,[12] and *Healthy People Year 2010*[13] exemplify our

capacity for monitoring quality and assessing change. These reports tell us that the American quality of care is inconsistent and could be substantially improved. The associated cost of health care services is monitored by the Centers for Medicare & Medicaid Services (CMS). CMS reports tell us that American health care is the most expensive in the world, consuming approximately 16 percent of America's gross domestic product.[14]

Beyond health policy, HSR examines the process of care and the interactions of patients and providers. For example, HSR methods have been developed to describe doctor-patient communication patterns and examine their impact on patient adherence, satisfaction, and outcomes of care.[15–17]

Advances in HSR measurement methodologies have made possible policy innovations. Prospective payment of hospitals, nursing homes, and home health care by Medicare became possible with the development of robust case-mix measurement systems.[18] CMS was able to initiate a pay-for-performance demonstration, rewarding hospitals with better quality performance, using valid and robust measures of quality.[14] Innovations in health care policy are frequently made possible by advances in measurement of indicators of health system performance.

History of Health Services Research

The history of HSR is generally considered to have begun in the 1950s and 1960s with the first funding of grants for health services research focused on the impact of hospital organizations.[19, 20] On the contrary, HSR began with Florence Nightingale when she collected and analyzed data as the basis for improving the quality of patient care and outcomes.[21] Also significant in the history of HSR was the concern raised about the distribution, quality, and cost of care in the late 1920s that led to one of the first U.S. efforts to examine the need for medical services and their costs, undertaken in 1927 by the Committee on the Costs of Medical Care.[22] The committee published a series of 28 reports and recommendations that have had a significant impact on how medical care is organized and delivered in the United States.[23] Other key reports of historical importance to HSR were, for example, the national health survey in 1935–1936 by the Public Health Service, the inventory of the nation's hospitals by the American Hospital Association's Commission on Hospital Care in 1944, and studies by the American Hospital Association's Commission on Chronic Illness on the prevalence and prevention of chronic illness in the community.[23]

In 1968, the National Center for Health Services Research and Development was established as part of the U.S. Public Health Services to address concerns with access to health services, quality of care, and costs. The Center funded demonstration projects to measure quality and investigator-initiated research grants. In 1989, Congress created the Agency for Health Care Policy and Research and broadened its mission to focus attention on variations in medical practice, patient outcomes of care, and the dissemination of evidence-based guidelines for the treatment of common disorders. Later Congress reauthorized and renamed the agency, Agency for Healthcare Research and Quality (AHRQ). AHRQ provides Federal leadership for the field, investing in methods for quality measurement, development of patient safety methods, and health information technology (e.g., electronic health records and decision support systems).

The Federal role in HSR has expanded over time, and investments in HSR are made by multiple Federal agencies. In addition to AHRQ, the U.S. Department of Veterans Affairs, Centers for Disease Control and Prevention, the National Institutes of Health, CMS, and other

Federal agencies fund HSR. The diversification of funding comes, in part, from the recognition that HSR is important in managing health care systems, such as the Veterans Health Administration, and provides essential information on the translation of scientific discoveries into clinical practice in American communities, such as those funded by National Institutes of Health. It is estimated that total Federal funding of HSR was $1.5 billion in 2003, of which AHRQ was responsible for approximately 20 percent.[24]

Private funding of HSR has also grown over time. Funding by private foundations has a significant role and complements Federal funding. Among the many foundations funding HSR are the Robert Wood Johnson Foundation, Commonwealth Fund, Kaiser Family Foundation, Kellogg Foundation, and Hartford Foundation. Other private funding sources include the health care industry, for example, pharmaceutical companies, health insurers, and health care systems.

Goals for Health Services and Patient Outcomes

The goal of health services is to protect and improve the health of individuals and populations. In a landmark 2001 report, *Crossing the Quality Chasm: A New Health System for the 21st Century*,[25] the Institute of Medicine (IOM) of the National Academy of Sciences proposed that the goals for health services should include six critical elements:

1. **Patient Safety:** Patients should not be harmed by health care services that are intended to help them. The IOM report, *To Err Is Human*,[26] found that between 46,000 and 98,000 Americans were dying in hospitals each year due to medical errors. Subsequent research has found medical errors common across all health care settings. The problem is not due to the lack of dedication to quality care by health professionals, but due to the lack of systems that prevent errors from occurring and/or prevent medical errors from reaching the patient.
2. **Effectiveness:** Effective care is based on scientific evidence that treatment will increase the likelihood of desired health outcomes. Evidence comes from laboratory experiments, clinical research (usually randomized controlled trials), epidemiological studies, and outcomes research. The availability and strength of evidence varies by disorder and treatment.
3. **Timeliness:** Seeking and receiving health care is frequently associated with delays in obtaining an appointment and waiting in emergency rooms and doctors' offices. Failure to provide timely care can deny people critically needed services or allow health conditions to progress and outcomes to worsen. Health care needs to be organized to meet the needs of patients in a timely manner.
4. **Patient Centered:** Patient-centered care recognizes that listening to the patient's needs, values, and preferences is essential to providing high-quality care. Health care services should be personalized for each patient, care should be coordinated, family and friends on whom the patient relies should be involved, and care should provide physical comfort and emotional support.
5. **Efficiency:** The U.S. health care system is the most expensive in the world, yet there is consistent evidence that the United States does not produce the best health outcomes[27–30] or the highest levels of satisfaction.[31] The goal is to continually identify waste and inefficiency in the provision of health care services and eliminate them.
6. **Equity:** The health care system should benefit all people. The evidence is strong and convincing that the current system fails to accomplish this goal. The IOM report, *Unequal Treatment*,[32] documented pervasive differences in the care received by racial and ethnic minorities. The findings were that racial and ethnic minorities are receiving poorer quality of

care than the majority population, even after accounting for differences in access to health services.

Crossing the Quality Chasm concludes that for the American health care system to attain these goals, transformational changes are needed.[25] The field of HSR provides the measurement tools by which progress toward these goals is assessed, as seen in the *National Healthcare Quality Report.*[11] Equally important, health services researchers are developing and evaluating innovative approaches to improve quality of care, involving innovations in organization, financing, use of technology, and roles of health professionals.

Evaluating the Quality of Health Care

HSR evaluation of quality of care has proven to be an inexact science and complex, even though its definition is relatively simple: "Quality of care is the degree to which health services for individuals and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge."[1] This definition draws attention to the importance of the application of current professional knowledge in the diagnostic and treatment processes of health care. The goal of quality care is to increase the likelihood of achieving desired health outcomes, as expressed by the patient.

The complexity in measuring quality comes from gaps in our knowledge regarding which services, for which patients, will actually improve the likelihood of desired health outcomes. Also, patients need not have the same desired health outcomes and therefore might not receive the same care for an identical health problem, further complicating the measurement of quality of care. Quality measurement has advanced substantially, but it remains early in its development.

The conceptual framework widely applied in evaluating quality comes from years of research and the insightful analysis of Avedis Donabedian.[33] He formalized the conceptual model for describing, analyzing, and evaluating the quality of care using three dimensions: (1) structure, (2) process, and (3) outcome. This model is applied in the evaluation of health services and the accreditation of health care providers and organizations.

Seminal research about variation in the quality of care patients received brought to focus the need to monitor and improve the quality of health care. Wennberg and Gittelsohn[34, 35] found wide variation in practice patterns among community physicians, surgical procedures, and hospitals. Brook and colleagues[36] found that a small number of physicians were responsible for a large number of improperly administered injections. This was the precursor to research on the appropriateness of procedures and services under specific circumstances[36, 37] as well as the development of practice guidelines and standards for quality care.[38] Yet the challenge of research on variations in care is the implication of the inappropriateness of care. The challenge is determining whether there is a direct relationship between rates of utilization, variations in appropriateness, and quality of care.

One of the challenges in understanding quality, how to measure it, and how to improve it is the influence of physical, socioeconomic, and work environments. Income, race, and gender—as well as individuals within society and organizations—influence health and risks to health.[40] Researchers have found that differences in internal factors, such as collaborative relationships with physicians, decentralized clinical decisionmaking, and positive administrative support, impact nurse and patient outcomes[41, 42] and the quality and safety of care.[43] Differences in external factors, such as insurance and geographic location, can influence access to available health care professionals and resources, what type of care is afforded patients, and the impact of

care on patients. The structure, process, and outcome dimensions of quality are influenced by both internal and external factors.

Structure of Health Care

The structure of health care broadly includes the facilities (e.g., hospitals and clinics), personnel (e.g., number of nurses and physicians), and technology that create the capacity to provide health services. Structural characteristics are expected to influence the quality of health care services. One component in the accreditation of health care facilities (e.g., hospitals, nursing homes) is the review of the adequacy of structural characteristics, including staffing, on-call resources, technology, and support services (laboratory, pharmacy, radiology). The structural resources of health care facilities and organizations are the foundation upon which quality health care services are provided.

Process of Care

The interactions between the health care providers and patients over time comprise the process of health care. The process of care may be examined from multiple perspectives: the sequence of services received over time, the relationship of health services to a specific patient complaint or diagnosis, and the numbers and types of services received over time or for a specific health problem. Examining the time sequence of health care services provides insights into the timeliness of care, organizational responsiveness, and efficiency. Linking services to a specific patient complaint or diagnosis provides insights into the natural history of problem presentation and the subsequent processes of care, including diagnosis, treatment, management, and recovery. Examining the natural history of a presenting health complaint across patients will reveal variations in patterns of care. For example, presenting complaints for some patients never resolve into a specific diagnosis. An initial diagnosis may change as more information is obtained. Patients may suffer complications in the treatment process. Also, the process of care may provide insights into outcomes of care (e.g., return visit for complications). Generally it is not possible to examine the process of care and determine how fully the patient has recovered prior health status by the end of the episode of treatment. For this reason, special investigations are needed to assess outcomes of care.

Evaluation of the process of care can be done by applying the six goals for health care quality.[25] Was the patient's safety protected (i.e., were there adverse events due to medical errors or errors of omission)? Was care timely and not delayed or denied? Were the diagnosis and treatments provided consistent with scientific evidence and best professional practice? Was the care patient centered? Were services provided efficiently? Was the care provided equitable? Answers to these questions can help us understand if the process of care needs improvement and where quality improvement efforts should be directed.

Outcomes of Care

The value of health care services lies in their capacity to improve health outcomes for individuals and populations. Health outcomes are broadly conceptualized to include clinical measures of disease progression, patient-reported health status or functional status, satisfaction with health status or quality of life, satisfaction with services, and the costs of health services.

Historically, quality assessment has emphasized clinical outcomes, for example, disease-specific measures. However, disease-specific measures may not tell us much about how well the patient is able to function and whether or not desired health outcomes have been achieved. To understand the patients' outcomes, it is necessary to ask patients about their outcomes, including health status, quality of life, and satisfaction with services. HSR has developed valid and robust standardized questionnaires to obtain patient-reported information on these dimensions of health outcomes. As these are more widely applied, we are learning about the extent to which health care services are improving health.

Public Health Perspective on Health Services

Another perspective on health care services comes from the field of public health in which preventive health services are conceptualized at three levels: primary, secondary, and tertiary prevention.[44] Primary prevention includes immunizations, healthy lifestyles, and working and living in risk-free environments. Primary prevention seeks to prevent disease or delay its onset. Examples of primary prevention include immunizations against infectious disease; smoking prevention or cessation; and promotion of regular exercise, weight control, and a balanced diet. Secondary prevention includes the range of interventions that can reduce the impact of disease morbidity once it occurs and slow its progression. With the increasing burden of chronic diseases, much of the health care provided is directed at secondary prevention. Tertiary prevention is directed at rehabilitation for disabilities resulting from disease and injury. The goal of tertiary prevention is to return individuals to the highest state of functioning (physical, mental, and social) possible. The public health framework expands the structure, process, and outcome conceptual model by identifying the role and value of health services at three stages: prior to onset of disease, disease management, and disease recovery and rehabilitation.

Methodologies and Data Sources Used in Health Services Research

The interdisciplinary character of HSR draws on methods and data sources common to the many disciplines that form the intellectual underpinnings of the field. This section discusses the measurement of effectiveness and efficacy of health services and some of the methods and data sources used to understand effectiveness. Effectiveness is one of the six goals of health services. Effectiveness is interrelated with the other five goals, and some of these interrelationships are discussed.

Efficacy and Effectiveness

An important distinction is made between efficacy and effectiveness of health services. Efficacy is generally established using randomized controlled trial (RCT) methods to test whether or not clinical interventions make a difference in clinical outcomes. A good example is the series of studies required for Food and Drug Administration approval of a new drug before it is certified as safe and efficacious and allowed to be used in the United States. Efficacy research is generally done with highly select groups of patients where the impact of the drug can be validly measured and results are not confounded by the presence of comorbid conditions and

their treatments. The efficacy question is: What impact does a clinical intervention have under ideal conditions?

In contrast, effectiveness research is undertaken in community settings and generally includes the full range of individuals who would be prescribed the clinical intervention. Many of these individuals will have multiple health problems and be taking multiple medications, unlike those who were recruited to the RCT. Effectiveness research is seeking to answer the question: Who will benefit from the clinical intervention among all those people in the community who have a specific health problem(s)?

Both efficacy and effectiveness questions are important. Logically, effectiveness research would be conducted after finding the clinical intervention to be efficacious. However, there are many treatments for which no efficacy information exists; the treatments are accepted as common practice, and it would not be ethical to withhold treatments from a control group in an RCT. As a result, effectiveness research may not have the benefit of efficacy findings.

The routine use of an RCT to evaluate efficacy began in the 1960s and is the accepted procedure for evaluating new medications. However, this standard is not applied across all health care services and treatments. Most surgical procedures are not evaluated using an RCT. Intensive care units have never been evaluated using an RCT, nor are nurse staffing decisions in hospitals or the evaluation of many medical devices. We currently accept different standards of evidence depending on the treatment technology. As a result, the level of evidence guiding clinical and public health decisionmaking varies.

Methods for Effectiveness Research

A variety of methods are used to examine effectiveness of health services. RCT methods are not usually applied in effectiveness research because the intervention being studied has demonstrated efficacy or is acknowledged as accepted clinical practice. When this is true, it would be unethical to randomly assign individuals who would be expected to benefit from the intervention to a control group not receiving an efficacious treatment. We will discuss when RCT methods can be used to test effectiveness and provide several examples. More commonly, effectiveness research uses statistical methods for comparing treatments across nonequivalent groups.

RCT and Policy Research

RCT study methods can be used to compare the effectiveness and costs of services across randomly assigned representative population groups. In an RCT, study participants are randomly assigned to two or more groups to ensure comparability and avoid any selection bias. At least one group receives an intervention (clinical, organizational, and/or financial), and usually one group serves as a control group, receiving a current standard of care, sometimes referred to as "usual care." Two examples of effectiveness research using an RCT methodology to answer policy questions are described.

Health insurance experiment. Probably the first application of RCT methods in effectiveness research was undertaken in the 1970s as a health insurance experiment. The experiment was designed to test the impact on cost and health outcomes of different levels of insurance deductibles and copayment rates. A total of 3,958 people, ages 14–61, were randomized to a set of insurance plans and followed over 3 to 5 years.[45]

The economic impact of receiving free care in one plan versus being in a plan requiring payment out-of-pocket of deductibles and co-insurance had the expected impact on utilization. Those paying a share of their medical bills utilized approximately one-third fewer doctor visits and were hospitalized one-third less frequently.

The impact on 10 health measures of free health insurance versus paying a portion of medical care costs out of pocket was evaluated. The findings were that there was largely no effect on health as measured by physical functioning, role functioning, mental health, social contacts, health perceptions, smoking, weight, serum cholesterol, diastolic blood pressure, vision, and risk of dying.[46] The exceptions were that individuals with poor vision improved under free care, as did low-income persons with high blood pressure.

Medicare preventive services experiment. A more recent example of RCT methods applied in HSR is the Baltimore Medicare Preventive Services Demonstration. The study evaluated the impact on cost and outcomes of offering a defined preventive services package to Medicare beneficiaries. This was compared to usual Medicare coverage, which paid for few preventive services. The preventive services coverage being evaluated included an annual preventive visit with screening tests and health counseling. The physician could request a preventive followup visit during the year, which would also be covered. Medicare beneficiaries (n = 4,195) were randomized to preventive services (the intervention group) or usual care (the control group). Sixty-three percent of those in the intervention group had at least one preventive visit. Significant differences were found in health outcomes between intervention and control groups. Among the 45 percent with declining health status, as measured by the Quality of Well-Being scale,[47] the decline was significantly less in the group offered preventive services. Mortality was also significantly lower in the intervention group. There was no significant impact of preventive services on utilization and cost.[48]

Comparative Clinical Effectiveness and RCTs

The passage of the Medicare Prescription Drug, Improvement, and Modernization Act of 2003 (MMA) included provisions for the funding of comparative effectiveness studies. AHRQs' Effective Health Care Program (authorized under MMA Section 1013) informs comparative clinical effectiveness efforts by conducting and supporting research and evidence syntheses on priority topics to CMS.

Comparative effectiveness studies ask the question: Which of the alternative treatments available is best and for whom? Interest in this question reflects how advances in science have provided multiple treatment options for many conditions. Currently, there is no systematic process by which treatment options are compared and matched to the needs of different types of patients. Frequently, patients are started on one treatment and then may be prescribed alternative treatments if they cannot tolerate the treatment or if it is not as effective as expected. RCT methods can be used to evaluate comparative effectiveness of an intervention in treatment and control populations. This is ethical to do when there is no evidence that the treatments are not equivalent.

An example of a comparative effectiveness study using RCT methods is the CATIE study, testing alternative antipsychotic medications in the treatment of schizophrenia. A study of 1,493 persons with schizophrenia compared five of the newer antipsychotic medications (second generation) and also compared them against one of the first-generation antipsychotic medications.[49, 50] The findings were surprising to many. The second-generation antipsychotics

were no more effective in controlling psychotic symptoms than the first-generation drug. There was one exception, the drug Clozapine.[51] Furthermore, second-generation medications showed significant side effects that can affect health outcomes. These included weight gain, metabolic changes, extrapyramidal symptoms, and sedation effects. Each medication showed a somewhat different side-effect risk profile. From a positive perspective, the findings indicated that the clinician and patient can choose any of these medications as first-line treatment except Clozapine, which is generally used for treatment-resistant cases due to more intensive clinical monitoring requirements. The ultimate choice of treatment will depend on the patient's ability to tolerate side effects that vary by drug.

The conduct of any RCT is resource intensive, requiring the recruitment of participants, and participants must give informed consent to be randomized. The rationale for making this investment may depend on the importance of the policy or practice issue. As shown, RCT methods can be applied to address policy and clinical care concerns with effectiveness. To the extent that the RCT includes a broad cross-section of people who would be affected by a policy or receive a clinical treatment, this methodology provides robust effectiveness findings.

Comparing Effectiveness and Costs Across Nonequivalent Groups

A range of statistical methods can be used to compare nonequivalent groups (i.e., groups receiving different treatments or exposures when there has been no random assignment to ensure comparability of group membership). It is not practical to review all the specific statistical approaches that can be applied. In general, the statistical methods seek to adjust for nonequivalent characteristics between groups that are expected to influence the outcome of interest (i.e., make the comparisons fair). Statistical adjustment for nonequivalent characteristics is referred to as "risk adjustment." The foundations for risk adjustment come from multiple disciplines. Epidemiologic methods are routinely used to identify and estimate disease and outcomes risk factors. These methods are applicable in comparative effectiveness evaluations.[52]

Operations research uses methods for creating homogeneous groups predictive of cost or disease outcomes. These methods are used to make fair comparisons across provider practices and health plans and to control the cost of health care. They also have been used in designing payment systems, including diagnostically related groups used in Medicare's Prospective Payment System to reimburse hospitals for care rendered to Medicare beneficiaries, and resource-based relative value scales used in Medicare's physician payment system. Diagnostically related groups are used to standardize and rationalize patient care in hospitals—provided largely by nurses and other health professionals—and resource-based relative value scales are used to standardize and rationalize patient care in outpatient settings—care provided largely by physicians and nurse practitioners. Other disciplines also contribute to our understanding of risk factors for the range of health outcomes, including mortality, health and functional status, quality of life, and rehabilitation and return to work

The basic form of a nonequivalent group comparison includes adjusting the outcomes of each group for the risk factors that are known to affect the occurrence and/or severity of the outcomes being evaluated.[53] For many disease outcomes, risk factors include demographic characteristics (age, gender), disease-specific risk factors (e.g., health behaviors, environmental exposures, and clinical indicators of risk), and indicators of health status (e.g., presence of comorbid conditions). After adjustment for risks factors, variations in access to care and quality of care (e.g., choice of treatment and adherence to treatment) would be expected to explain the remaining observed

variation in outcomes. Ideally, the nonequivalent group comparison makes it possible to compare the effectiveness of alternative treatments and assess the impact of poor access to care. One limitation of this methodology is the limit of current knowledge regarding all relevant disease risk factors. Even when risk factors are known, limits on data availability and accuracy of risk factor measurement have to be considered.

Risk adjustment methods are also used to make cost comparisons across health care providers to determine which providers are more efficient. Instead of adjusting for disease risk factors, adjustments are made for the costliness of the patient mix (case mix) and differences in costs of labor, space, and services in the local area. Comparisons may be made to assess efficiency of providing specific services (e.g., hospitalization, office visit, or laboratory test). These comparisons would use case-mix measures that adjust for the costliness of different mixes of hospital episodes.[18] Comparisons of the total cost of care for insured populations would apply case-mix measures that adjust for disease and health factors that affect total cost of care.[54]

Data Sources for Effectiveness Research

A range of data sources is used in effectiveness research, including administrative and billing data, chart reviews and electronic health records, and survey questionnaires. The following discussion identifies major attributes of each category of data source.

Medical records. Medical records document the patient's presenting problem or condition, tests and physical exam findings, treatment, and followup care. The medical record is generally the most complete source of clinical information on the patient's care. However, medical records are generally not structured to ensure the physician or other provider records all relevant information. The completeness of medical record information can vary considerably. If the patient does not return for followup care, the medical record may provide no information on outcomes of care. If a patient sees multiple providers during the course of treatment, each with its own separate medical record, complete information on treatment requires access to all the records. Lack of standardization of medical records also can make abstracting records for research very resource intensive.

Administrative and billing data. Health care providers generally have administrative and billing data systems that capture a limited and consistent set of data on every patient and service provided. These systems uniquely identify the patient and link information on insurance coverage and billing. Each service received by the patient is linked to the patient using a unique patient identifier. Services are identified using accepted codes (e.g., ICD9-CM, CPT), together with date of service, provider identifier, and other relevant information for billing or management reporting. Administrative data make it possible to identify all individual patients seen by a provider and produce a profile of all services received by each patient over any defined time period. Administrative data are comprehensive and the data are generally complete (i.e., no problems with missing data). The primary limitation is the data set collected by administrative systems is very limited and lacks the detail of the medical record.

Administrative data systems can provide some insights into quality and outcomes of care. AHRQ has developed software that provides quality indicators and patient safety measures using one administrative data set, hospital discharge abstracts.[55, 56] Utilization-based indicators of outcome include rehospitalization, return to surgery during a hospitalization, and incidence of complications; some systems include information on death. Administrative data can efficiently provide quality and outcomes indicators for defined populations and for health systems. Other

applications of administrative data include assessing efficiency, timeliness, and equity. The limitation is that there are many health conditions and health outcomes that cannot currently be measured using administrative data.

Survey questionnaires. Neither the medical record nor the administrative data capture information on the patient's experience in health or patient-reported outcomes of care. Survey questionnaires are routinely used to obtain information on patient satisfaction in health plans. A widely used example is the Consumer Assessment of Healthcare Providers and Systems or CAHPS.[57]

Information on the impact of health conditions on health and functional status has to come from the patient. This may be obtained at the time of a visit or hospitalization. However, to assess patient outcomes of care, systematic followup of patients after the completion of treatment is generally required. This can be done using mail questionnaires, telephone interviews, or in-person interviews. The HSR field has developed health-status and quality-of-life measures that can be used no matter what health conditions the patient has.[47, 58–60] Numerous condition-specific measures of outcome are also used.[53]

Effectiveness research relies on a range of data sources. Some are routinely collected in the process of medical care and patient billing. Others may require special data collection, including medical record abstracts to obtain detailed clinical data and survey questionnaires to gain information on the patient's perspective on treatment and outcomes. Efficient strategies for examining effectiveness may use administrative data to examine a limited set of data on all patients, and a statistically representative sample of patients for in-depth analysis using data from chart abstracts and survey questionnaires.

Using HSR Methods To Improve Clinical Practice

HSR research tools can be applied in clinical settings to improve clinical practice and patient outcomes. These tools are used as part of quality improvement programs in hospitals, clinics, and health plans. Two examples illustrate applications to improve quality-of-care performance.

Evidence-based treatment. For many chronic medical conditions, clinical research has evaluated the efficacy of diagnostic methods and treatment interventions. As a result, evidence-based reviews of research literature can provide a basis for establishing quality-of-care criteria against which to judge current practice. In a national study of quality of medical care, it was found that only 55 percent of patients received evidence-based treatments for common disorders and preventive care.[61] The researchers examined treatment for a range of health conditions, using a national sample of medical records abstracts. For each quality criterion, a classification was applied to determine if the quality-of-care deficiency was one of underuse, overuse, or misuse. Greater problems were found with underuse (46 percent) than with overuse (11 percent). Quality of care varied by condition: senile cataracts scored highest, 78 percent of recommended care received, and alcohol dependence scored lowest, 10 percent of recommended care received. Overall, only about half of recommended care was received, frequently due to underuse of services.

Researchers have sought to identify why rates of conformance with evidence-based treatments are low. Frequently cited barriers to evidence-based practice include physician disagreement with the evidence, perception that patients will not accept treatment, low ratings of self-efficacy as a provider of the treatment, and difficulty of integrating the evidence-based

treatment into existing practice.[62] More needs to be learned how to assist health care providers to overcome barriers to the adoption of evidence-based practices.

The described data sources and methods can be applied in clinical settings to assess conformance to evidence-based quality criteria and provide feedback to clinicians. If electronic health records are available, the feedback and reminders may be directly incorporated into the medical record and seen by the clinician at the time of a visit. Intermountain Health Care utilizes its electronic health records to monitor adherence to evidence-based quality standards and to provide decision support to clinicians when seeing patients. This strategy has contributed to substantial improvements in their quality performance.[63]

Outcomes management system. In 1988, Paul Ellwood proposed the adoption of outcomes management system (OMS) as a method to build clinical intelligence on "what treatments work, for whom, and under what circumstances."[64] OMS would require linking information on the patient's experience with outcomes of care and information on diagnosis and treatment that would usually come from the medical record.

In 1991, the Managed Health Care Association, an employer organization, brought together a group of employers and their health plan partners who were interested in testing the OMS concept in health plans.[65] To do so would require a set of methods that could be widely applied across health plans with differing information systems. The methodology chosen was for each of 16 health plans to identify all adult enrollees with at least two diagnoses of asthma over the previous 2 years. A stratified sample was chosen with half of the enrollees having more severe asthma (e.g., hospitalization or emergency room visit in the past 2 years) and the other enrollees having less severe asthma (outpatient visits only). Each adult received a questionnaire asking about their asthma treatment and health status. Followup surveys were done in each of 2 successive years to track changes over time.

The findings were compared to national treatment recommendations for adult asthma.[66] Across the health plans, 26 percent of severe asthmatics did not have a corticosteroid inhaler, and 42 percent used it daily, as recommended.[67] Only 5 percent of patients reported monitoring their asthma using a home peak flow meter. Approximately half of adults with asthma reported having the information they needed to avoid asthma attacks, to take appropriate actions when an asthma flare-up occurs, and to adjust medications when their asthma gets worse. Health plans used the baseline findings to develop quality-improvement interventions, which varied across health plans. Followup surveys of the patient cohort provided feedback to health plans on their success in improving asthma treatment and outcomes over time.

Conclusion

This chapter has provided a definition and history of the field of health services research and discussed how this field is examining quality-of-care issues and seeking to improve quality of care. Comparisons of current practice to evidence-based standards with feedback to clinicians and the integration of patient-reported outcomes are two examples of how HSR tools can be used to provide quality-improvement information for health care organizations. These examples utilize multiple data sources, including medical records, patient surveys, and administrative data. The opportunities for nurse researchers to provide invaluable contributions to the growing field of health services research are innumerable.

Chapter 9. Synergistic Opportunity to Connect Quality Improvement and Emergency Preparedness

Sally Phillips, Ronda G. Hughes, and Lucy A. Savitz

Background

A critical element in the mission of health care organizations is high quality health care. Organizationally, the hospital enterprise is a hierarchical structure that has separate functional charges, lines of authority, and personnel resources for quality improvement and emergency management. The overall umbrella of safety and health care delivery can be viewed to encompass quality improvement and emergency preparedness, and nursing plays an integral role in ensuring continuous quality improvement. The interaction of quality improvement and emergency preparedness resources in hospital settings promises to yield a combined effect that is greater than the sum of their individual efforts to ensure patient safety and enhanced health care quality. By strengthening communication channels and fostering opportunities for collaborative project implementation across quality improvement, emergency preparedness and organizational functions can be highly synergistic.

Engaging People in Place

According to the current working knowledge of quality improvement and emergency management in hospitals, it is suggested that the bioterrorism/emergency response function resides in the facilities management area, while quality improvement is incorporated into clinical operations. Job enlargement of selected nursing staff can serve to bridge the quality improvement–emergency preparedness gap. Quality improvement and patient safety initiatives are led by executives who report directly to the chief medical officer and/or vice president for quality/safety. Emergency management typically has a less direct reporting route through the chain of command; however, there are exceptions. Exceptions are likely to appear in hospitals and health systems that have experience with natural disasters (e.g., University of North Carolina Hospitals' experience with hurricanes), known manmade threats (e.g., Intermountain Healthcare's experience with chemical stockpiles and manufacturing research facilities), and/or specialized facets of bioterrorism threats (e.g., University of Pittsburgh Medical Center Health System). The boards of directors of such health systems are beginning to request methodologically rigorous research and comparative preparedness data for benchmarking and quality improvement of emergency management—the customary practice over the past decade for health care quality and, more recently, patient safety.

The Agency for Healthcare Research and Quality (AHRQ) sponsored the Integrated Delivery System Research Network (IDSRN),[*] a network of five health systems with nearly 70 hospitals in seven States across the United States committed to applied research representing a cross-section of the hospital industry. In-depth knowledge of these health care systems—and more

[*] RTI Master Task Order Contract No. 290-00-0018, L.A. Savitz, Director; 2004.

general knowledge of the hospital industry—was obtained, affording the opportunity to identify several common practices. The leadership of the administrative emergency management function in health care organizations was often former military personnel with security experience or individuals who had worked their way up through increasing responsibility in facility/environmental services. Only those organizations with the most visible commitment to emergency preparedness also had clinical champions who partnered with the administrative emergency management function. Conversely, quality management typically had clinical leaders (i.e., physicians and/or nurses) with some training or on-the-job experience in health care administration. These individuals were repeatedly trained through continuing education and professional society meetings, used a journal specifically dedicated to implementation science (visit http://www.implementationscience.com), and reinforced change management principles using the Institute for Healthcare Improvement collaborative model (visit http://www.ihi.org). A corollary for support of similar change management efforts does not exist for emergency management. However, fostering transfunctional collaboration of emergency preparedness and quality improvement is promising; both the Joint Commission (see the Joint Commission–issued, revised emergency management standards that were effective January 1, 2008 – visit http://www.jcrinc.com/28380) and the American Hospital Association are working toward increasing opportunities for such dialogues.

Recent experience with Hurricane Katrina has highlighted the "soft underbelly" of hospital preparedness and emphasized the inseparable role that emergency management plays in the overall quality and safety of health care delivery. The emergency preparedness of this country is based on a robust health care delivery system. The public expects and is entitled to receive the highest quality evidence-based care within the most efficient delivery system possible. At times of crisis be it a disaster, natural or man made, or a major infectious disease, SARS or Pandemic, the already stressed health care system operating at the margins will be challenged to deliver this level of care without concerted planning and cooperation. Nurse executives must lead a cultural shift towards using evidence-based management and clinical practices (Williams 2006) in both quality improvement and emergency preparedness. Principal team players must include nurses, who are the essential back-bone of successful change efforts in hospitals (Savitz & Kaluzny, 2000). The extent to which nursing leaders, including middle managers, can be engaged in change management activities (Dopson & Fitzgerald, 2006) for emergency preparedness will be an important investment in successful design and implementation of targeted interventions. There is not good visibility for emergency preparedness commitment on the part of clinical staff in operational areas demonstrated, for example by most staff avoiding required drills failing to see the priority from their leaders. Health system leadership can change this by appropriately acknowledging and rewarding such efforts and modeling the commitment.

Opportunity for Learning Exchange

Development of meaningful working relationships and opportunities for learning exchanges between quality improvement and emergency preparedness initiatives could fundamentally enhance change management efforts within these separate functional areas in hospitals. There are differences in the degree to which initiatives in emergency preparedness are germane to quality improvement with respect to knowledge utilization (e.g., community collaboratives, data sharing, information technology solutions, measurement and feedback reporting to involved staff). This is because nurses can be involved in both quality improvement and emergency response in their

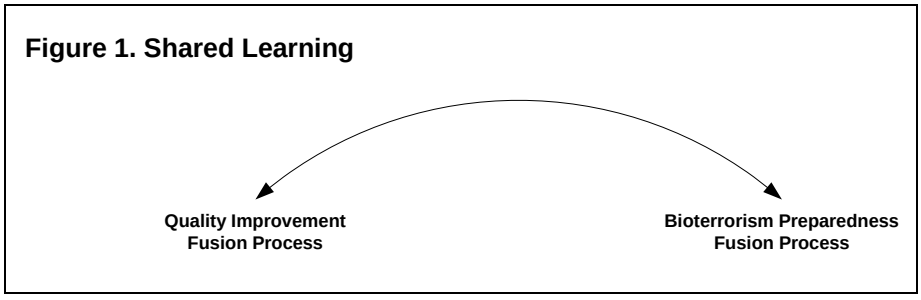
role as caregivers and clinical managers. Consequently, it would be possible to link knowledge-based learning about how interventions are implemented (a.k.a., implementation science) so that advancements in our understanding are not confined to any single aspect of quality health care delivery, but are opportunities for cross-fertilization and synergy.

As stated by Mittman,[4] implementation science focuses on a second level of research translation where one takes evidence-established benchmarks from limited settings (i.e., level 1 translation) to practice innovations, and more broadly to disseminate that knowledge. Implementation science (or second-level research translation) is an evolving, multidisciplinary area, and the terminology has not yet been consistently established. For example, Chapter 7 ("The Evidence for Evidence-Based Practice Implementation") in this *Handbook* discusses "translation science" to describe the same concept. Despite the inconsistent terminology, researchers and practitioners are committed to implementing and disseminating promising practices.

Disseminating and Implementing Promising Practices

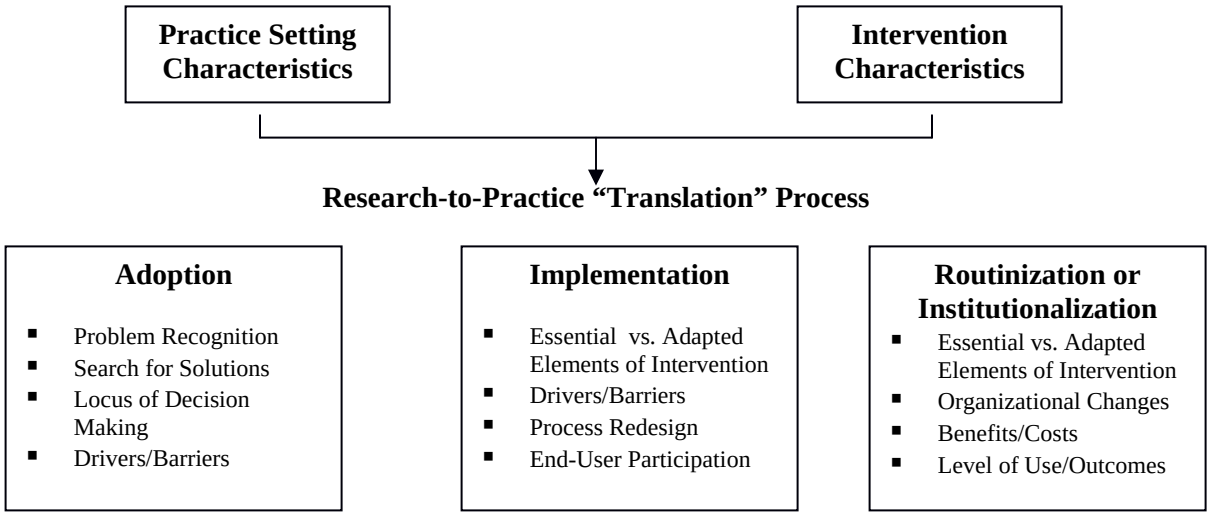
The difficulty of disseminating innovations is a persistent conundrum across settings and situations. There is limited ability to spread successful interventions across a single health care organization, let alone to unaffiliated organizations. The real challenge for health care implementation science is figuring out how to "flatten our world."[5] Opportunities for shared learning (Figure 1) could serve to accelerate the diffusion of innovation processes.[6] By directly engaging nursing leadership, current organizational barriers that inhibit application and shared approaches that promote quality improvement[3] and readiness for emergency response could be ameliorated, but integrating both tacit (i.e., personal experience) and explicit knowledge (e.g., evidence) can be difficult to achieve.[7] The challenge to nursing will be translating quality improvement research into practice to address both functional roles—quality and preparedness.

Figure 1. Shared Learning



The notion of an implementation deficit between what is planned versus achieved and the challenge of effectively translating research into practice has a long-standing literature base, primarily in organizational studies and public policy analysis.[6, 8, 9] In terms of nursing, the research has been inconclusive even about the evidence for specific interventions.[10] A generalized conceptual model of translational implementation, based on Rogers's seminal work,[6] has been incorporated into numerous change management efforts such as the RE-AIM[11, 12] (Figure 2).

Figure 2. Conceptual Model



What we know from reported studies and have been learning in subsequent research is that change will be a nonlinear process stymied by individual and organizational barriers.[2, 13–16] Attempts to advance implementation science in health care have focused on the factors that affect adoption and sorting out different strategies to accelerate that second level of translating of research into practice.[2, 17, 18] A recent report by Hamel[19] described the conditions necessary for management innovation that produced bold breakthroughs in how business was done, including commitment to a big problem (e.g., bioterrorism preparedness), new approaches (e.g., application of information technology such as electronic medical records), deconstruction of management orthodoxies (via exchanged resources and knowledge between the quality improvement and emergency management silos), and shared stories from diverse organizations that redefined what is possible. Early adopters lead the way.

Over the past decade, targeted research related to understanding how clinical process innovations are adopted has been funded by the AHRQ. Building on that base effort, the AHRQ funded the Partnership for Advancing Quality Together (PAQT) grant[*] (part of the AHRQ's Partnerships for Quality initiative) to achieve the following specific aims: strengthen an existing research network that promotes sharing of local innovations, explore factors that impede and facilitate inter- and intra-organizational sharing of knowledge, provide a mechanism to test the transportability of clinical process innovations, influence the breadth and depth of the evidence base for quality improvement, and accelerate the rate at which knowledge utilization occurs. Underlying these aims was a directive to explore the potential synergies between quality improvement and emergency preparedness.

Collaborative efforts to address these issues was done in a focused manner through 17 applied research projects, which led to several important findings and strategies for supporting knowledge transfer and implementation science that are relevant to both quality improvement and emergency preparedness. The three main findings are:

[*] AHRQ 5 U18 HS13706.

- Organizational modeling by credible organizations can accelerate knowledge transfer.
- The primary evidence base (the peer-reviewed literature) is limited to the extent that many innovations are not reported and there is a bias toward reporting only successful efforts, when we can often learn as much from failed attempts.
- Innovations in health care delivery are often complex interventions with multiple elements that are not fully reported, and essential versus adaptable elements of these complex interventions are not clearly delineated.

The bedrock propositions, common to all innovation packages, are that (1) how we deliver preventive or therapeutic services and how we organize those efforts within health care systems and facilities should, whenever possible, be based on knowledge of what works; and (2) effectively sharing such knowledge is a common feature of successful efforts generalized beyond a single program or facility.[20, 21] Understanding how knowledge (i.e., research information and data together with developed tools) can be used to drive high-quality and safe care delivery is critical. This understanding will allow for necessary and innovative changes in practice and processes at both the organizational level and at the point of service.[16]

Health care organizations typically view information and analysis in the context of local data derived from the experiences of patients served in their own organizational settings. Efforts to drive change innovations have expanded this notion of information to include both health services research conducted locally and studies reported in the peer-reviewed literature. Such research reports offer tested models for improvement; however, various barriers such as publication bias,[22] reporting time lags,[23] journal prestige,[24] and the overwhelming volume of a dispersed body of literature diminish the accessibility of such needed evidence. The problem of nontransportability of potential advances in health care information technology efforts is just the newest illustration of a much larger dilemma of generalizability beyond single institutions or systems. The challenge is to build an evidence base and place such evidence in the hands of those who are charged to operationalize knowledge transfer.

Evidence-Based Quality and Safety

Health services researchers and organizational leaders have more recently advocated evidence-based health care or EBHC.[8, 15, 20, 25–27] Sackett[28] defined EBHC as a "bottom-up approach based on good clinical management and supported by the best available evidence and taking into account patient priorities." The "enthusiasts of EBHC naively assumed that the case for implementation would be self-evident and that it would spread automatically and quickly"[8] (p. 29). Further, the authors contend, "There should be a strategy of creating evidence in priority areas, with concomitant systematic efforts to accumulate evidence in the form of robust bodies of knowledge" (p. 30). AHRQ has led the way for the synthesis of evidence through its Evidence-Based Practice Centers or EPCs (visit http://www.ahrq.gov/clinic/epc). Such evidence should be actively disseminated to where it is most needed and made available for the widest possible use.[8]

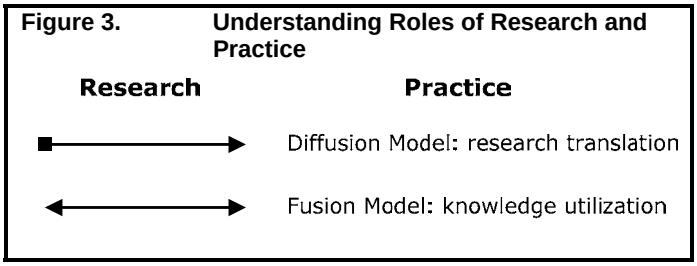
Health care organizations characterized by different levels of experience with clinical process innovation and staff tolerance for change set the "evidence bar" quite differently.[2] Mature organizations with extensive experience and local pilot projects require independent research by affiliated researchers whose results were published in the peer-reviewed literature. Less experienced organizations are comfortable simply modeling clinical process innovations based on evidence in the peer-reviewed literature, but without local development and testing. Further,

we have learned[29] that there is a life cycle associated with organizational learning, and where an organization or unit sits on that life cycle is influenced by staff tolerance for change and experience with innovation implementation over time. Whether the evidence is self-generated or modeled from reports in the literature, a primary issue is how to appropriately target intended end users. Novel approaches and use of preexisting dissemination channels will be needed to accelerate the rate at which such knowledge is put into practice.

Implementation Science in Practice

A great deal of attention has been paid to understanding the process of implementing science into practice.[30–33] Recent work conducted by Helfrich and colleagues[34] in studies funded by the Centers for Disease Control and Prevention and AHRQ suggest that it is more meaningful to examine how knowledge is used to influence changes in organizations and the microsystems of care by viewing this as a "fusion versus diffusion" process. Level 2 translation of research into practice (Figure 3) traditionally presumes a unidirectional flow or diffusion of information from research to practice; this presumption may act as a barrier to uptake quite apart from the limitations of the evidence base noted above. In contrast, a fusion perspective acknowledges shared learning between research and practice (i.e., knowledge utilization) whereby each informs the other to advance understanding.[35, 36] Concomitantly, the source of evidence and how that evidence is packaged and communicated greatly influences its use. Active engagement of organizational leaders and clinical investigators in the research process, as we propose herein, has proven critical to effective fusion/knowledge transfer.[13, 15, 37–39] Chapter 7 in this *Handbook* discusses steps for evidence-based practice in greater detail, drawing on Rogers's[6] work and the AHRQ model (Figure 3).

Figure 3. Understanding Roles of Research and Practice



Our review of literature reporting on health care innovations suggests that there are three overarching problems to the dissemination of evidence-based innovations: (1) incomplete reporting of interventions being implemented, (2) biased literature, and (3) the fact that interventions evolve over time as an effort moves through various stages from adoption to implementation through institutionalization/routinization.

Implementation efforts are not fully reported, limiting dissemination and uptake in other places. With this limitation in mind, we demonstrated our ability to fully capture all elements of complex interventions in a recent study of diabetes management in 15 community-based sites: *Evaluation of the Robert Wood Johnson Foundation Diabetes Initiative* (2003–2005), L.A. Savitz, Qualitative Research Director. A key finding from the formative evaluation was the breadth and complexity of interventions that evolved as the programs were implemented. Indeed, without probing, none of the sites visited had fully reported the breadth of intervention elements (ranging from 9 to 37) they developed and were using.

We have observed that interventions are adapted as they are implemented in varying clinical settings and/or for different patient populations. In addition to our understanding of the extent to which innovations are underreported and bias in the literature (limiting knowledge transfer), our observation that interventions evolve during implementation through institutionalization/

routinization is important; and we have the tools to monitor such evolution in comparing and contrasting a single intervention across multiple clinical sites.

Generalized Approach for Implementing Quality and Safety Interventions

Basic tenets of quality improvement in health care organizations include the necessity to embed and routinize an intervention into the normal work process. From an emergency preparedness perspective, this same issue is addressed through the design of dual-use tools and technologies. The shared intent is to ensure that an intervention is practiced and available when needed (e.g., resuscitation procedures on medical units, personal protective equipment and isolation precautions hospital-wide). The construction of such interventions follows a knowledge management and decision support model whereby

- A problem is identified and has visibility with executive management.
- A clinical champion is identified and a team is formed.
- The process is flow charted before and after implementation of the intervention so that changes in responsibility and resource needs are transparent.
- Necessary tools to support the change are developed and used (outcomes tracking, built into decision support information systems, and education/training materials).
- Monitoring with feedback is provided to involved staff on a periodic basis for review.
- Continual detailing of the intervention is recorded for ongoing improvement and maintenance.

While quality improvement in health care has built on the existing evidence base around how to manage and guide change, similar evidence is virtually nonexistent in the emergency/bioterrorism preparedness literature. Nevertheless, similar strategies for improved functioning are observed (e.g., systematically conducting drill exercises with evaluation measures for monitoring, feedback, and improvement), and these initiatives would likely benefit from the growing implementation science evidence base.

Specific examples of similar, yet separate, strategic interventions for enhanced functioning used in hospital settings include the following:

- **Drilling:** Scenario-based event drills are used in both functional areas; for example, emergency preparedness drills[40–42] and maternity ward eclampsia drills[43] have been used to train and refresh staff knowledge of key processes and protocols in the event of an infrequent yet crisis situation.
- **Training and simulation technology:** Skill-based training is deeply rooted in both areas with tools developed to support such efforts.[44–46] For example, simulation as a training and assessment tool has been used at Cornell-Weill, UPMC Wiser Center, and in the United Kingdom for intubation training.
- **Triage:** This is a common concept used in providing quality health care and in emergency response.[47, 48] However, a major departure from clinical training for triage activities occurs when a health care facility has scarce resources and is overwhelmed by the victim load, requiring battlefield triage in which the most likely survivors are treated first (i.e., frail elderly and small children may not be the highest priority given their vulnerability to succumb).[49]
- **Surveillance:** Quality improvement and infection control have long-standing experience in conducting surveillance for nosocomial infections, and a growing area in patient safety

is targeted injury detection systems. Surveillance systems for bioterrorism have been deployed at the health system (e.g., Intermountain Healthcare during the Winter Olympics) and regional levels for monitoring select illness and disease patterns to mitigate potential events.

- **Performance measurement:** Performance measurement in quality improvement is currently getting a great deal of attention[50] due to the early mantra of leading thinkers like Juran—*you can't manage what you can't measure*. Boards are now asking for emergency preparedness measures to ascertain comparative readiness.[*]

As illustrated by these examples, both areas—quality improvement and emergency preparedness—are focused on preparedness, and both face the challenge of how to implement targeted interventions. As one seeks to implement new programs and interventions in complex health care settings, one faces the same challenges associated with adoption, implementation, and maintenance of the intervention. Teams in both domains should consistently report both successes and failures within their settings and in publications that reach those most likely to use such information and be open to understanding how such reports can advance their respective work. Further, taking successful quality improvement or emergency preparedness interventions and disseminating such promising practices across a health system, a community, and/or to the industry is a hurdle at best.

Generalized Approach to Dissemination and Implementation

As part of the PAQT work, a committed group of organizational liaison staff was established that has worked successfully together on 17 projects in both bioterrorism preparedness and quality improvement. This PAQT grant has allowed the investigators to bring staff from partner health systems together for in-person meetings to discuss key organizational and care process issues, create a community for shared issue identification and learning, and explore the diffusion of knowledge within and across integrated delivery systems. In particular, the focus has been to study successful bioterrorism preparedness and quality improvement interventions, their adoption, and diffusion across the research network, together with identifying synergies across quality/safety and emergency preparedness. From the assessment of required implementation in the PAQT grant, a six-step strategy to promote cross-system diffusion of learning has been identified (Table 1).

Table 1. Generalized Strategy for Dissemination and Implementation

	"Implementation Science" Learning from Partnership in Advancing Quality Together
Step 1	Pilot innovation in credible place by a credible clinical champion with an engaged team that is empowered with resources.
Step 2	Create a toolkit or manual that serves as a conduit with audit tool for performance monitoring and feedback to involved staff.
Step 3	Review by adopting organization/unit facilitated by linking agent/clinical champion and his/her team.
Step 4	Adaptation by adopting organization/unit.
Step 5	Phased implementation: seeding the innovation on a small scale to support minimal adaptation and demonstrate value.
Step 6	Spread; organization-wide diffusion as appropriate.

[*] The American Hospital Association is currently fielding a survey that is intended to generate data that will yield comparative results on hospital preparedness.

Visibility with facility leadership and a six-step approach have been developed from observed implementation efforts over the past 2 years. This generalized approach to dissemination and implementation is both evidence- and experience-based, having been used successfully in leading partner health systems for both bioterrorism preparedness and quality improvement interventions.

Key among these six steps is the preparation of the training manual (the *conduit*) and the site-specific clinical champions (*linking agents*), which are believed to be essential in accelerating innovation diffusion and institutionalization.[*] The constructs of conduits and linking agents were recently conceptualized by Rogers[6] within his diffusion of innovation framework and related literature. Conduits are those tools or dissemination vehicles developed to facilitate uptake of research into practice (i.e., a DVD and companion training manual). Using conduits has been a major focus of our applied research and dissemination efforts to date. Linking agents have been described both in terms of agencies within a system (e.g., community hospital policies) and individuals (e.g., staff nurses implementing guideline recommendations); linking agents are the same as opinion leaders/champions or change agents. While the importance of conduits and linking agents are separately acknowledged in the change management and quality improvement literature, integration of the conduit and linking agent constructs into formal implementation planning processes has not been done.

Practice Implications

As a hospital addresses quality improvement throughout its operating structure, it should be examining all aspects of performance relating to delivering safe and high-quality services to its patients in all situations. These quality improvement efforts not only address the day-to-day services and functions, but also address the ability to meet those challenges presented during an emergency. Institutions should be incorporating evidence-based quality improvement measures that build on efforts already in place and begin to build the evidence and experience for emergency preparedness that complement these efforts. Maintaining separate structures for these activities is not only inefficient, but counterproductive.

As health care systems institute change management efforts, they should be incorporating emergency preparedness initiatives. Health care organizations should address a series of emergency preparedness activities and should initiate them within their quality improvement framework. For example, if an exercise is conducted to test the emergency preparedness plan, meeting one of the performance standards of the Joint Commission accreditation, it should be set up within a quality improvement framework. The institutional or unit performance should be measured for emergency preparedness using evidence-based tools like the one developed by AHRQ.[51] This quality improvement strategy—deployed throughout the system to address efficiency, effectiveness, and safety/quality—is no different or separate from this one dimension of emergency preparedness. As the metric of preparedness performance is measured, focused quality improvements can be initiated.

There is an impressive body of quality improvement literature that can be brought to bear on emergency preparedness. However, the literature on the metrics for preparedness and quality

[*] The research evidence for this approach is reviewed in depth in Chapter 7 of this *Handbook*.

improvement is scant and inconclusive.[52] Health care organizations on the cutting edge of this field are encouraged to report the use of evidence-based tools and piloted quality improvement measures in the literature and share their experience with colleagues. It was mentioned earlier in this paper that there are few forums that address institutional emergency preparedness measures that are initiated within a quality improvement framework. Hospitals and health systems should create opportunities for dialogue and shared learning; they should support the development of leaders within their organizations who bridge the chasm between the two activities. Nurses are well positioned to provide such leadership. The astute manager of these organizations should address vital strategies for reorganization that merge these activities and consider the career path for clinical leaders within the organization who can participate and provide leadership in the planning and evaluation strategies for these innovations. To achieve organizational awareness and commitment, the merged mission activities need to be supported though open dialogues and structured committee discussions at all levels of the organization affected by emergency preparedness.

The emergency preparedness activities thrust on an organization can either be presented as an annoying add-on function that distracts the organization from its primary mission, or they can be incorporated into the fabric of the mission and staff roles. The unique exercises and training activities required for emergency preparedness could be expanded to incorporate testing and evaluating new quality improvement measures. For example, resuscitation competency training in the emergency department could easily be incorporated into a drill testing the emergency department's response to an explosive or mass-casualty attack—thereby testing a day-to-day activity that can be measured for improvement and instituting remedial training alongside other skills and competencies for an effective emergency response. Also, essential in emergency preparedness planning are critical functions and strategies that require activities to protect the staff and the facility (e.g., avoiding contact with an infectious agent or a contaminant). Strategies such as fit testing masks, decontamination procedure, mass prophylaxis of staff and their families, and enhanced infection control measures are not unique to emergency preparedness and, therefore, are easily accommodated in day-to day-quality improvement, education, and training requirements of any health care institution. A good clinical champion from the infectious disease department (usually a nurse) can easily translate the interrelatedness of the two functions and readily get on board with an integrated approach.

Research Implications

This is an exciting and dynamic area in which little is currently known. Nurse leaders, nurse researchers and other nurses should and can have a critical role in taking these aforementioned concepts and design strategies, building on quality improvement and emergency preparedness methods, and demonstrating their effectiveness and impact. High priority should be given to developing and testing models that can be generalizable and actionable for clinicians that clearly define the roles and impact of nursing leadership. In so doing, the actual process of integrating quality improvement and emergency preparedness needs to be clearly delineated so that the successes of demonstration projects can be understood and replicated, particularly in preparation for unanticipated catastrophic events.

Conclusions

Nursing leadership has the opportunity to use new emergency preparedness evidence- and experienced-based measures that are or can be developed and disseminated. To realize this integrated approach locally, it is essential to embed interventions into the fabric of work and make these efforts visibly present so that staff are perpetually readied for the day-to-day issues of improving quality and safety, and the extraordinary issues of an unanticipated catastrophic event. With strong mission leadership to merge the two areas structurally and functionally, acceptance of valid measures and cross-integration can be achieved. In conclusion, hospital leadership should

1. Recognize the synergies between quality improvement and emergency preparedness, providing support, visibility, and performance feedback for these shared functions;
2. Empower clinical leaders to formally bridge the gap and share knowledge across these functional areas; and
3. Support the evidence base by providing resources to contribute to the literature on implementation science that can foster modeling in other facilities and communities.

Building the evidence base and recognizing the synergies between quality improvement and emergency preparedness is vital for the safety of patients in the resource-constrained environment in which we provide hospital care. Executive management is challenged to think prospectively to connect the dots and take advantage of these synergies to efficiently provide the highest quality health care possible to their patients.

Chapter 10. Fall and Injury Prevention

Leanne Currie

Background

Fall and injury prevention continues to be a considerable challenge across the care continuum. In the United States, unintentional falls are the most common cause of nonfatal injuries for people older than 65 years. Up to 32 percent of community-dwelling individuals over the age of 65 fall each year, and females fall more frequently than males in this age group.[1, 2] Fall-related injuries are the most common cause of accidental death in those over the age of 65, resulting in approximately 41 fall-related deaths per 100,000 people per year. In general, injury and mortality rates rise dramatically for both males and females across the races after the age of 85, but males older than 85 are more likely to die from a fall than females.[2-6] Unfortunately, fall-related death rates in the United States increased between 1999 and 2004, from 29 to 41 per 100,000 population.[2, 7] Sadly, these rates are moving away from the Healthy People 2010 fall-prevention goal, which specifically seeks to reduce the number of deaths resulting from falls among those age 65 or older from the 2003 baseline of 38 per 100,000 population to no more than 34 per 100,000.[8] Thus, falls are a growing public health problem that needs to be addressed.

The sequelae from falls are costly. Fall-related injuries account for up to 15 percent of rehospitalizations in the first month after discharge from hospital.[9] Based on data from 2000, total annual estimated costs were between $16 billion and $19 billion for nonfatal, fall-related injuries and approximately $170 million dollars for fall-related deaths across care settings in the community.[10, 11] Several factors have been implicated as causes of falls and injuries; to date, however, no definitive predictor profile has been identified. Although the underlying status of the individual who sustains a fall may contribute to the fall and subsequent injury, the trauma resulting from the fall itself is most often the cause of morbidity and mortality.

Over the past 20 years gerontology researchers, spearheaded by Mary Tinnetti from Yale University, have carried out a significant amount of research to address the problem of falls and injuries in the community. However, ubiquitous use of successful interventions is not yet in place in the community. As health care moves toward patient-centered care, and as a growing body of research provides guidance for widespread fall-prevention programs, fall- and fall-related-injury prevention now has the potential to be addressed across the care continuum.

Inpatient fall prevention has been an individual area of concern for nursing for almost 50 years.[12, 13] Traditional hospital-based incident reports deem all inpatient falls to be avoidable, and therefore falls are classified as adverse events. Indeed, falls are the most frequently reported adverse events in the adult inpatient setting. But underreporting of fall events is possible, so injury reporting is likely a more consistent quality measure over time and organizations should consider judging the effects of interventions based on injury rates, not only fall rates. Inpatient fall rates range from 1.7 to 25 falls per 1,000 patient days, depending on the care area, with geropsychiatric patients having the highest risk.[14-18] Extrapolated hospital fall statistics indicate that the overall risk of a patient falling in the acute care setting is approximately 1.9 to 3 percent of all hospitalizations.[16-18] In the United States, there are approximately 37 million hospitalizations each year;[19] therefore, the resultant number of falls in hospitals could reach more than 1 million per year.

Injuries are reported to occur in approximately 6 to 44 percent of acute inpatient falls.[5, 20-23] Serious injuries from falls, such as head injuries or fractures, occur less frequently, 2 to 8 percent, but result in approximately 90,000 serious injuries across the United States each year.[20] Fall-related deaths in the inpatient environment are a relatively rare occurrence. Although less than 1 percent of inpatient falls result in death, this translates to approximately 11,000 *fatal falls* in the hospital environment per year nationwide. Since falls are considered preventable, fatal fall-related injuries should *never* occur while a patient is under hospital care.

In the long-term care setting, 29 percent to 55 percent of residents are reported to fall during their stay.[24, 25] In this group, injury rates are reported to be up to 20 percent, twice that of community-dwelling elderly. The increase in injury rates is likely because long-term care residents are more vulnerable than those who can function in the community.[26] Rubenstein[27] reported 1,800 long-term care fatal falls in the United States during1988. The current number of long-term care fatal falls has not been estimated; however, there are 16,000 nursing homes in the United States caring for 1.5 million residents in 2004.[28] This population will likely grow in the coming years, thus fall and injury prevention remains of utmost concern.

Fall and Fall-Related Injury Reporting

Falls and related injuries have consistently been associated with the quality of nursing care in the acute care setting. They are included as a nursing-quality indicator monitored by the American Nurses Association, National Database of Nursing Quality Indicators (ANA–NDNQI) and by the National Quality Forum.[29, 30] Participation in the ANA–NDNQI provides hospitals with the ability to view their fall and injury rates in relation to other hospitals of similar type and size. However, participation in ANA–NDNQI is voluntary; despite a rapidly growing participation rate, it is not yet ubiquitous (1,089 hospitals as of June 2007, approximately 15 percent of U.S. hospitals). The National Quality Forum also advocates for voluntary reporting of quality indicators for acute care (falls prevalence and fall-related injuries) and ambulatory care (fall-risk screening for geriatrics).[31, 32]

The Maryland Quality Indicator Project is a second voluntary national repository that provides fall and fall-related injury benchmarks for the behavioral health, long-term care, and home care settings.[33] Unfortunately, this project has a participation level of approximately 1,000 hospitals (approximately 14 percent), making national benchmarking difficult. In the home care setting, the Centers for Medicare & Medicaid Service's Outcome and Assessment Information Set (CMS–OASIS) provides the reporting basis for the patients' physical functioning.[34] Growing efforts to expand patient safety initiatives to the home care setting seek to include falls as a quality indicator for patients who are cared for at home, but who are not completely bed bound.[35, 36] Collection of these data has the potential for organizations to track fall rates of vulnerable patients and to identify patients at risk for falls and injuries. However, further research is required to validate such screening and to examine which interventions are effective based on risk status.

In the nursing home setting, the long-term care minimum dataset (LTCMDS) is used for reporting all aspects of care. The LTCMDS captures fall and injury histories via assessments that are performed on admission and at regular intervals during a resident's stay.[37] In addition, residents are evaluated for balance and for the ability to perform activities of daily living (ADLs), with the goal to apply fall-prevention measures should the patient be deficient in these areas. Recent research by Hill-Westmoreland and Gruber-Baldini[38] indicated only a 75 percent

concordance between chart abstraction and minimum dataset reporting for a group of long-term care facilities. A more recent development in the long-term care setting, the Nursing Home Quality Initiative, promotes the collection of a list of enhanced quality indicators, including those that track declines in functional and cognitive status.[34, 37] The Agency for Healthcare Research and Quality (AHRQ) has elected to monitor only postoperative hip fracture as their fall-related preventive quality indicator, which is consistent with thinking that monitoring fall-related injuries is a more dependable measure of quality.[39, 40] However, tracking of all fractures would be of benefit. The Health Plan Employer Data and Information Set has recently added Fall Risk Assessment to its dataset, which will provide a method to benchmark the evaluation of fall risk between health insurance providers.[41] However, application of fall- and injury-prevention programs is not included as an indicator, which will make it difficult to benchmark these important measures. Increased and more accurate monitoring of these elements has the potential to reduce falls among nursing home residents; however, the effect of these efforts has yet to be established.

Definitions of Falls and Fall-Related Injuries

Falls and related injuries have had varying definitions.[42, 43] Falls may be precipitated by intrinsic or extrinsic factors. Intrinsic factors are those that have a physiologic origin, and extrinsic factors are those precipitating from environmental or other hazards. Distinguishing between intrinsic or extrinsic risk factors can facilitate identification of preventive strategies. According to Tinetti, Speechley, and Ginter,[44] a fall in the nonhospitalized geriatric population is defined as "an event which results in a person coming to rest unintentionally on the ground or lower level, not as a result of a major intrinsic event (such as a stroke) or overwhelming hazard." Agostini, Baker, and Bogardus[45] adapted this definition for the inpatient, acute, and long-term care areas to define a fall as "unintentionally coming to rest on the ground, floor, or other lower level, but not as a result of syncope or overwhelming external force."

Other definitions are broader and include falls related to intrinsic events such as syncope or stroke. For example, Nevitt's[46] definition of a fall is "falling all the way down to the floor or ground, or falling and hitting an object like a chair or stair." The ANA–NDNQI provides an all-inclusive definition[47] (p. 26):

> An unplanned descent to the floor (or extension of the floor, e.g., trash can or other equipment) with or without injury. All types of falls are included, whether they result from physiological reasons or environmental reasons.

The International Classification of Diseases 9 Clinical Modifications (ICD-9-CM) uses several codes to categorize falls, all of which have broad descriptions: Accidentally bumping against moving object caused by crowd with subsequent fall (E917.6); Fall on or from ladders or scaffolding (E881); Fall from or out of building or other structure (E882); Other fall from one level to another (E884); Fall on same level from slipping, tripping, or stumbling (E885); Fall on same level from collision, pushing, or shoving by or with another person (E886); and Other and unspecified fall (E888).[48] In the inpatient care setting, E888 is the code that is typically used to record a fall in a medical record. However, this ICD-9-CM code is not consistently used for reporting; therefore, institutions generally rely on incident reports as the method of counting fall events.[48]

Fall-related injuries in the community, home care, and long-term care areas are generally characterized by ICD-9-CM diagnoses for the related injured body part. In contrast, incident reports in the acute care setting use the following ANA–NDNQI fall-related injuries categories:

(1) *None* indicates that the patient did not sustain an injury secondary to the fall.
(2) *Minor* indicates those injuries requiring a simple intervention.
(3) *Moderate* indicates injuries requiring sutures or splints.
(4) *Major* injuries are those that require surgery, casting, further examination (e.g., for a neurological injury).
(5) *Deaths* refers to those that result from injuries sustained from the fall.[29]

According to Morse,[21] inpatient falls can be classified into three categories: accidental falls (derived from extrinsic factors, such as environmental considerations), anticipated physiologic falls (derived from intrinsic physiologic factors, such as confusion), and unanticipated physiologic falls (derived from unexpected intrinsic events, such as a new onset syncopal event or a major intrinsic event such as stroke). Morse asserts that using this classification, approximately 78 percent of the falls related to anticipated physiologic events can be identified early, and safety measures can be applied to prevent the fall. Research to identify precursors to unexpected intrinsic events, such as screening for predictors of syncopal events, might increase the early identification of anticipated physiologic falls, which could ultimately prevent more falls.[49-51]

Falls and Fall-Related Injuries as Medical Errors

The definition of a fall is consistent with that of a medical error: "the failure of a planned action to be completed as intended" (i.e., error of execution) or "the use of a wrong plan to achieve an aim" (i.e., error of planning).[52, 53] For example, an error of execution might be the failure to perform the planned action of placing a call light within the patient's reach, and an error in planning might be to provide aggressive physical therapy before a patient's balance has been established. An error of commission is "an error that occurs as a result of an action taken," for example, a fall that occurs subsequent to a behavioral health patient's electroconvulsive therapy. An error of omission, "an error which occurs as a result of an action not taken," might occur if the patient is not assessed for fall and injury risk, which prevents appropriate interventions from being applied. Latent errors related to fall and injury prevention are those in which an agency does not apply appropriate standards, training, or support for the practice-based fall- and injury-prevention processes. Recent efforts by the Joint Commission (formerly the Joint Commission on Accreditation of Healthcare Organizations [JCAHO]) in its National Patient Safety Goals advocate for institution-wide risk assessment for falls and documentation of a fall-prevention program.[54] These efforts have the potential to eliminate latent errors related to falls and injuries. Monitoring errors might occur if the patient is not monitored to identify fall risk, or if the patient is not monitored to identify a post-fall injury such as a subdural hematoma.

This review summarizes the current research related to fall and injury prevention. The chapter is organized to present research from two perspectives: (1) community setting, and (2) acute and long-term settings. For each setting, the research that addresses risk factors, risk assessment instruments, and fall- and injury-prevention interventions are reviewed. Reports on the outcomes of fall- and injury-prevention research using experimental or quasi-experimental research design is summarized in tables at the end of the chapter.

Research Evidence

Falls and Related Injuries in the Community

In the following section, research about falls and related injuries in the community were identified and categorized as follows: risk factor identification, risk assessment instruments, and prevention strategies.

Risk factors in the community. The pivotal research of Tinetti, Speechly and Ginter[44] related to fall and injury prevention in community-dwelling individuals older than 65 years identified the following risk factors for falling: (1) postural hypotension, (2) use of any benzodiazepine or sedative-hypnotics, (3) use of four or more prescription medications, (4) environmental hazards, and (5) muscular strength or range of motion impairments. Other researchers have identified additional patient or treatment risk factors: (1) comorbidities, including diabetes, diabetic foot ulcer,[55] stroke,[56] syncope,[57] anemia,[58, 59] Alzheimer's disease,[60] Parkinson's disease,[61] vitamin D deficiency,[62, 63] and vitamin D deficiency in combination with low creatinine clearance;[64] (2) patient characteristics, including fallophobia (also known as "fear of falling"),[65, 66] gait problems (e.g., weakness and impaired sensation),[67] postural hypotension, inability to get out of chair, impaired ability to perform ADLs, frailty,[68-70] inability to follow instructions,[71] and inability to adapt to changing environment;[72] and (3) other characteristics, including recent hospitalization,[9] nonsupportive footwear (e.g., slippers),[73] reckless wheelchair use,[74] environmental hazards, and use of psychotropic medication.[75, 76] Age and gender are also associated with falls and fall-related morbidity and mortality. Fall rates increase with age,[77] and in community-dwellers between 65 and 85 years of age, females are more likely to fall, but males are more likely to die from fall-related injuries than females in this group.[1, 2]

The roles of ethnicity and race in relation to falls and injury have also been studied. Reyes-Ortiz and colleagues[78] examined risk factors for Mexican-Americans and found that in the community, the risk factors are the same as for their White counterparts. Hanlon and colleagues[79] examined predictors of falls between Caucasians and African Americans and found that African Americans were 23 percent less likely to fall than Whites (odds ratio = 0.77). Faulkner and colleagues[80] explored this difference in women and found that Caucasian women were 50 percent more likely to fall than African American women, although this was not statistically significant (relative risk = 1.50, 95% confidence interval [95% CI] = 0.90–2.49). The researchers further examined situations leading to falls and found that circumstances differed by ethnicity: Caucasian women were more likely to fall outdoors versus indoors (odds ratio = 1.6, 95% CI = 1.0–2.7) and laterally versus forward (odds ratio = 2.0, 95% CI = 1.1–3.4), but less likely to fall on the hand or wrist (odds ratio = 0.6, 95% CI = 0.3–1.0). This research suggests that activities differ between older African American women and their Caucasian counterparts and should be considered when making fall- and injury-prevention plans.

Risk factors for injury in the community. Risk factors for injury in the community are increasingly well characterized. Porthouse and her research team[81] performed a comprehensive cohort study of almost 4,300 women older than 70 years and confirmed the following risk factors for various types of fall-related fractures: (1) fall in the past 12 months, (2) increasing age, (3) previous fracture, and (4) low body weight. This work also identified that smoking was not associated with fracture risk. A growing body of research is examining vitamin D deficiency as a risk factor for fracture; however, results are conflicting to date, but bear further research.[81, 82]

Colon-Emeric and colleagues[83] used data from a large community epidemiologic study to identify whether historical and functional information could help to predict fracture risk. The researchers identified nine characteristics that were predictors of fracture: (1) female sex, (2) age greater than 75 years, (3) White race, (4) body mass index (BMI) of less than 22.8 kg/m^2, (5) history of stroke, (6) cognitive impairment, (7) one or more ADL impairments, (8) one or more Rosow-Breslau impairments (e.g., perform heavy work, walk a mile, climb stairs), and (9) antiepileptic drug use. Ohm and colleagues[84] recently identified that elderly community-dwelling individuals with traumatic head injuries were more likely to die based on the use of antiplatelet therapy (relative risk = 2.5 for those taking antiplatelet therapies; $P = 0.016$). A similar body of research related to chronic subdural hematomas has identified that patients on anticoagulant or antiplatelet therapy are at higher risk for chronic subdural hematoma and that many of these are first identified when a patient is evaluated after a fall.[85] Many injury risk factors are consistent with fall risk factors, accentuating the need for effective screening of elderly community-dwelling individuals. However, factors that make people more susceptible to injury, such as antiplatelet therapy, establish the need for additional safety measures for individuals at risk for injury. Table 1 lists the intrinsic and extrinsic risk factors for falls, injuries, and fall-related deaths in the community.

Table 1. Risk Factors for Falls, Injuries, and Fall-Related Deaths in the Community

Intrinsic Risk Factors	Fall Risk	Injury Risk	Mortality Risk
Demographics			
• Age: Older Age (especially >70yrs)	Yes	Yes	Yes
• Gender	Female	Female	Male >85
• Race	Caucasian	Caucasian	Caucasian
Cognitive Function			
• Cognitive impairment	Yes	No data	No data
• Fallophobia (fear of falling)	Yes	Yes	No data
• Inability to follow instructions	Yes	No data	No data
• Inability to adapt to changing environment	Yes	No data	No data
Physical Function			
• Gait problems	Yes	No data	No data
• Impaired ability to perform ADLs	Yes	Yes	No data
• Impaired muscle strength or range of motion	Yes	Yes	No data
• Poor/fair self-reported health	Yes	Yes	No data
• Rosow-Breslau impairment	No data	Yes	No data
• Vision problems	Yes	No data	No data
Physical Status			
• BMI less than 22.8 kg/m^2	No data	Yes	Yes
• Frailty	No data	Yes	Yes
• Low body weight (<58 kg=BMI 23 if height 5'3")	Yes	Yes	No data
Comorbidities			
• Alzheimer disease	Yes	No data	No data
• Anemia (including mild anemia)	Yes	No data	No data
• Diabetes	Yes	No data	No data
• Diabetic foot ulcer	Yes	No data	No data
• Fall in the past 12 months	Yes	Yes	No data

Intrinsic Risk Factors	Fall Risk	Injury Risk	Mortality Risk
• Parkinson disease	Yes	No data	No data
• Postural hypotension	Yes	No data	No data
• Previous fracture	No data	Yes	No data
• Stroke	Yes	Yes	No data
• Subdural hematoma (chronic)	Yes	Yes	No data
• Syncope	Yes	No data	No data
• Vitamin D deficiency	Yes	Yes	No data
• Vitamin D deficient w/ low creatinine clearance	Yes	No data	No data
Medications			
• Use of 4 or more medications	Yes	No data	No data
• Anti-epileptics	No data	Yes	No data
• Antihypertensives	Yes	No data	No data
• Antiplatelet therapy	No data	No data	Yes
• Psychotropics	Yes	No data	No data
• Sedatives and hypnotics	Yes	No data	No data
Extrinsic Risk Factors	**Fall Risk**	**Injury Risk**	**Mortality Risk**
• Environmental hazards	Yes	No data	No data
• Footwear, non-supportive (e.g., slippers)	Yes	No data	No data
• Hospitalization, recent	Yes	No data	No data
• Wheelchair use, reckless wheelchair use	Yes	No data	No data

Risk assessment instruments for community dwellers. Tinetti[86] developed a fall risk assessment index based on the following nine risk factors: mobility, morale, mental status, distance vision, hearing, postural blood pressure, back examination, medications, and ability to perform ADLs. This instrument has been the most widely used and tested, with a reported sensitivity of 80 percent and specificity of 74 percent.[87] Other instruments used in the community include the following (with reported sensitivities and specificities in parentheses): (1) Berg Balance Test (sensitivity = 77 percent; specificity = 86 percent), (2) Elderly Fall Screening Test (sensitivity = 93 percent; specificity = 78 percent), (3) Dynamic Gait Index (sensitivity = 85 percent; specificity = 38 percent), and (4) Timed Get Up and Go test (sensitivity = 87 percent; specificity = 87 percent).[87] Aside from the Timed Get Up and Go test, which takes less than a minute for a health care provider to administer, these instruments generally take 15 to 20 minutes to complete.[87]

Lord and colleagues[88] recently evaluated the effect of an exercise-related fall-prevention program, but found that the intervention was not useful in community dwellers who were not screened for risk. The researchers concluded that screening to identify individuals at high risk for falls would be necessary for a successful fall-prevention program. Further research to identify the most accurate, yet easy-to-use risk assessment instrument would be necessary to move these efforts forward.

A recent systematic review by Scott and colleagues[89] examined fall risk assessment instruments in the community. The authors concluded that, in general, risk assessment instruments are available; however, most have been tested in only one setting. Therefore, further validation studies should be conducted on fall risk assessment instruments before any specific instrument can be recommended.

A potential time point for risk assessment is in the emergency department (ED). Several researchers have examined the effect of fall- and injury-prevention interventions applied to patients who are discharged from the ED after a noninjury or nonserious-injury fall. The overarching goal of these studies is to evaluate the ability of comprehensive risk assessment followed by targeted interventions to prevent future falls and fall-related injuries. Several studies have successfully shown that screening followed by tailored management can decrease repeat falls.[42, 90-94] Close and colleagues[42] found that fall rates were reduced by 61 percent and recurrent falls were reduced by 67 percent for patients who had comprehensive risk assessment after a fall, compared to individuals who received standard treatment. Davison and colleagues[90] found a 36 percent decrease in fall rates after 1 year for patients who received a multimodal intervention for fall prevention after being identified as a faller on admission to the ED. In addition, these researchers noted an increase in falls self-efficacy, which is a measure of an individual's perception of their ability to manage situations where they are at high risk for falling – the higher self-efficacy, the more able a person is able to manage high risk situations. In a related study, Lee, Hurley, and colleagues[91] conducted a randomized controlled trial to examine the impact of a personal emergency response system and found that there was no difference between treatment and control groups for self-efficacy or patient anxiety. The Lee and colleagues study is informative in that emergency contact alone was not sufficient to improve a patient's belief in their ability to manage fall risk situations. Although no standardized instrument has yet been developed for use in the ED environment, the potential for the prevention of falls and related injuries in the community would be increased with the accurate identification of patients at risk for falls while they are in the ED.

Automated risk assessment in the community setting. To date, a limited number of computer-based, community-based fall assessment instruments have been described. By far the most complex and integrated is the Fall Risk Assessment and Management System, which was developed by the Australia Family Practice Group for use in the community by family practice physicians.[95] Fall Risk Assessment and Management System includes automated recommendations after the clinician executes a thorough patient assessment. Although this system appears promising, its efficacy has not yet been reported.

Lord, Menz, and Tiedemann[96] describe an electronic fall risk assessment instrument that provides a method to measure several risk factors, including vision, peripheral sensation, muscle force, reaction time, and postural sway. Although this instrument is thorough, it is meant for use by a physical therapist or a physician, nurse practitioner, or physician assistant for a focused fall risk assessment, rather than as a triage or screening tool. The novel aspect of this instrument is the comparison of the individual's score to the normative scores for each of the assessments, which provides the clinician with an anchor and may facilitate improved screening over time. However, the predictive validity of this instrument has not been reported, and its use may be limited to a fall-prevention clinic.

Another electronic fall risk assessment instrument, described by Dyer and colleagues,[97] is an electronic checklist in a fall-prevention clinic. Unfortunately, the researchers concluded that the clinic itself was more successful than the instrument in identifying risk factors for falling, underscoring the reality that the implementation of an instrument without associated policy and procedure changes may have limited effect.

The presence of these automated systems indicates that there is movement toward computerized fall risk assessment. Indeed, many clinical information systems have adapted paper-based assessment instruments for use in the acute care setting. However, the efficacy of

these systems has not been reported, and their effectiveness is likely to be constrained by the limits of the original instrument, the system in which they are placed, and the design team in ensuring that the automated instrument accurately reflects the original instrument.

Prevention strategies in the community. To date, several reviews conducted to examine the evidence available to support practice in this area have identified the need for multimodal, interdisciplinary prevention programs; the need for more accurate risk assessment instruments; and the need for more research related to this complex and costly problem.[11, 98-107]

Cumming[100] reviewed 21 trials and concluded that exercise programs were the most promising, and reduction of antipsychotic medications should be considered. However, Cumming also concluded that none of the reviewed research studies provided a definitive prevention strategy. Chang and collaborators[99] conducted a similar review targeted at examining interventions for older adults in the community and found that multimodal assessments with targeted intervention reduced risk of falls by 37 percent, and that exercise interventions reduced fall risk by 14 percent. Hill-Westmoreland, Soeken, and Spellbring[38] conducted a recent meta-analysis, including a sensitivity analysis, which identified an improved effect on fall prevention in the community when individualized management was added to exercise interventions. They concluded that exercise interventions were not sufficient in and of themselves, and interventions needed to be tailored to address individual risk factors.

Researchers have explored several other individual prevention strategies, including fall prevention clinics, exercise interventions with leg strengthening (e.g., Tai Chi), vitamin D supplements, home visits for safety evaluations, cataract surgery, and cardiac pacing. Falls and balance clinics present a promising community-based solution to the problem of falls.[108] Perell and colleagues[109] found a 50 percent reduction in fall rates for patients who were screened at a clinic and who had tailored interventions applied; however, this study had no control group and the researchers did not report injury rates, so the results are tentative. Clinics such as these provide focused intervention planning for patients identified at risk for falling, but the success of such clinics is contingent upon accurate identification of high-risk patients.

Identification of recurrent fallers via comprehensive screening followed by tailored interventions has been successful at reducing recurrent falls. Screening and intervention done in the ED reduced recurrent falls by 36 percent in one study,[90] and a nurse-led intervention that provided home assessment and tailored interventions reduced recurrent falls by 38 percent in another study.[110] Hogan and colleagues[111] also evaluated tailored interventions for patients who had had a fall within the past 3 months. They found no significant differences between the intervention and control groups in fall rates or time to first fall; however, the intervention group had a longer time between falls ($P = 0.001$). However, the Hogan and colleagues study limited inclusion criteria to patients older than 65 years of age who had fallen in the past 3 months, and these two factors alone are likely insufficient to determine risk. These recent studies add to early work in the PROFET study, which found a 61 percent decrease in falls for patients who were identified in the ED and who had subsequent detailed risk assessment and tailored interventions.[42]

Exercise-related interventions are by far the most commonly studied individual community prevention strategy. Most of this research indicates that exercise is beneficial for patients, and some research demonstrates that exercise regimes that involve leg strengthening and balance training, such as Tai Chi, are most effective.[112-122] Robertson and colleagues[123] performed a meta-analysis of four studies that examined effects of home exercise programs. They found in the pooled effect analysis that both fall and injury rates decreased by 35 percent. Exercise in

conjunction with cognitive behavioral therapy, where patients are taught how to increase self-awareness about risky situations, has demonstrated promising results, including a longer time to first fall and decreased injuries.[124] Unfortunately, this work did not demonstrate an effect on falls efficacy, fear of falling, or actual fall rates. More recently, balance training has been compared to general exercise, and results show that balance training can prevent falls in the nonfrail elderly, but not in the frail elderly.[125] Lin and colleagues[126] found that deployment of large scale Tai Chi training to the general community had mixed results. Luukinen and colleagues[127] found a decrease in fall and injury rates with a targeted exercise program when compared to usual care, but the results were statistically significant only in a group that was not homebound—suggesting that early intervention may be more effective. Further research to explore interventions for homebound community dwellers, particularly for the very old and frail, will be important.

Laboratory studies indicate that calcium and vitamin D reduce bone loss,[128] and a growing body of work is examining the ability for vitamin D supplementation to prevent fractures in individuals who are vitamin D deficient. A meta-analysis performed by Bischoff-Ferrari and team[129] revealed that larger doses of vitamin D supplementation (700–800 IU/deciliter) reduced the risk of fracture by up to 26 percent, whereas smaller doses of vitamin D (400 IU/deciliter) did not reduce fracture risk. However, research to date has been inconclusive, and larger, more recent studies have indicated that the use of vitamin D does not reduce fracture risk in the general community.[130] On the other hand, vitamin D supplementation may be integral in preventing falls themselves:[131] Recently, Latham and colleagues[132, 133] demonstrated that vitamin D intake is an individual predictor for fall reduction, primarily by improving muscle strength. Bischoff-Ferrari and colleagues[134] have also identified a reduction in fall risk for women, but not for men, using vitamin D supplementation. Although these results are promising, more research is required to identify best practice recommendations related to vitamin D deficiency screening and vitamin D supplementation or other bone-supporting medication regimes.

Other researchers are exploring the ability for osteoporosis-prevention medications to reduce fracture risk.[135] Sato and colleagues[136, 137] reported that risedronate, an oral bisphosphonate for osteoporosis prevention, was effective at preventing fracture in older females, older males who have had a stroke, and older females with Alzheimer's disease. A recent large study by McCloskey and colleagues[138] (N = 5579) demonstrated a 20–29 percent decrease in clinical fractures in community-dwelling females older than 75 years with and without osteoporosis who were prescribed clodronate 800 mg daily. However, this study did not find a decrease in hip fractures. Recent reports of adverse side effects of large doses of bisphosphonates, including osteonecrosis of the jaw, indicate that further research is warranted and that patients should be monitored for side effects of these drugs. Other related fall prevention efforts include home assessment for risk factors with the implementation of safety devices such as handrails, nonslip surfaces on stairs, and removal of throw rugs.[139-143] Researchers who conducted a recent randomized controlled trial found that thin-soled shoes were found to be the best type of shoe for patients, rather than running shoes, which have sticky soles.[144] Research addressing syncope-related falls indicate that cardiac pacing may be appropriate for individuals with syncope.[145]

Summary of community-based research on falls and related injuries. In summary, authors of several reviews have examined the efficacy of community-based fall- and injury-prevention programs. These reviewers have indicated that individualized multimodal interventions are effective at reducing falls and related injuries in the community setting.[105] However, multimodal interventions are not in place across primary care areas, which hinders their potential efficacy, and the aging community would likely benefit from large-scale

implementation of these proven preventive interventions. (See Evidence Tables 1 through 9 for individual study results.)

Falls and Related Injuries in the Acute and Long-Term Care Settings

Fall and related injury prevention is a major focus for both acute and long-term health care organizations. In 2005, the Joint Commission added the requirement for fall risk assessment and periodic reassessment as a National Patient Safety Goal in the acute care setting.[54] The goal of this requirement is to ensure that all patients are screened for falls and thus seeks to reduce harm from falls. However, the outcome is unpredictable because fall and injury risk assessment instruments have shown inconsistent reliability and validity A more promising extension of this goal starting in 2006 and continuing forward is the additional requisite of implementing and evaluating a fall-prevention program.[146] National compliance with these goals has the potential to significantly impact the problem of falls in the acute care setting. Efforts to enhance quality of care in the long-term care environment via improved reporting have the potential to reduce falls and related injuries in these particularly vulnerable patients; however, the successful implementation of fall-prevention programs will be necessary to improve the problem.

Falls in the acute and long-term care settings have several possible consequences. Recurrent falls have been identified as contributing to increases in the length of stay (LOS) in elderly psychiatric patients.[147] However, some research has suggested that LOS itself may be a predictor. A fall may also lead to a poorer quality of life because of fallophobia, a fear of future falls, which may itself contribute to fall risk.[148] Injuries occur in between 6 and 44 percent of falls in the acute care setting.[20, 21, 23] In the long-term care population, between 9 and 15 percent of falls result in injury, with approximately 4 percent of these falls resulting in fractures.[149] Additionally, patients who have underlying disease states are more susceptible to injuries; for example, osteoporosis can increase the risk for fracture, and bleeding disorders can increase the risk for subdural hematomas.[150] Moreover, fall-related injuries increase resource utilization: injuries from falls lead to increased LOS and an increased chance of unplanned readmission or of discharge to residential or nursing home care.[151] Furthermore, inpatients who have incurred an injury due to a fall have approximately 60 percent higher total charges than those who did not fall or those who fell and did not sustain an injury.[152]

Evans and colleagues,[153] via the Joanna Briggs Institute, performed a systematic review of the evidence up to 1997 for fall and injury prevention in the acute care setting. They examined 200 studies related to identification of predictors, risk assessment instrument development and testing, and fall- and injury-prevention interventions. Of these studies, only two were randomized controlled trials (RCTs). The trial by Tideiksaar and colleagues[154] examined the use of bed alarms to notify staff when patients at high risk for falls got out of bed; however, this study had a sample size that was too small to identify an effect from using bed alarms. The other RCT examined the use of colored bracelets to identify patients at high risk for falls. Again, the study results were inconclusive.[155] Evans and colleagues concluded that the fall risk assessment instruments available were not generalizable. However, they did not adequately compare the psychometric properties of the instruments in question; rather they evaluated research related to the implementation of such instruments, which was relatively weak up to that time. In addition, Evans and colleagues concluded that individual interventions were not more useful that any of the fall-prevention programs that might be developed at a particular institution for a specific subset of patients. However, recent research has seen a growing number of RCTs, which will

facilitate the ability to make stronger practice recommendations for this complex and challenging problem.

For this review, research related to falls and related injuries in the acute and long-term care settings were identified and categorized as follows: risk factor identification, risk assessment instruments, and prevention strategies. Each category of research is discussed below.

Acute care and long-term care risk factors. Factors associated with patients at risk of falling in the acute care setting have been explored extensively, particularly over the past two decades.[17, 87, 156-160] Evans and colleagues[161] conducted a systematic review of research and identified 28 risk factors for falling, including impaired mental status, special toileting needs, impaired physical status, and to some extent age and medications. Oliver and colleagues[159] reviewed risk factor and risk assessment literature and identified five risk factors consistent across studies: unsteady gait, increased toileting needs, confusion, sedative-hypnotics, and history of falling. In the long-term care environment, risk factors are largely the same, with the addition of inability to transfer effectively[162] and short-term memory loss.[163] Although ability to transfer and short-term memory function might be characterized by unsteady gait and confusion, these items are expressly captured via the LTCMDS.

Research has consistently demonstrated that multiple factors are associated with falling in elderly and hospitalized patients and that fall risk increases as the number of factors increases.[98, 153, 156-159, 164-166] Although increased age is a strong predictor of falling in the community, increased age has not always been identified as a predictor in the acute care setting. Some studies have found increased age to be a risk factor,[17, 165] but others have found that increased age is not a factor in acute care.[157, 167, 168] Comorbidities and impaired functional status may be more important predictors of falls and subsequent injury in this setting.[150, 157] Recent work by Hendrich[169] did not support the association between increasing age (older than 65 years) and increasing risk of falling in the inpatient environment. Instead, Hendrich and colleagues[169] found that confusion was the most important risk factor associated with the risk of falling. Nevertheless, age must be considered when discussing injury associated with falls because often with age comes frailty. Several researchers have identified gender as a risk factor, with female gender being a stronger risk factor in the older population[170] and male gender a stronger factor in the younger population.[167, 169, 171] A recent retrospective analysis by Krauss and colleagues[170] found that altered mental status was not a factor in falls, but that patients in academic medical centers were more likely to fall. This research was limited because it did not control for patient acuity or staffing levels.

Harwood and colleagues[172, 173] reviewed the literature related to visual problems and falls and found that uncorrected visual impairment nearly doubled the risk of falling. Cardiovascular causes of falls derive predominantly from neurally mediated disorders (e.g., vasovagal syncope) and cardiac abnormalities (e.g., arrhythmias, infarction, valvular stenosis).[174, 175] Time of day has also been implicated; Tutuarimia and colleagues[176] identified a higher rate of falls on the night shift, but this is inconsistent with other research and may in fact be explained by staffing patterns. Association of falls to the lunar cycle has also been explored, but no association was found.[177]

Vitamin D deficiency has been implicated as a risk factor for falls and fracture in the long-term care setting.[178] In addition, elevated alkaline phosphatase and low serum parathyroid hormone have been identified as predictors for falls,[179, 180] and anemia has also been implicated.[181]

A number of researchers are exploring the relationship between nurse-to-patient staffing ratios and an increase in the incidence of falls.[20, 176, 182-184] Some of this work has identified an

inverse association between licensed nurse staffing ratios and fall rates (i.e., a higher proportion of nurses is associated with lower fall rates);[176, 182, 184, 185] however, the overall the results are inconclusive.[186] In addition, a growing body of research related to failure to rescue, defined as being "based on the premise that although deaths in hospitals are sometimes unavoidable, many can be prevented,"[187-189] supports the inclusion of unanticipated physiologic events in the definition of falls since the patient's safety issues should be addressed at all times. Other researchers examining nurse staffing ratios and fall rates suggest that fall rates are reduced by increasing the number of nurse aids rather than licensed nursing staff.[190] This is potentially supported by recent work by Krauss and colleagues;[191] of the fallers in their case-control study, 85 percent of those in need of assistance or supervision with ambulation fell while not being supervised.

Certain subgroups of patients have been identified at higher risk because of the inherent characteristics of their disease process or treatment modalities. These groups include geriatric, behavioral health, oncology, rehabilitation, stroke, and multiple sclerosis patients. In the behavioral health setting, fall rates range from 4.5 to 25 falls per 1,000 patient days.[192, 193] Researchers have identified the typical faller in the behavioral health setting as a female with a history of falls; who was younger than 65 years of age; who was experiencing anxiety and agitation; and who was receiving a sedative, a tranquilizer, or a laxative.[194] Irvin[195] explored risk factors in the psychiatric setting and found that gait or balance problems and history of falls were the primary predictors. Although many of these characteristics are consistent with patients in the acute care setting, younger age and comorbidities such as depression and psychosis are often predictors in the behavioral health population.[196-199] In addition, treatments specific to behavioral health patients are different than those in the acute care setting. For example, patients being treated for late-life depression are at risk for falling in the first weeks of using a tricyclic antidepressant and should be monitored closely while they are adjusting to the new medication.[75] De Carle and Kohn[200, 201] have described risk factors in behavioral health patients and have identified electroconvulsive therapy as a predictor.

Patients in rehabilitation units are also at higher risk, likely because they have suffered neurological injuries such as stroke or head injury, which precipitate muscle weakness, impaired cognition, and impulsivity.[202-205] In addition, these patients are being physically challenged, which places them in higher-risk situations and thus at greater risk for falling.[206]

In the pediatric inpatient setting, fall rates range from 0 to 0.8 per 1,000 patient days.[207] These rates are very low compared to adult inpatient and long-term care rates. The factors that limit the number of falls in this population are unclear, but may be related to increased supervision of pediatric patients via higher nurse-to-patient staffing ratios and the common practice of parents staying with pediatric inpatients.

Injury risk factors in the acute and long-term care setting. In general, injury risk factors are similar across care areas. Vassallo and colleagues[208] examined the risk factors associated with injury in a group of inpatient fallers and found that three factors were associated with injuries related to falls: (1) history of falls, (2) confusion, and (3) unsafe gait. In addition to these, Rothschild and colleagues[134] identified physiological processes, such as increased bleeding tendencies and osteoporosis, as factors that increased risk for bleeding or fracture. The risk for medications or physiologic factors to precipitate injuries related to bleeding have been explored on a limited basis in the inpatient population. Contrary to results in the community,[84] Stein and team[209] found that hospitalized stroke patients who are anticoagulated are not at higher risk for injury than nonanticoagulated patients; however, this study was small and the issue warrants

further research. Bond and colleagues[210] examined over a 4-year period the risk for bleeding injury among 1,600 patients who fell while hospitalized. These researchers found that half of the patients were on thrombotic therapy and that the incidence of fall-related intracranial hemorrhage was low, even in persons taking warfarin. The authors suggested that selection bias may be a factor because physicians might withhold anticoagulant therapy for patients who have a higher fall risk. More recently, Spector and colleagues[211] performed a large study of nursing homes and found that 85 percent of fractures were caused by falls, and that those with epilepsy, those with agitation, and those taking anticonvulsants had the highest risk of sustaining a fracture if they fell.

Table 2. Risk Factors for Falls and Injuries in Acute and Long-Term Care

Intrinsic Risk Factors	Fall Risk	Injury Risk
Demographics		
• Age	Across ages	Older
• Gender	Male	Female
Cognitive Function		
• Agitation	Yes	Yes
• Anxiety	Yes	No data
• Cognitive impairment	Yes	No data
• Impulsivity	Yes	No data
• Inability to follow instructions	Yes	No data
• Short-term memory loss	Yes	No data
Physical Function		
• Fall history	Yes	Yes
• Fatigue	Yes	No data
• Gait problems	Yes	No data
• Impaired muscle strength	Yes	No data
• Impaired physical functioning	Yes	No data
• Toileting needs increased	Yes	No data
• Postural hypotension	Yes	No data
• Visual impairment	Yes	No data
Physiologic Status		
• Alkaline phosphatase level elevated	Yes	No data
• Anemia	Yes	No data
• Parathyroid hormone deficiency	Yes	Yes
• Prolonged bleeding time	No data	Yes
• Vitamin D deficiency	Yes	Yes
Comorbidities		
• Alzheimer's disease	Yes	No data
• Depression	Yes	No data
• Diabetes	Yes	No data
• Comorbidities in general	Yes	No data
• Multiple sclerosis	Yes	No data
• Parkinson disease	Yes	No data
• Stroke	Yes	No data
• Syncope	Yes	No data
Medications		
• Anticoagulants	No data	Yes
• Antiepileptics	Yes	No data
• Chemotherapeutics	Yes	No data

Intrinsic Risk Factors	Fall Risk	Injury Risk
• Laxatives	Yes	No data
• Psychotropics	Yes	No data
• Sedatives and hypnotics	Yes	No data
Extrinsic Risk Factors	**Fall Risk**	**Injury Risk**
Other Factors		
• Staffing	Yes	No data
• Time of day	Yes	No data
• Electroconvulsive therapy (in behavioral health)	Yes	No data
• Being physically challenged (in rehab)	Yes	No data

Acute care risk assessment instruments. Many tools have been developed to identify patients at highest risk for falling in the acute care setting.[21, 159, 167, 169, 212-215] Perell and colleagues[87] reviewed risk assessment tools and identified 6 functional assessment instruments and 15 fall risk assessment instruments developed by nursing. Vassallo and colleagues[216] concurrently examined the predictive validity in the acute care setting of four commonly used risk assessment instruments (STRATIFY, Downton, Tullamore, and Tinetti) and found that the STRATIFY instrument was the easiest to use, was most effective of the four at predicting falls in the first week of inpatient admission (total predictive accuracy of 66.6 percent), but had the poorest sensitivity (68.2 percent).

The most commonly reported risk assessment instrument is the Morse Falls Risk Assessment Tool.[217] In 2002, O'Connell and Myers[218] conducted psychometric testing with this tool on 1,059 patients admitted to an Australian hospital. In this study, the Morse Falls Risk tool had a sensitivity of 83 percent and a specificity of 29 percent, but a positive predictive value of only 18 percent. This resulted in a very high false-positive rate, with the tool identifying more than 70 percent of patients who did not fall at high risk for falling. This research was confounded by the fact that the interventions were applied based on the instrument's predictions; therefore, the predictive validity cannot be conclusively stated. The STRATIFY Falls Prediction tool also had a low positive predictive value (30 percent) and relatively low sensitivity (66 percent) and specificity (47 percent).[212]

The Heinrich Falls Risk Model I is reported to be more robust (sensitivity, 77 percent; specificity, 72 percent) than either of the others, and the Hendrich Falls Risk Model II demonstrated even more improvement (sensitivity, 74.9 percent; specificity 73.9, percent; positive predictive value, 75 percent).[169] The inclusion of a Get Up and Go test in the Heinrich II tool was the major change between version I and version II. The Get Up and Go test evaluates a person's ability to rise from a chair in a single movement, which is an assessment method that has been explored in earlier fall-prediction research. It is surprising that the sensitivity and specificity of the tool increases only slightly with the addition of this factor, underscoring the complexity of predicting patient falls. In addition, prospective evaluation of the use of the Hendrich II instrument has yet to be reported.

Several studies have tested the predictive validity of fall risk assessment instruments in relation to the judgment of nurses. Myers and Nikoletti[219] concluded that neither the fall risk assessment instrument nor nurses' clinical judgment acted as a reliable predictor. Eagle and colleagues[220] compared the Functional Reach test, the Morse Falls Scale, and nurses' clinical judgment in the rehabilitation and geriatric environment. This study also concluded that the two standardized assessment processes were no better at predicting falls than the clinical judgment of nurses. A limitation in both of these studies was that the evaluation occurred only at one time

point close to admission, which does not account for the variability of patient status throughout a patient's hospital stay.

In the domain of rehabilitation medicine, Ruchinskas[221] compared structured assessments—including the Mini-Mental State Exam, the Geriatric Depression Scale, the Functional Intervention Model, and the clinical judgment of physical and occupational therapists—on admission and discharge. This study concluded that the clinical judgment of therapists had a positive predictive power of 33 percent and a negative predictive power of 82 percent. However, the more accurate predictors of falling for the patients in their sample were a history of falls and presence of a neurological diagnosis. In the residential care environment, Lundin-Olson and colleagues[222] found that clinical judgment can contribute to the accurate prediction of fall risk, but is not sufficient on its own as a valid predictor.

Although fall-prediction research has been performed for two decades, it is clear that fall prevention is a complex problem that cannot be solved by risk assessment alone, hence the dissatisfaction with available risk assessment instruments.

Long-term care assessment instruments. Lundin-Olson and colleagues[223] developed the Mobility Interaction Fall Chart (MIF chart), which is an instrument based on a patients' ability to walk and talk at the same time, the ability to maintain pace while carrying a glass of water, visual impairment, and difficulty concentrating. When the predictive validity of the MIF chart was evaluated, the researchers found that the chart was helpful only when used in conjunction with clinical judgment and knowledge of a patient's history of falls, thus making the use of this instrument on its own limited.[222]

The Downton instrument, originally developed in the community setting, characterizes risk by five factors: (1) increased dependency, (2) cognitive impairment, (3) increased number of physical symptoms, (4) presence of anxiety, and (5) presence of depression.[224] This instrument has recently been prospectively evaluated in the long-term care setting with a reported sensitivity ranging from 81 to 95 percent and specificity ranging from 35 to 40 percent.[225] Although the specificity is low, this instrument might provide a standardized measure to identify those at risk in the long-term care environment.

Becker and colleagues[162] have recently described an algorithm to assess fall risk in the long-term care setting, categorizing long-term care residents into three subgroups: (1) residents requiring assistance to transfer, (2) residents able to transfer with history of falls and requiring the use of restraints, and (3) residents able to transfer and with no history of falls but with urinary incontinence and visual impairment. The researchers found that the residents with the history of falls were at highest risk for falls, which is consistent with other research in this domain, but might be useful to tailor interventions and would warrant prospective evaluation.

Acute care pediatric risk assessment instruments. Falls in the acute care pediatric setting are relatively rare; however, standardized assessment may be beneficial to reduce falls and injuries in this population. Graf[207] has recently developed an instrument for acute care pediatric risk assessment. According to Graf, factors associated with pediatric falls include (1) seizure medication (odds ratio 4.9), (2) orthopedic diagnosis, (3) not using an IV (odds ratio 3.6), (4) physical/occupational therapy ordered, and (5) LOS (odds ratio 1.84 for every 5 days). This model has a sensitivity and specificity of 69 percent and 84 percent, respectively, and is being prospectively evaluated by the investigator with the hope that standardized assessment will facilitate reduction in these already-low rates.

Automated risk assessment in the acute and long-term care settings. Recent national patient safety efforts highlight the promise of using informatics processes to manage patient

safety issues such as the management of patient falls. However, to date, most automated risk assessment techniques in the acute care setting are electronic versions of existing fall risk assessment instruments, with limited use of computerized decision support.[167, 226, 227] Promising new work in data mining for fall prediction has demonstrated that use of the LTCMDS has the potential to use existing data to generate risk models for patients in this setting. Volrathongchai[228] has recently explored the ability to use computerized data mining techniques to identify elderly residents of long-term care facilities who were at risk for falls. Although this work has not been prospectively evaluated, the research found that the use of these data mining techniques, in conjunction with nursing knowledge, had the potential to identify fallers.

Acute and long-term care prevention strategies. The goal of any fall- and injury-prevention effort is to decrease adverse outcomes for the patients who are most vulnerable to falling. A beneficial consequence of fall- and related-injury-prevention programs is the potential to streamline resource use, with the added potential for decreased costs associated with this problem.[229-231] To date, however, a ubiquitous fall- and injury-prevention strategy has not been identified for hospitalized patients, and implementation of multifaceted strategies is often difficult to introduce in the complex clinical environment.[232]

Several reviews have examined fall-prevention strategies in the acute and long-term care settings.[98, 99, 153, 159, 233] Oliver, Hopper, and Seed[234] examined 10 studies, including 3 RCTs and 7 prospective studies with historical controls. Oliver and colleagues found that the pooled effects ratio was 1.0 (95% CI = 0.60–1.68), indicating that overall the interventions were not able to prevent falls. More recently, Oliver and colleagues[235] have performed a meta-analysis of fall- and injury-prevention strategies and found a decrease in fall rates with multimodal intervention and a decrease in hip fractures with hip protectors in the long-term care setting. Agostini, Baker, and Bogardus[98] conducted a review of the literature related to fall prevention for hospitalized and institutionalized older adults. This review did not pool the results, but examined the literature related to the use of armbands, bed alarms, and restraints for fall prevention, all of which will be discussed individually below.

The use of physical restraints to prevent falls has been refuted because restraints limit mobility, contribute to injuries, and don't prevent falls.[236, 237] Agostini and colleagues[98] examined literature related to fall prevention via restraint and side rail use, as well as fall rates when restraints were removed. Six studies found that restraints were associated with increased injuries, and restraint and side rail removal did not increase fall rates. Evans, Wood, and Lambert[238] also examined the literature and found 16 studies that examined restraint minimization, concluding that restraint-minimization programs involving effective staff education can reduce injuries and do not increase fall rates.

Several individual fall-prevention interventions have been examined, including the use of armband identification bracelets, exercise regimen, postfall assessment, bed alarms, toileting regimen, and vitamin D supplementation. Mayo and colleagues[155] conducted a randomized controlled trial to examine if armbands would help identify high-risk patients in a rehabilitation unit and prevent falls in the high-risk group. The researchers, however, found that high-risk patients with a blue armband had higher fall rates than those without the armband. Despite widespread use, only one study from 1993 has examined bed alarms. Tideiksaar and colleagues[154] found that bed alarms were an effective method for fall prevention (relative risk = 0.32), but the intervention warrants further research. An associated intervention, a movement detector, has recently been developed. Kwok and colleagues[239] studied movement detectors and found no difference between intervention and control groups. However, a pilot study examined

the use of a movement detection patch attached to the thigh, which alerts clinicians when elderly long-term care residents are moving about.[240] Kelly and colleagues found a 91 percent decrease in falls during the 1-week testing period. Although this study quality was poor, the intervention might be suitable for select patients and bears further testing. Rask and colleagues[224] and Taylor and colleagues[225] evaluated the use of a fall-prevention program with a fall coordinator in the long-term care setting; they found that the control nursing homes had increases in fall rates over 4 years, whereas the intervention nursing homes had stable fall rates during the same time period.

Mulrow and colleagues[241] examined the effects of a physical therapy exercise intervention for frail long-term care residents and found that fall rates increased in the intervention group. However, the intervention group in this study also showed an increase in general strength and a decrease in the use of assistive devices, making one wonder if the physical therapy intervention sought to decrease the use of assistive devices in inappropriate situations. Rubenstein and colleagues[242] examined the ability for post-fall assessment to identify underlying factors that could be remedied to prevent further falls. Choi and colleagues[243] examined the effect of Tai Chi in the long-term care setting and found a 38 percent decrease in falls in the Tai Chi group, but this was not statistically significant (relative risk = 0.62; 95% CI = 0.32–1.19). A larger study may demonstrate statistical significance. A more recent study by Nowalk[244] reported no difference between groups who received strength training. The authors concluded that long term care residents may require individualized training, rather than group training.

Bakarich, McMillan, and Prosser[245] examined the impact of a toileting regimen for elderly confused patients with mobility problems in the acute care units of a large metropolitan teaching hospital. The researchers found that there were 53 percent fewer falls during shifts in which the risk assessment and toileting intervention was used, but that compliance with the assessment and intervention was difficult to maintain. More recently, Klay and Marfyak[246] found that a continence specialist in the long-term care environment reduced falls by 58 percent. Vitamin D has also reduced falls in elderly females in the long-term care setting by up to 49 percent, and in both males and females by 25 percent.[129, 134, 178, 247, 248] Further investigation of the use of vitamin D in the acute care and rehabilitation setting for fall and injury prevention is warranted. Jensen and colleagues[249] examined the effect of exercise training on elderly residential care patients and found an increase in strength and balance, and a nonstatistically significant decrease in falls. This study was limited by its small sample size and unequal distribution of important risk factors such as Mini-Mental State Exam scores across groups.

As with community interventions, tailored, multipronged prevention strategies are being shown to be more effective in acute and long-term care settings than individual interventions alone. Hofmann and colleagues[250] used three concurrent interventions—staff education, an exercise program, and environmental modifications—for a frail elderly population. The concurrent use of these interventions decreased the fall rate by 38 percent and decreased the fracture rate by 50 percent. Haines and colleagues[251] also examined a multipronged intervention involving staff and patient education, an exercise program, and the use of hip protectors. Researchers found a 22 percent decrease in falls and a 28 percent decrease in injuries in the intervention group.

One of the most promising studies by Jensen and her research team[252] investigated the effects of a comprehensive fall risk assessment and tailored intervention program in the long-term care setting. The intervention included assessment via the Mobility Interaction Fall Chart, visual evaluation, medication evaluation, and delirium screening by all members of the care team—physicians, nurses, and physical and occupational therapists. This research demonstrated that the

comprehensive assessment and tailored interventions reduced falls by 51 percent and injuries by 77 percent over a 34-week period. Healy and colleagues[253] also found a statistically significant reduction in falls (RR = 0.71) by applying a tailored plan of care to adult inpatients who were deemed at high risk for a fall based on having had a previous fall. In effect, this research used history of fall as a method to triage high-risk patients, who then received a comprehensive risk assessment with targeted interventions. This research did not demonstrate a decrease in injuries; however, further research using this technique will be useful. McMurdo, Millar, and Daly[254] found up to a 55-percent reduction in fall rates in a group of 133 nursing home residents with comprehensive risk assessment and balance training, but these results were not statistically significant. A larger sample size would provide a better understanding of the effect of the intervention.

Other research examining multimodal interventions have had mixed outcomes. A recent study by Vassallo and colleagues[255] in long-term care facilities found a decrease in falls was nullified when the results were controlled for LOS. However, controlling for LOS removes the ability for LOS to be identified as a predictor, which may be the case for patients who stay longer in a hospital setting. Kerse and colleagues[256] found that in a group of nursing homes, long-term care residents who were randomized to risk assessment followed by tailored interventions showed an increase in falls (incident rate ratio = 1.34; $P = 0.018$). Semin-Goossens, van der Helm, and Bossuyt[257] evaluated the effect of a guideline with semistructured interventions and found that fall rates in high-risk neurology and medical patients were not reduced. The researchers attributed the failure of the program to resistance by nurses to changing attitudes toward falls with the statement that nurses did not find falls troublesome enough. However, the failure was more likely due to system issues, such as ability to implement and agreement with the guideline, and training issues, which are common with guideline implementation failures.[258, 259] In addition, the Semin-Goossens guideline did not use a standardized risk assessment instrument, which might have made it difficult to identify patients at risk. Fonda and colleagues[260] studied a multimodal process-improvement plan and found that after 3 years, fall rates were decreased by 19 percent and injuries were decreased by 77 percent. Furthermore, this effect was sustained with continued use of the multimodal intervention. Schwendimann and others[261] found a moderate, but not statistically significant decrease in fall rates, and no change in injury rates after implementing an interdisciplinary fall-prevention program. Lane[262] found no decrease in patient fall rates before and after implementation of a fall-prevention program. Although the results of multimodal studies are conflicting, it is important to note that none of the studies of multimodal interventions—whether effective or ineffective results—controlled for staffing ratios or skill mix.

An increasing number of studies are examining the prevention of injury in the acute and long-term care settings. Hip protectors have been evaluated in the long-term care environment since the early 1990s. Although early work found that hip protectors were effective in reducing hip fractures in the frail or osteoporitic elderly,[263] more recent work indicates that compliance with using hip protectors is difficult to maintain, making recommendation for hip protector use conditional.[264, 265] Ray and colleagues[266] examined the ability of a 2-day staff safety education plan to reduce serious fall-related injuries and found that this intervention was not effective, but the result may have been confounded by lack of staff compliance with the safety plan. (See Evidence Tables 1 to 9 for individual study results.)

Summary of acute and long-term care falls and related injuries. In summary, fall prevention in the acute and long-term care settings is a complex and demanding problem with

multiple patient types and risk factors to manage. Standardized risk assessment with multimodal tailored interventions appears to be the most successful method of prevention; however, implementation of comprehensive interventions across care settings can be challenging. Further research toward overcoming barriers to implementation, guideline adherence, staffing ratios, and tailored interventions for newly identified risk factors such as vitamin D deficiency and anemia are warranted. Furthermore, research must be conducted on a larger scale to demonstrate generalizability and to be able to translate evidence into practice.

Evidence-Based Practice Implications

Screening for fall and injury risk should be performed across settings. In the community, all patients older than 65 years should be screened, and in the home care, acute care, and long-term care settings, patients of all ages should be screened. Screening needs to include injury risk, not just fall risk. The most effective interventions are multimodal ones that address specific areas of risk and work with interdisciplinary fall-prevention teams.

In the community, screening can take place with a general annual physical exam or other routine health care visit. A standardized risk assessment tool should be used, such as the Tinnetti screening tool, which has the highest sensitivity and specificity for use in the community, but screening for injury risk must be included. If a patient is seen in an emergency room because of a fall, evidence suggests that focused fall and injury risk evaluation is warranted, especially if the patient is to be discharged home, i.e., the discharge prescription should include a focused fall risk assessment by the primary care provider or by a fall-prevention clinic. Tailored interventions for elderly community dwellers can decrease fall rates. Interventions that have had the most success in the community include exercise interventions with leg strengthening and balance training (e.g., Tai Chi), medication adjustment, management of cardiac-related syncope, effective diabetes management, management of vitamin D deficiency, and home safety modifications. Interventions to prevent injury in the community include calcium with vitamin D for fracture prevention, and additional fall precautions and increased screening for patients on anticoagulant therapy.

In the acute and long-term care settings, screening should be carried out using a standardized assessment tool for all patients. The Morse tool is the most commonly used in the acute care setting, but it does not screen for injury risk. In the long-term care setting, the LTCMDS may be an effective screening tool. In both acute and long-term care, effective interventions are multimodal and include medication adjustment, environmental adjustment, alarm devices, staff safety education, calcium and vitamin D, exercise interventions, and treatment of other underlying disorders. Interventions to prevent injury in the acute and long-term care settings include limiting restraint use, lowering bedrails, using hip protectors in long-term care, calcium with vitamin D, and possibly bisphosphonates in long-term care. Across the health care continuum, effective interventions have been identified, but their use is not ubiquitous.

Research Implications

In the community setting, identification of the best timing for screening and reassessment is needed. Identification of methods to build fall- and injury-prevention programs in the community is needed to guide policymakers. In the acute and long-term care settings, large multisite intervention studies that use multimodal interventions tailored for individual risk factors and that control for comorbidities, acuity, staffing, and other environmental factors are needed. Cost-

effectiveness studies to characterize the impact of fall- and injury-prevention programs are needed in the acute and long-term care settings.

Recommendations From Evidence-Based Practice and Research Implications

1. Recommendations for screening and assessment

- Fall and injury risk screening should be performed in all settings.
- All patients who fall should receive a comprehensive postfall assessment.
- Methods for computerized screening and followup should be explored.

Table 3. Recommendations for Screening and Assessment

Evidence-Based Practice Recommendations	Research Implications
Community:	
• Screen all patients over 65 during routine or other visit.	• Examine risk factors related to race and gender.
• For patients who screen positive, refer to fall-injury prevention clinic for focused fall-injury risk assessment, if available.	• Identify barriers to widespread screening. • Examine barriers to establishment of fall-injury prevention clinics.
• Use a standardized risk assessment tool, such as Tinetti's 9-item screening tool for (1) mobility, (2) morale, (3) mental status, (4) distance vision, (5) hearing, (6) postural blood pressure, (7) back examination, (8) medications, and (9) ability to perform activities of daily living (ADLs). (*Note:* This tool does not overtly assess for injury risk.)	• Validate risk assessment instruments across culture, race, and language. • Examine predictive validity of injury risk factors such as antiplatelet therapy, bleeding disorders, vitamin D deficiency, and chronic subdural hematomas. • Develop instruments for patient self-assessment for fall and injury risk.
• For patients > 65 years who present to the emergency department (ED) with a fall, refer to primary care provider for focused fall-injury risk assessment.	• Examine the effect of identification in the ED using large, multicenter randomized controlled trials. • Identify barriers to widespread adoption.
Evidence-Based Practice Recommendations	**Research Implications**
Home Care and Long-Term Care:	
• Screen patients of all ages.	• Validate home care assessment instruments.
• Use a standardized risk assessment tool, such as Tinetti's 9-item screening tool.	• Examine predictive validity of Long Term Care Minimum Data Set.
• Reassess at regular intervals.	• Examine best timing for reassessment in home care and long-term care.
Evidence-Based Practice Recommendations	**Research Implications**
Acute Care Setting:	
• Screen patients of all ages.	• Develop and validate instruments for subgroups.
• Use a standardized risk assessment instrument such as the Morse, Hendrich II, or STRATIFY tools. (*Note:* These tools do not assess for injury risk.)	• Validate instruments in multiple settings. • Explore predictive validity of physiologic factors such as low creatinine clearance, vitamin D deficiency, and anemia.
• Assess for injury risk for patients with injury risk factors such as low BMI, frailty, osteoporosis, vitamin D deficiency, and antiplatelet therapy.	• Validate instruments that assess for injury risk.
• Reassess patients at regular intervals.	• Examine the best timing for reassessment.

2. Recommendations for interventions in the community setting

- Apply multimodal interventions as identified by risk assessment.
- Participate in national reporting activities such as ANA–NDNQI.
- Examine the use of computer-based guidelines in all settings.

Table 4. Recommendations for Community Setting

Evidence-Based Practice Recommendations	Research Implications
Fall Prevention:	
• Provide balance training with leg strengthening, such as Tai Chi.	• Examine effect of starting balance training at younger age (i.e., 50 years). • Examine barriers to establishment and use of balance training centers.
• Monitor medication side effects for patients older than 65.	• Identify medications with minimal side effect profiles for patients older than 65.
• Limit medications to fewer than four, if possible.	• Examine medication dosing for groups of medications.
• Monitor and treat calcium and vitamin D deficiency.	• Examine factors related to calcium and vitamin D metabolism in relation to muscle function.
• Manage underlying disorders such as cardiac-related syncope, diabetes, and vision problems (e.g., cataracts).	• Explore factors to manage groups of disorders. • Explore other diseases that may predict falls.
• Provide home safety modifications.	• Explore barriers to home safety modification.
• Educate about use of thin-soled shoes (not running shoes).	• Further explore shoe type for specific patient groups.
• Provide education about how to manage risky situations.	• Explore fall prevention self-management strategies.
Injury Prevention:	
• Monitor for calcium and vitamin D deficiency; provide supplements for fracture prevention.	• Conduct large studies that control for comorbidities, age, and other factors to explore efficacy of hip protectors in the community.
• Increase screening for patients on anticoagulant therapy, those with bleeding disorders, and for the frail and very old.	• Identify safety measures for bleeding-injury prevention. • Explore interventions for the very old and frail.
• Use bisphosphonates for patients with documented osteoporosis.	• Explore safety of long-term use of bisphosphonates.

3. Recommendations for interventions in the acute and long-term care settings

- Apply multimodal interventions as identified by risk assessment.
- Participate in national reporting activities such as ANA–NDNQI.
- Examine the use of computer-based guidelines in all settings.
- Large, multi-site randomized controlled trials that evaluate tailored interventions while controlling for organizational culture, staffing, comorbidities, acuity, and other factors are needed. Injury rates should be the primary outcome of interest, since fall-rate reporting may be an imprecise measure.
- Characterize the cost effectiveness of bundles of tailored interventions.

Table 5. Recommendations for Acute and Long-Term Care

Evidence-Based Practice Recommendations	Research Implications
Fall Prevention	
• Educate staff about safety care. • Train medical team, including students and residents, for fall-injury risk assessment and postfall assessment.	• Examine impact of safety education across interdisciplinary team.
• Use alarm devices.	• Examine impact of alarms on caregiver satisfaction.
• Monitor medication side effects and adjust as needed.	• Examine effect of computerized decision support for medication management.
• Adjust environment (e.g., design rooms to promote safe patient movement).	• Examine cost effectiveness of environmental adjustments.
• Provide exercise interventions (e.g., Tai Chi) for long-term care patients.	• Examine usefulness of exercise interventions for acute care patients.
• Provide toileting regimen for confused patients (e.g., check patients every 2 hours).	• Study barriers to maintaining and sustaining monitoring activities.
• Monitor and treat calcium and vitamin D levels for long-term care patients.	• Examine effects of calcium and vitamin D management for acute care patients.
• Treat underlying disorders such as syncope, diabetes, and anemia.	• Examine constellations of disorders that might precipitate falls.
Injury Prevention	
• Limit restraints use.	• Identify methods to overcome barriers to restraints reduction.
• Lower bedrails.	• Study efficacy of environmental changes.
• In addition to fall rates, monitor injury rates.	• Establish fatal fall rates across settings.
• Use hip protectors for geriatrics and long-term care.	• Identify methods to overcome barriers to use of hip protectors.
• Use floor mats.	• Examine effect of safety flooring.
• Monitor prothrombin time, international normalized ration (PT/INR) for patients at risk for falling.	• Identify safety measures for bleeding-injury prevention.
• Ensure postfall assessment.	• Examine barriers to postfall assessment.
• Use bisphosphonates for patients with documented osteoporosis.	• Explore safety of long-term use of bisphosphonates.

Conclusion

Falls and related injuries are an important issue across the care continuum. National efforts in the community via Healthy People 2010, in the acute care setting via the Joint Commission's National Patient Safety Goals, and in the long-term care setting via the Nursing Home Quality Initiative project have the potential to significantly reduce falls and related injuries. The growing number of randomized controlled trials related to fall-prevention efforts is promising. However, most of these studies have been carried out in the community and long-term care environments, with few randomized controlled trials evaluating fall- and injury-prevention measures in the acute care setting. As with other nursing-sensitive quality indicators, recent research demonstrating an association between fall rates and nurse staffing ratios needs to be more fully explored. In addition, further research needs to explore automated methods of assessing and communicating fall risk, better methods for risk identification, and the identification of

prevention measures. Indeed, with coordinated efforts to apply the evidence to practice, the problem of falls might be managed more effectively.

Search Strategy

MEDLINE,® the Cumulative Index to Nursing and Allied Health Literature (CINAHL®), and Cochrane databases from inception to March 2007 were searched for medical subject heading terms, both individual terms and combinations of the following: accidental falls, patient safety, medical errors, nursing-sensitive quality indicators, and fall prevention. In addition, references from relevant articles were searched using the snowball technique, as were archives of select nursing research and gerontology journals. The Related Links function in MEDLINE was also used to maximize the search strategy. Google, Google Scholar, and citations from identified articles were also searched for additional possible references. Articles related to occupational falls, sports-related falls, alcohol-related falls, and physical abuse-related falls were excluded. Articles that reported physiologic characteristics that are suspected to preclude falls but that did not examine falls or fall-related injuries as outcomes were also excluded because the causative effect on falls and fall-related injuries is, to date, inconclusive. Further, articles that were published in a foreign language were excluded. Two hundred and twenty seven articles were reviewed. Sixty-one of these were intervention research studies related to fall and injury prevention (32 from the community setting; 33 from the acute and long-term care setting).

Evidence Table 1. Reviews Examining Fall-Prevention Interventions in the Community

Source	Safety Issue Related to Clinical Practice	Design Type*	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Weigand 2001[93]	Fall and injury prevention in the community	Literature Review	**Design:** Review **Outcomes:** Fall rates	**Setting:** Community **Population:** Emergency patients	Assessment of fallers & targeted interventions	*Falls:* No definitive evidence to support ED assessment followed by targeted interventions is effective for preventing falls. More research required.
Cumming 2002[100]	Fall and injury prevention in the community	Literature Review	**Design:** Review **Outcomes:** Fall rates	**Setting:** Community **Population:** Older adults	Multiple interventions; 21 trials reviewed	*Falls:* • Exercise programs most promising. • Reduction of antipsychotic medications should be considered. • No definitive prevention strategy.
Gillespie 2003[104]	Fall and injury prevention in the community	Meta-analysis	**Design:** Systematic Review **Outcomes:** Fall rates	**Setting:** Community **Population:** 21,668 people	Multiple interventions; 62 trials reviewed	*Falls:* Multimodal, interdisciplinary prevention programs are most successful. *Risk Assessment:* Need more accurate risk assessment instruments.
Chang 2004[99]	Fall and injury prevention in the community	Meta-analysis	**Design:** Review **Outcomes:** Fall rates	**Setting:** Community **Population:** Older adults	Multiple interventions; 40 trials reviewed	*Falls:* Multimodal assessments with targeted intervention reduced risk of falls by 37 percent, and exercise interventions reduced fall risk by 14 percent.
Hill-Westmore-land 2005[38]	Fall and injury prevention in the community	Meta-analysis	**Design:** Meta-analysis **Outcomes:** Fall rates	**Setting:** Community **Population:** Older adults in long-term care setting	Multiple interventions; 12 studies reviewed	*Falls:* Decrease in fall rates when individualized management added to exercise interventions.
Stevenson 2005[135]	Fall and injury prevention in the community	Systematic Review	**Design:** Systematic review **Outcomes:** Fracture, vertebral and nonvertebral	**Setting:** Community **Population:** Older women at risk for fracture	Review of calcium, vitamin D, and bisphosphonates	*Fractures:* • Calcium, with or without vitamin D, reduces fractures in patients with high risk for fracture. • Calcium with vitamin D can prevent fractures in women not at risk for fractures.

* Study Design Type: (1) Meta-analysis, (2) Randomized controlled trials, (3) Nonrandomized trials, (4) Cross-sectional studies, (5) Case control studies, (6) Pretest and post-test (before and after) studies, (7) Time series studies, (8) Noncomparative studies, (9) Retrospective cohort studies, (10) Prospective cohort studies, (11) Systematic literature reviews, (12) Literature reviews, nonsystematic/narrative, (13) Quality-improvement projects/research, (14) Changing-practice projects/research, (15) Case series, (16) Consensus reports, (17) Published guidelines, (18) Unpublished research, reviews, etc.

Source	Safety Issue Related to Clinical Practice	Design Type*	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Shekele 2003[11]	Fall and injury prevention in the community	Meta-analysis	**Design:** Meta-analysis **Outcomes:** Fall and injury rates	**Setting:** Community **Population:** Medicare recipients	Mulriple interventions	*Falls:* Multifactorial fall prevention programs decrease fall rates

Evidence Table 2. Studies on Community-Based Fall-Prevention Screening with Tailored Interventions (listed chronologically)

Source	Safety Issue Related to Clinical Practice	Design Type†	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Close 1999[42]	Tailored interventions for falls in the community	RCT	**Design:** RCT **Outcomes:** Fall rates, repeat fall rates, hospital admissions, Barthel Score (Max 100; higher score = higher functioning)	**Setting:** Community **Population:** 397 patients ≥ 65 years who presented to an accident and emergency department with a fall	Detailed medical and occupational-therapy assessment with referral to relevant services if indicated with 1 year followup.	*Falls:* Decreased by 61 percent for patients who were identified in the emergency department and who had subsequent detailed risk assessment and tailored interventions (odds ratio = 0.39, 95% CI = 0.23–0.66; *P* = 0.0002). *Recurrent falls:* Decreased by 67 percent (odds ratio = 0.33, 95% CI = 0.16–0.68). *Hospital admissions*: Decreased by 39 percent (odds ratio = 0.61, 95% CI = 0.35–1.05). *Barthel score:* Decline in score with time greater in the control group (*P* < 0.00001).
Hogan 2001[111]	Tailored interventions for falls in the community	RCT	**Design:** Randomized controlled trial **Outcomes:** Fall rates, repeat fall rates, time between falls, emergency department visits, hospital admissions	**Setting:** Community **Population:** 152 patients ≥ 65 years who had fallen within the previous 3 months	In-home assessment in conjunction with the development of an individualized treatment plan, including an exercise program for those deemed likely to benefit.	*Cumulative number falls:* No significant differences (311 v. 241, *P* = 0.34) *One or more falls*: No significant difference (79.2 percent v. 72.0 percent, *P* = 0.30) *Mean number of falls:* 4.0 v. 3.2, *P* = 0.43. *Repeat fall rates*: No significant difference *Time between falls*: Longer time between falls in intervention group (*P* < 0.001) *For multiple fallers at baseline:* • Intervention group less likely to fall (*P* = 0.046) • Time between falls longer for intervention group (*P* < 0.001) *Emergency department visits:* No significant difference *Hospital admissions:* No significant difference

† Study Design Type: (1) Meta-analysis, (2) Randomized controlled trials, (3) Nonrandomized trials, (4) Cross-sectional studies, (5) Case control studies, (6) Pretest and post-test (before and after) studies, (7) Time series studies, (8) Noncomparative studies, (9) Retrospective cohort studies, (10) Prospective cohort studies, (11) Systematic literature reviews, (12) Literature reviews, nonsystematic/narrative, (13) Quality-improvement projects/research, (14) Changing-practice projects/research, (15) Case series, (16) Consensus reports, (17) Published guidelines, (18) Unpublished research, reviews, etc.

Source	Safety Issue Related to Clinical Practice	Design Type†	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Lightbody 2002[110]	Tailored interventions for falls in the community	RCT	**Design:** RCT **Outcomes:** Falls, functional ability, emergency department visits, admission to hospital	**Setting:** Community **Population:** 348 consecutive patients ≥ 65 years who were discharged from emergency room after sustaining a fall	Home assessment for medication, ECG, blood pressure, cognition, visual acuity, hearing, vestibular dysfunction, balance, mobility, feet and footwear	*Recurrent Falls:* Reduced by 38 percent *Falls:* Decreased falls in intervention group, but not statistically significant. *Admissions and bed days:* Fewer fall-related admissions and bed days in intervention group (8 and 69, respectively) than the control group (10 and 233, respectively).
Nikolaus 2003[141]	Tailored interventions for falls in the community	RCT	**Design:** RCT **Outcomes:** Number of falls, compliance with recommendations	**Setting:** Patients identified in university-affiliated geriatric hospital; intervention carried out in patients' homes **Population:** 360 patients showing functional decline, especially in mobility, admitted to a geriatric hospital (mean age 81.5 years)	Comprehensive geriatric assessment followed by diagnostic home visit and home intervention or a comprehensive geriatric assessment with recommendations	*Falls:* Intervention group had 31 percent fewer falls than control group (incidence rate ratio = 0.69, 95% CI = 0.51–0.97). *Falls:* For subgroup with ≥2 falls during previous year, there was a 37 percent decrease in falls (incident rate ratio = 0.63, 95% CI = 0.43–0.94).
Nitz 2004[108]	Tailored interventions for falls in the community	RCT	**Design:** pilot RCT **Outcomes:** Fall rates, balance measures	**Setting:** Australia; academic medical center **Population:** 73 adults (92 percent female) ≥ 65 yrs	Balance training sessions once a week for 10 weeks	*Falls:* Intervention and control groups both showed reduction in fall rates, but no differences between groups. *Balance measures:* Improved for intervention group.

Source	Safety Issue Related to Clinical Practice	Design Type†	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Davison 2005[90]	Tailored interventions for falls in the community	RCT	**Design:** RCT **Outcomes:** Fall rates, number of fall-related admissions, LOS, balance	**Setting:** Accident & emergency departments in a teaching hospital and associated general hospital in the United Kingdom **Population:** 313 cognitively intact patients ≥ 65 years with fall or fall-related injury and at least one additional fall in preceding year	Multimodal postfall assessment, including medical, physiotherapy, and occupational therapy evaluation	*Falls:* 36 percent fewer falls in the intervention group (relative risk = 0.64, 95% CI = 0.46–0.90). *Proportion of fallers:* 65 percent of subjects in the intervention group continued to fall compared with 68 percent in the control group (relative risk = 0.95, 95% CI = 0.81–1.12). *Hospital admissions*: Number of fall-related visits and hospital admissions was not different between groups. *Hospitalization:* Duration of hospital admission was reduced (mean difference admission 3.6 days, 95% CI = 0.1–7.6). *Activities-specific balance confidence score:* Improved in the intervention group.
Perell 2006[109]	Tailored interventions for falls in the community	Pretest post-test design	**Design:** Pretest, post-test **Outcomes:** Falls, repeat falls	**Setting:** Urban Los Angeles – Veterans Affairs System **Population:** 120 elders referred to the clinic. Gender not reported.	Screening following by tailored interventions at falls clinic	*Falls:* Reduction of total falls (pre = 297; post = 141; *P* = 0.0002). Increase in falls reported by 12.5 percent patients. *Mean fall rates:* Reduction in mean falls (pre = 4.1;post = 2.0). *Repeat falls:* Reduction in repeat falls (pre = 86 percent; post = 51 percent).

EvidenceTable 3. Studies Examining Exercise-Related Interventions in the Community (listed chronologically)

Source	Safety Issue Related to Clinical Practice	Design Type‡	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Reinsch 1992[124]	Exercise-related interventions for fall prevention in the community	RCT	**Design:** Four-arm RCT **Outcomes:** Fall rates, time to first fall, injury rates	**Setting:** 16 senior centers in Orange County, California **Population:** 230 older adults who were participants at senior centers	Exercise in conjunction with cognitive behavioral therapy for safety self-awareness	*Falls:* No effect on fall rates, falls efficacy, or fear of falling. *Time to first fall:* Longer time to first fall. *Injuries:* Decreased injuries. Even though a relatively high percentage (38.6 percent) suffered at least one fall, only 7.8 percent of these community-residing elderly required medical attention.
Province 1995[115]	Exercise-related interventions for fall prevention in the community	Meta-analysis	**Design:** Preplanned meta-analysis of 7 RCTs **Outcomes:** Time to each fall (fall-related injury) by self-report and/or medical records	**Setting:** Two nursing homes and five community sites **Population:** Patients ages 60–75, ambulatory, cognitively intact	Exercise training one area or more of endurance, flexibility, balance platform, Tai Chi (dynamic balance), and resistance	*Falls:* • Fall rates decreased in group with general exercise (odds ratio = 0.90, 95% CI = 0.81–0.99). • Fall rates decreased for those with exercise plus balance training (odds ratio = 0.83, 95% CI = 0.70–0.98). *Injuries:* Patients who did not exercise had an increase in injurious falls, but power was low to detect this outcome.
Wolf 1997[120]	Exercise-related interventions for fall prevention in the community	RCT	**Design:** RCT **Outcomes:** Frailty indicators, occurrence of falls	**Setting:** Community **Population:** 200 men and women ≥ 70 years	Tai Chi, computerized balance training, or education	*Multiple falls:* Risk of multiple falls decreased by 47.5 percent

‡ Study Design Type: (1) Meta-analysis, (2) Randomized controlled trials, (3) Nonrandomized trials, (4) Cross-sectional studies, (5) Case control studies, (6) Pretest and post-test (before and after) studies, (7) Time series studies, (8) Noncomparative studies, (9) Retrospective cohort studies, (10) Prospective cohort studies, (11) Systematic literature reviews, (12) Literature reviews, nonsystematic/narrative, (13) Quality-improvement projects/research, (14) Changing-practice projects/research, (15) Case series, (16) Consensus reports, (17) Published guidelines, (18) Unpublished research, reviews, etc.

Source	Safety Issue Related to Clinical Practice	Design Type‡	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Steinberg 2000[143]	Exercise-related interventions for fall prevention in the community	RCT	**Design:** RCT with four arms **Outcomes:** Self-reported slips, trips, or falls	**Setting:** Community, Australia **Population:** 252 active, community-dwelling Australians ≥ 50 yrs.	Education re: fall risk factors, strength/balance exercises, home safety advice, medical evaluation	*Falls:* 30 percent reduction in falls; hazard ratio 0.70 (95% CI = 0.48–1.01). *Slips:* 58 percent reduction in slips; hazard ratio 0.42 (95% CI = 0.29–0.69). *Trips:* 64 percent reduction in trips; hazard ratio 0.36 (95% CI = 0.26–0.66).
Rubenstein 2000[116]	Exercise-related interventions for fall prevention in the community	RCT	**Design:** RCT **Outcomes:** Muscle strength, endurance, mobility, balance, fall rates	**Setting:** Community-living men **Population:** 59 men ≥ 65 years with specific fall risk factors	90 min. exercise sessions 3x/week Focus on increased strength and endurance, improving mobility and balance	*Falls:* • Exercise group had lower fall rates than nonexercisers when adjusted for baseline activity level (6 falls/1,000 hours of activity vs 16.2 falls/1,000 hours, $P < 0.05$). • Total number of falls not decreased. *Strength:* Exercise achieved no significant effect on hip or ankle strength, balance, self-reported physical functioning.
Robertson 2002[123]	Exercise-related interventions for fall prevention in the community	Meta-analysis	**Design:** Meta-analysis of four studies **Outcomes:** Fall rates, injury rates	**Setting:** Community setting: nine cities and towns in New Zealand **Population:** 1,016 women and men ages 65 to 97	Muscle strengthening and balance retraining exercises designed specifically to prevent falls	*Falls and injuries:* Fall and injury rates decreased by 35 percent; no difference between genders. • Fall rate incidence rate ratio (IRR) = 0.65, 95% CI = 0.57–0.75 • Participants reporting a fall in the previous year had a higher fall rate (IRR = 2.34, 95% CI = 1.64–3.34). • Injury rate IRR = 0.65, 95% CI = 0.53–0.81.
Barnett 2003 [113]	Exercise-related interventions for fall prevention in the community	RCT	**Design:** RCT **Outcomes:** Fall rates, balance, muscle strength, fear of falling	**Setting:** Community, South Western Sydney, Australia. **Population:** 163 subjects ≥ 65 years identified as at risk of falling using a standardized assessment screen by general practitioner or physical therapist	Weekly group exercise program with ancillary home exercises over 1 year	*Falls:* Fall rates decreased by 40 percent in the exercise group (IRR = 0.60, 95% CI = 0.36–0.99). *Balance measures*: Improved in exercise group. *Other measures:* No difference between groups in strength, reaction time, and walking speed or on Short-Form 36, Physical Activity Scale for the Elderly or fear of falling.

Source	Safety Issue Related to Clinical Practice	Design Type‡	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Wolf 2003[122]	Exercise-related interventions for fall prevention in the community	RCT	**Design:** RCT **Outcomes:** Time to first fall, fall rates, balance	**Setting:** 20 congregate living facilities in the greater Atlanta area **Population:** 291 women and 20 men ages 70 to 97 who were transitioning to frailty	Intense Tai Chi exercise program or wellness education program	*Falls:* Fall rates decreased in Tai Chi group, but no statistical difference between groups (relative risk = 0.75, 95% CI = 0.52–1.08).
Clemson 2004 [114]	Exercise-related interventions for fall prevention in the community	RCT	**Design:** RCT **Outcomes:** Fall rates	**Setting:** Community **Population:** 310 men and women ≥ 70 years who had had a fall in the previous 12 months or were concerned about falling	Occupational therapy home visits, lower-limb balance and strength training, environmental safety education	*Falls:* • 31 percent reduction in falls for both genders (relative risk = 0.69, 95% CI = 0.50–0.96; *P* = 0.025). • For men alone, 68 percent reduction in falls (relative risk = 0.32, 95% CI = 0.17–0.59).
Morgan 2004[140]	Exercise-related interventions for fall prevention in the community	RCT	**Design**: RCT **Outcomes:** Falls	**Setting:** Community **Population:** 294 men and women ≥ 60 years who had either a hospital admission or bed rest for 2 days or more within the previous month	Exercise sessions lasting 45 minutes, including warm-up and cool-down, 3 times a week for 8 weeks (24 sessions)	*Falls:* • 49 percent reduction in falls for patients with low baseline physical functioning. • 3.5 times increase in falls for patients with high baseline physical functioning.
Suzuki 2004[118]	Exercise-related interventions for fall prevention in the community	RCT	**Design:** RCT **Outcomes:** Fall rates	**Setting:** Community, Japan **Population:** 52 elderly Japanese women	Exercise intervention—home and community center	*Falls:* Fall rates decreased in intervention group (13.6 percent v. 54.5 percent; *P* = 0.0097).

Source	Safety Issue Related to Clinical Practice	Design Type‡	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Li 2005[112]	Exercise-related interventions for fall prevention in the community	RCT	**Design:** RCT **Outcome:** Fall rates, functional balance, physical performance, fear of falling	**Setting:** Community in Portland, Oregon **Population:** 256 physically inactive elders ages 70 to 92	Tai Chi or stretching 3x/week for 6 months	*Falls:* 55 percent reduction in falls in Tai Chi group (relative risk = 0.45, 95% CI = 0.30–0.70). Fewer falls in the Tai Chi group (Tai Chi = 38 vs. stretch = 73; *P* = 0.007), (Tai Chi = 28 percent vs. stretching = 46 percent; *P* = 0.01). *Injuries:* Fewer injurious falls (Tai chi = 7 percent vs. stretching = 18 percent; *P* = 0.03).
Lord 2005[88]	Exercise-related interventions for fall prevention in the community	RCT	**Design:** RCT **Outcome:** Fall rates	**Setting:** Community in Australia **Population:** 620 people ≥ 75 years	Interventions to maximize vision and sensation or brief advice or usual care	*Falls:* The rate of falls during the trial period were similar in the three groups. *Injuries:* The rate of injurious falls during the trial period were similar in the three groups.
Faber 2006[125]	Exercise-related interventions for fall prevention in the community	RCT	**Design:** RCT **Outcomes:** Falls, mobility, physical performance, and self-reported disability	**Setting**: 15 homes for the elderly in Amsterdam, The Netherlands **Population:** 287 elderly men and women (mean age +/- standard deviation, 85+/-6yrs)	20-week exercise program of balance training inspired by Tai Chi or daily mobility activities or control	*Falls:* Fall incidence rate lower in balance training group (2.4 falls/yr) compared to the mobility activities group (3.3 falls/yr) and control (2.5 falls/yr), but not statistically significant. *For frail subjects:* Risk of becoming a faller in the exercise groups increased almost 3 times (hazard ratio = 2.95; 95% CI = 1.64-5.32). *For pre-frail subjects:* Risk of becoming a faller decreased by 61 percent (hazard ratio = 0.39; 95% CI = 0.18–0.88).
Lin 2006[126]	Exercise-related interventions for fall prevention in the community	RCT	**Design:** RCT **Outcomes:** Falls, fall-related injuries, related functional outcomes	**Setting:** 6 rural villages in Taiwan: 2 villages received intervention, 4 villages acted as controls **Population:** 1,200 men and women ≥ 65 years screened; 88 participants	Tai Chi training plus fall-prevention education or fall-prevention education alone	*Falls:* 50 percent greater decrease in fall rates among the Tai Chi practitioners (relative risk = 0.5; 95% CI = 0.11–2.17), but not statistically significant. *Tinetti Balance Scale*: Tai Chi practitioners increased by 1.8 points (95% CI = 0.2–3.4). *Tinetti Gait Scale:* Tai Chi practitioners increased by 0.9 point (95% CI = 0.1–1.8). *Fear of Falling:* No significant changes in the fear of falling.

Source	Safety Issue Related to Clinical Practice	Design Type‡	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Luukinen 2007[127]	Exercise-related interventions for fall prevention in the community	RCT	**Design:** RCT **Outcomes:** Fall rates, time to first fall	**Setting:** Community, home-dwelling Finnish **Population:** 555 older men and women (67 percent ≥ 85 years), most with history of recurrent falls or at least one mobility risk factor	Suggestions for a program consisting of home exercise, walking exercise, group activities, self-care exercise, or routine care	**For all subjects:** *Falls:* • 12 percent decrease in falls from baseline for intervention group (hazard ratio = 0.88, 95% CI = 0.74–1.04). • 7 percent decrease in all falls, but not statistically significantly (hazard ratio = 0.93, 95% CI = 0.80–1.09). **For subjects not homebound:** *Falls:* • 22 percent decrease in falls (hazard ratio = 0.78, 95% CI = 0.64–0.94). • 12 percent decrease in first four falls (hazard ratio = 0.88, 95% CI = 0.74–1.05).

Evidence Table 4. Studies examining physiologic interventions in the community (listed chronologically)

Source	Safety Issue Related to Clinical Practice	Design Type[§]	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Latham 2003[132]	Physiologic interventions to prevent falls in patients discharged from acute care to the community	RCT	**Design:** RCT **Outcomes:** Falls over 6 months	**Setting:** Five hospitals in Auckland, New Zealand, and Sydney, Australia **Population:** 243 frail older people (53 percent female)	One dose vitamin D 300,000 IU versus placebo OR 10 weeks of high-intensity home-based exercise versus attention lessons	*Falls:* • Increase in falls for patients receiving vitamin D as compared to placebo, but not statistically significant (relative risk = 1.12, 95% CI = 0.79–1.59). • Decrease in falls for patients in exercise group compared to attention group, but not statistically significant (relative risk = 0.96, 95% CI = 0.67–1.36). *Injury:* Patients in the exercise group were at increased risk of musculoskeletal injury (risk ratio = 3.6, 95% CI = 1.5–8.0).
Bischoff-Ferrari 2004[178]	Physiologic interventions to prevent falls and fall-related injuries in the community	Meta-analysis	**Design:** Meta-analysis of five RCTs **Outcomes:** Fracture	**Setting:** Community **Population:** 1,237 participant in the five studies	Vitamin D: Large dose = 700–800IU/d Small dose = 400 IU/d	*Falls:* Compared with patients receiving calcium or placebo, vitamin D reduced risk of falling by 22 percent (corrected odds ratio = 0.78, 95% CI = 0.64–0.92). *Fracture:* • Vitamin D 700–800IU/d reduced the risk of fracture by up to 26 percent. • Vitamin D 400 IU/d did not reduce fracture risk. *Numbers needed to treat:* 15 patients would need to be treated with vitamin D to prevent 1 person from falling. *Sensitivity analysis of 5 additional studies:* Total sample 10,001 – smaller effect size (corrected relative risk = 0.87, 95% CI = 0.80–0.96).

[§] Study Design Type: (1) Meta-analysis, (2) Randomized controlled trials, (3) Nonrandomized trials, (4) Cross-sectional studies, (5) Case control studies, (6) Pretest and post-test (before and after) studies, (7) Time series studies, (8) Noncomparative studies, (9) Retrospective cohort studies, (10) Prospective cohort studies, (11) Systematic literature reviews, (12) Literature reviews, nonsystematic/narrative, (13) Quality-improvement projects/research, (14) Changing-practice projects/research, (15) Case series, (16) Consensus reports, (17) Published guidelines, (18) Unpublished research, reviews, etc.

Avenell 2005[107]		Meta-analysis	**Design:** Metanalysis of RCTs or quasi-randomized trials **Outcomes:** Fractures	**Setting:** Community **Poplulation:** 7 trials; 18,668 participants	Vitamin D or an analogue alone, or vitamin D with calcium, or Placebo, no intervention, or calcium	**Vitamin D or analogue alone:** • No effect on hip fracture (relative risk = 1.17; 95% CI = 0.98–1.41). • No effect on vertebral fracture (relative risk = 1.13; 95% CI = 0.50–2.55). • Any new fracture (relative risk = 0.99; 95% CI = 0.91–1.09). **Vitamin D or analogue with calcium:** • Marginal reduction in hip fractures (relative risk = 0.81; 95% CI = 0.68–0.96). • Marginal reduction in nonvertebral fractures (relative risk = 0.87; 95% CI = 0.78–0.97). • No effect on vertebral fractures. • Calcitriol may be associated with an increased incidence of adverse effects.
Grant 2005[130]	Physiologic interventions to prevent falls and fall-related injuries in the community	RCT	**Design:** Factorial-design trial **Outcomes:** New low-energy fractures	**Setting:** Patients identified in 21 UK hospitals then treated at home after discharge **Population:** 5,292 people ≥ 70 years (85 percent female) with new low-trauma fracture, and who were mobile before that fracture	800 IU vitamin D daily or 1,000 mg calcium daily or 800 IU vitamin D plus 1,000mg calcium daily or placebo	*Falls:* No differences between groups (hazard ratio = 0.94; 95% CI = 0.81–1.09). *Fractures:* • No difference between vitamin D and placebo (hazard ratio = 1.02; 95% CI = 0.88–1.19). • No difference between combination treatment and placebo.
Sato 2005[137]	Physiologic interventions to prevent fall-related injuries in acute care	RCT	**Design:** RCT **Outcomes:** Vertebral factures, hip fractures	**Setting:** Community in Japan **Population:** 500 women ≥ 70 years with Alzheimer's disease, vitamin D deficiency, and hyperparathyroidism	Risedronate 2.5 with 1,000 IU vitamin D plus 1,200 mg calcium or placebo with 1,000 IU vitamin D plus 1,200 mg calcium	*Fractures:* 72 percent decrease in fractures in the risedronate group (relative risk = 0.28; 95% CI = 0.13–0.59).

Source	Safety Issue Related to Clinical Practice	Design Type[§]	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Bischoff-Ferrari 2006[134]	Physiologic interventions to prevent falls and fall-related injuries in the community	RCT	**Design:** RCT **Outcomes:** Fall rates	**Setting:** Community **Population:** 199 men and 246 women ≥ 65 years living at home	700 IU of vitamin D plus 500 mg of calcium citrate malate per day or placebo	*Falls:* • Vitamin D plus calcium reduced the odds of falling in women by 46 percent (odds ratio = 0.54, 95% CI = 0.30–0.97). • Vitamin D plus calcium reduced the odds of falling in women by 65 percent in less active women (odds ratio = 0.35; 95% CI = 0.15–0.81). • Vitamin D plus calcium did not significantly reduced the odds of falling in men (odds ratio = 0.93, 95 percent CI, 0.50-1.72)
McCloskey 2007[138]	Physiologic interventions to prevent falls and fall-related injuries in the community	RCT	**Design: RCT** (double-blind) **Outcomes:** Hip and any clinical fracture	**Setting:** General community in South Yorkshire and North Derbyshire **Population:** 5,579 women ≥ 75 years	800 mg oral clodronate (Bonefos) or placebo	*Hip fracture:* Slight increase in risk for hip fracture in placebo group (hazard ratio = 1.02, 95% CI = 0.71–1.47). *Any fracture:* 20 percent decrease in risk for any clinical fracture for patients in clodronate group (hazard ratio = 0.80, 95% CI = 0.68–0.94). *Osteoporosis-associated nonhip fractures:* 29 percent decrease in clodronate group (hazard ratio = 0.71; 95% CI = 0.57–0.87).

Evidence Table 5. Reviews Examining Fall Prevention Interventions in Acute and Long-Term Care (listed chronologically)

Source	Safety Issue Related to Clinical Practice	Design Type**	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Evans 1998[153]	Fall and injury prevention in the acute care setting	Literature Review	**Design:** Review **Outcomes:** Fall rates	**Setting:** Acute care **Population:** Patients in acute care setting	Multiple interventions; 200 studies reviewed	*Falls:* Across settings, individual interventions are not more useful than fall-prevention programs for a specific subset of patients.
Oliver 2000[234]	Fall and injury prevention in the acute care setting	Meta-analysis	**Design:** Systematic review **Outcomes:** Fall rates	**Setting:** Acute care **Population:** Patients in acute care setting	Multiple interventions; 10 studies reviewed	*Falls:* Overall the interventions studied did not prevent falls (pooled effects ratio = 1.0; 95% CI = 0.60–1.68).
Agostini 2001[98]	Fall and injury prevention in the acute care setting	Review	**Design:** Review **Outcomes:** Fall rates	**Setting:** Acute care **Population:** Patients in acute care setting	Multiple interventions; two studies and one systematic review reviewed	*Falls:* Interventions with potential to decrease falls include identification bracelets, bed alarms, special flooring, and hip protectors.
Oliver 2007[235]	Fall and injury prevention in the acute care setting	Meta-analysis	**Design:** Systematic review **Outcomes:** Fall rates, fall-related fracture rate	**Setting:** Acute care **Population:** Patients in acute and long-term care setting	Multiple interventions; 43 studies included in meta-analysis	*Falls:* • Multimodal interventions in hospitals showed 18 percent decrease in fall rates (rate ratio = 0.82; 95% CI = 0.68–0.997). • Multimodal interventions in hospitals showed no significant effect on the number of fallers. *Injuries:* • Hip protectors in long-term care homes showed a 33 percent decrease in hip fractures (rate ratio = 0.67; 95% CI = 0.46–0.98). • Multimodal interventions in hospitals showed no significant effect on the number of fractures. *Other interventions:* Insufficient evidence to recommend other interventions.

** Study Design Type: (1) Meta-analysis, (2) Randomized controlled trials, (3) Nonrandomized trials, (4) Cross-sectional studies, (5) Case control studies, (6) Pretest and post-test (before and after) studies, (7) Time series studies, (8) Noncomparative studies, (9) Retrospective cohort studies, (10) Prospective cohort studies, (11) Systematic literature reviews, (12) Literature reviews, nonsystematic/narrative, (13) Quality-improvement projects/research, (14) Changing-practice projects/research, (15) Case series, (16) Consensus reports, (17) Published guidelines, (18) Unpublished research, reviews, etc.

Evidence Table 6. Studies Examining Environmental Interventions in Acute and Long-Term Care (listed chronologically)

Source	Safety Issue Related to Clinical Practice	Design Type††	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Tideiksaar 1993[154]	Environmental interventions for fall prevention in acute and long-term care	RCT	**Design:** RCT **Outcomes:** Bed falls, staff attitudes toward the use of the system	**Setting:** Geriatric evaluation and treatment unit **Population:** 70 patients (86 percent female), avg. age 84 years, at risk for falls	Bed alarm system	*Falls:* Bed alarms reduced falls by 68 percent, but this was not statistically significant (odds ratio = 0.32; 95% CI = 0.10–1.03). The bed alarm system was well accepted by patients, families, and nurses.
Mayo 1994[155]	Environmental interventions for fall prevention in acute and long-term care	RCT	**Design:** Blinded RCT **Outcomes:** Fall rates	**Setting:** Geriatric care unit at university hospital **Population:** 70 patients at risk for falls	Identification bracelet for patients at high risk for falls	*Falls:* Identification bracelets increase fall risk in high-risk patients (hazard ratio = 1.3, 95% CI = 0.8–2.4), but this was not statistically significant.
Kelly 2002[240]	Environmental interventions for fall prevention in acute and long-term care	Pretest and post-test study	**Design:** Crossover design for 1 week **Outcomes:** Fall rates	**Setting:** Medicare unit of a skilled nursing facility **Population:** 47 patients at high risk for falls	Movement detection patch attached to the thigh	*Falls:* Fall rates decreased from 4.0 falls per 100 patient days to 3.4 falls per 100 days for patients with movement detection patches.
Kwok 2006[222]	Environmental interventions for fall prevention in acute and long-term care	RCT	**Design:** RCT **Outcomes:** Physical restraints use, fall rates	**Setting:** Two geriatric stroke rehabilitation wards in a convalescent hospital in Hong Kong **Population:** 180 geriatric patients perceived by nurses to be at risk of falls	Bed-chair pressure sensor or control	*Falls:* No difference in fall rates between chair alarm group and control group. *Restraints:* No difference in physical restraint use between chair alarm group and control group.

Chapter 11. Reducing Functional Decline in Hospitalized Elderly

Ruth M. Kleinpell, Kathy Fletcher, Bonnie M. Jennings

Background

The elderly, or those older than 65 years, currently represent 12.5 percent of the U.S. population, and are projected to increase to 20 percent of the population by 2030—growing from 35 million to 72 million in number.[1, 2] By 2050, 12 percent of the population, or one in eight Americans, will be 75 years of age or older.[3] In 2002, the elderly accounted for 12.7 million (41 percent) of the 31.7 million hospitalizations in the United States,[4] and these numbers are expected to increase significantly as the population ages. Targeting the care needs of the hospitalized elderly and awareness of risks for illness-related complications are urgent concerns for managing acute health care conditions in this population.[4]

Hospitalization and Patient Safety Considerations for the Elderly

It is estimated that almost half of adults who are hospitalized are 65 years of age or older, although those older than 65 years represent only 12.5 percent of the population. The proportion of hospitalized adults who are elderly is only expected to increase as the population ages.[4] The average hospital length of stay for patients age 65 and older has decreased to 5.7 days, down from 8.7 days in 1990.[3] Shorter lengths of stay heighten the challenge to properly assess and address the care needs of older adults during hospitalization as well as their discharge needs. The focus of assessment and care is generally on resolving the immediate problem that triggered hospitalization; less attention is given to the underlying risk of functional decline and the vulnerability to hospital-associated complications.

A primary focus for improvement in health care is on promoting patient safety and avoiding injuries to patients.[5] This becomes especially important for hospitalized elders, who are at risk for functional decline due to altered mobility levels as well as iatrogenic risks. For the frail elderly in particular, hazards of hospitalization include falls, delirium, nosocomial infections, adverse drug reactions, and pressure ulcer development.[6–8]

A dissonance exists between the hospital environment and therapeutic goals for the hospitalized elderly. The hospital environment, a tertiary care setting, has traditionally focused on medically managing illness states, not on improving patient functioning. The environment is designed for the rapid and effective delivery of care—not for enhancing patient function. Hospital redesign to address the care needs of the elderly have been proposed.[9, 10] Consideration of the milieu as well as age-related physiological changes are important aspects of creating a safe hospital environment for the hospitalized elderly.

Age-Associated Changes

A number of known physiological changes occur with aging, including reduced muscle strength and aerobic capacity, vasomotor instability, baroreceptors insensitivity and reduced total body water, reduced bone density, reduced ventilation, and reduced sensory capacity.[4, 11, 12] Comorbid conditions and chronic illness may heighten these changes. Muscle mass and muscle strength are reduced with aging and contribute to a reduction of physical activity.[12] With aging, alterations in autonomic function, including baroreceptor insensitivity, occurs. Age-associated reduction in body water and plasma volume may predispose the elderly to syncope. Respiratory mechanics are also altered with aging, with reduced ventilation, increased residual capacity, and reduced arterial oxygen tension.[12] Other age-associated changes include reduced bladder capacity and increased urine production, prostrate enlargement, bone demineralization, loss of taste and smell, decreased skin integrity, and reduction in sensory input.[12, 13]

As a result, the elderly are at higher risk for adverse physiological consequences during acute illness, including impairment in functional status. Frailty—a state of musculoskeletal weakness and other secondary, widely distributed losses in structure and function—has been found to be attributed to decreased levels of activity and has been linked to the process of aging.[14] Advanced age, acute and chronic disease and illness, functional limitations, and deconditioning all contribute to the older adult's vulnerability to functional decline during hospitalization. Functional decline—the inability to perform usual activities of daily living due to weakness, reduced muscle strength, and reduced exercise capacity—occurs due to deconditioning and acute illness during hospitalization.[15]

Functional Status

Functional status is determined by the ability to perform activities of daily living (ADLs)—eating, dressing, bathing, ambulating, and toileting—and instrumental ADLs (IADLs)—shopping for groceries, meal preparation, housework, laundry, getting to places beyond walking distance, managing medications, managing finances, and using a telephone.[4] It is estimated that up to 8 percent of community-dwelling elders need assistance with one or more ADLs. Among those age 85 and older, the percentage who live at home but need assistance or who live in a nursing home increases significantly to 56 percent of women and 38 percent of men.[4] Chronic illness and comorbidities can directly impact functional status in the elderly. Chronic health care conditions that are most prevalent in the elderly include heart disease, hypertension, arthritis, diabetes, and cancer.[3] Acute illness due to chronic disease and chronic comorbidities accounts for a significant number of hospitalizations in the elderly.

Functional Decline During Hospitalization

During hospitalization, the elderly patient often experiences reduced mobility and activity levels. Functional decline, including changes in physical status and mobility, has been identified as the leading complication of hospitalization for the elderly.[16] The hazards of bed rest during hospitalization are well established and include immobility, accelerated bone loss, dehydration, malnutrition, delirium, sensory deprivation, isolation, sheering forces on the skin, and incontinence (see Table 1).[12, 17]

Bed rest results in a reduction of exercise capacity due to several physiologic changes that occur, including reductions in maximal stroke volume, cardiac output, and oxygen uptake.[17] The

muscle fatigue that results is associated with reduced muscle blood flow, red cell volume, capillarization, and oxidative enzymes.[17] Accelerated bone loss can lead to a higher risk for injury to bones and joints, including hips and spine.[18]

Table 1. Effects of Bed Rest

System	Effect
Cardiovascular	↓ Stroke volume, ↓ cardiac output, orthostatic hypotension
Respiratory	↓ Respiratory excursion, ↓ oxygen uptake, ↑ potential for atelectasis
Muscles	↓ Muscle strength, ↓ muscle blood flow
Bone	↑ Bone loss, ↓ bone density
GI	Malnutrition, anorexia, constipation
GU	Incontinence
Skin	Sheering force, potential for skin breakdown
Psychological	Social isolation, anxiety, depression, disorientation

Cardiovascular consequences of bed rest: effect on maximal oxygen uptake. Med Sci Sports Exerc 1997;29:191-6.

Deconditioning, which results in a decrease in muscle mass and the other physiologic changes related to bed rest, contributes to overall weakness.[19] Functional decline can then occur as a consequence of those physiologic changes and result in inability to perform usual ADLs.[19]

Low levels of mobility and bed rest were common occurrences during hospitalization for the elderly.[20] Deconditioning and functional decline from baseline was found to occur by day 2 of hospitalization in elderly patients.[21] Loss of functional independence during hospitalization resulted from not only the effects of acute illness, but also from the inability to maintain function during hospitalization.[22] In assessing physical activity of 500 hospitalized elderly patients, those who remained in bed or who had chair activity rarely received physical therapy, had physician orders for exercises, or performed bedside strengthening exercises.[21] Comparisons of functional assessment at baseline and day 2 of hospitalization in 71 patients over the age of 74 years demonstrated declining ability in mobility, transfer, toileting, feeding, and grooming.[23] Between day 2 and discharge, 67 percent demonstrated no improvement and 10 percent experienced further decline, highlighting the potential for delayed functional recovery in the hospitalized elderly.[23] A followup of 489 hospitalized elders age 70 years and older revealed that the prevalence of lower mobility in hospitalized elderly was significant, with 16 percent experiencing low levels of mobility, 32 percent experiencing intermediate levels of mobility, and 29 percent experiencing a decline in an ADL activity.[20] Yet for almost 60 percent of bed-rest episodes, there was no documented medical indication for limiting mobility status.

Preadmission health and functional status of the elderly can indicate risk of further functional decline associated with hospitalization. In examining the baseline functional status of 1,212 hospitalized patients age 70 years and older, the use of ambulation assistive devices, such as canes and walkers, was predictive of functional decline associated with hospitalization.[24] Use of a walker was associated with a 2.8 times increased risk for decline in ADL function by the time of hospital discharge ($P = 0.0002$). Moreover, 3 months after discharge, patients who had used an assistive device prior to hospitalization were more likely to have declined in both ADL status ($P = 0.02$) and IADL status ($P = 0.0003$).[24] Other risk factors found to be predictive of

functional decline in the elderly during hospitalization included having two or more comorbidities, taking five or more prescription medications, and having had a hospitalization or emergency room visit in the previous 12 months.[25]

Associations between functional status and other risk factors such as cognitive status must also be considered. Hospital-related complications or inadequate hospital care have been linked to the development of delirium in the hospitalized elderly.[26] Impairment in cognitive status was found to be associated with changes in functional status in the hospitalized elderly. A study of 2,557 patients from two teaching hospitals examined the association between level of impaired performance on a cognitive status screen and maintenance and recovery of functioning from admission through 90 days after discharge. Performance on a brief cognitive screen on admission was strongly related to subsequent change in function. Among patients who needed help performing one or more ADLs at the time of admission, 23 percent of patients with moderate to severely impaired cognitive performance, 49 percent of patients with mildly impaired cognitive performance, and 67 percent of patients with little or no impairment in cognitive performance recovered the ability to independently execute an additional ADL by discharge ($P < 0.001$).[22] Additional studies identified that prolonged recovery and continued ADL limitations occurred after hospitalization. In following 1,279 patients age 70 years and older after hospital discharge, a study found that 59 percent reported no change in ADL status, 10 percent reported improvement, and 39 percent reported declined ADL status at discharge when compared to preadmission status. At 3 months after discharge, 40 percent reported a new ADL or IADL disability compared with preadmission, reflecting the potential for continued functional decline after hospitalization for acute illness.[27]

Yet, the loss of functional independence is not an inevitable consequence of hospitalization for the elderly.[28, 29] Evidence exists that targeted interventions can impact the degree of functional independence for hospitalized elders.[30]

Research Evidence

Targeted measures that have proven beneficial in mitigating functional decline during hospitalization have included comprehensive geriatric assessments to identify patients at risk, structured geriatric care models, dedicated hospital units for acute care of the elderly, and the use of specific resources to enhance care for the hospitalized elder.

Comprehensive Geriatric Assessment

Comprehensive geriatric assessment (CGA) is used to create a plan of care for hospitalized elders. A specific goal of the CGA is early identification of elder care needs in order to provide interventions to minimize high-risk events such as falls or the onset of delirium.[31]

A CGA should include assessment of ADL and IADL performance as well as assessment of cognition, vision and hearing, social support, and psychological well-being.[19] A number of geriatric assessment tools can be used to make initial and ongoing evaluations of hospitalized elders. Commonly used tools include the Katz Index of Independence in Activities of Daily Living,[32] the Lawton Instrumental Activities of Daily Living Scale,[33] and the Hospital Admission Risk Profile (HARP), among others (see Table 2).

Table 2. Commonly Used Geriatric Assessment Measures*

Instrument	Areas of Assessment	Reference
SPICES	Sleep, problems with eating or feeding, incontinence, confusion, evidence of falls, skin breakdown	Fulmer 1991[59] Wallace 1998[66]
Geriatric Institutional Assessment Profile	Hospital staff knowledge of geriatric care principles, organizational environment	Abraham 1999[41]
Hospital Admission Risk Profile (HARP)	ADL, IADL, cognitive status	Sager 1996[34]
Lawton Instrumental Activities Daily Living Scale	IADL activities: medication management, housekeeping, food preparation, transportation, shopping, managing finances, laundry	Lawton 1969[33]
Functional Independence Measure (FIM)	Functional status in 7 areas: self-care, locomotion, communication, social cognition, cooperation, problem-solving, sphincter control	Kidd 1995[67] Keith 1987[68]
Timed UP and Go Test	Mobility, balance, gait, transfer ability, walking	Podsiadlo 1991[69]
2 Minute Walk Test	Exercise tolerance and exercise capacity	Brooks 2001[70]

* For additional geriatric assessment resources, the Try This series can be found at www.hartfordign.org/resources/education/tryThis.html.

As part of CGA, baseline admission assessments have proved beneficial in identifying patients at risk for functional decline during hospitalizations. The HARP was used in one study to assess preadmission risk factors among more than 800 patients age 70 years and older who were hospitalized for acute medical illness.[34] The HARP includes assessment of ADL status, IADL status, and cognitive status. Researchers found that three factors independently predict functional decline: increasing age, lower admission cognitive status, and lower preadmission IADL function. Patients at low risk of functional decline were more likely to recover ADL function and avoid nursing home placement at 3 months after discharge.

Another functional status instrument that can be used to assess baseline activity and functional levels is the Mobility Classification Tool, described by Callen and colleagues.[35] The tool may prove useful for nurses to assess, quantify, and communicate baseline levels and changes in mobility. Baseline assessments can provide useful information for structuring care during hospitalization and establishing goals for the care.

Aside from the use of formal assessment instruments that measure ADL and IADL function, a general idea of functional status can be ascertained by assessing mobility and activity performance during hospitalization. The frequency of hallway ambulation in hospitalized elders was examined in an observational study of 118 patients age 55 years and older in a single setting.[36] While all patients were considered by their primary nurse as able to walk the hallways,

72.9 percent did not walk at all per 3-hour period of observation, 18.6 percent walked once, 5.1 percent twice, and only 3.4 percent walked more than twice.[35] The median time of ambulation was 5.5 minutes. Of the 32 patients who walked in the hallways, 46.8 percent (n = 15) did so alone, 41 percent (n = 13) walked with a therapist, 41 percent (n = 13) walked with a member of the nursing staff, and 18.8 percent (n = 6) walked with a family member.

Based on the results of the CGA, functional problems or potential problems are identified and specific interventions can be implemented to promote functional ability in hospitalized elders. A number of interventions, including structured exercise, progressive resistance strength training, and walking programs, have been implemented to target elder care functioning during hospitalization.[35, 37, 38] A randomized control trial of a hospital-based general exercise program with 300 hospitalized elders that was started during hospitalization and continued for 1 month after discharge did not affect length of stay, but did demonstrate better IADL function at 1 month after discharge.[38] Measures to improve endurance—including exercise to enhance orthostatic stability, daily endurance exercise to maintain aerobic capacity, or specific resistance exercises to maintain musculoskeletal integrity[17, 39, 40]—need further study on their impact in reducing functional decline in hospitalized elders. As hospital-based exercise programs require coordination and focused implementation plans, strategies for adopting them need to recognize the shortened length of hospital stay and the effects of acute illness on the patients' ability to participate.

In addition to utilizing tools to assess the elderly hospitalized patient, assessments of the hospital culture for providing elder care can also be beneficial. The Geriatric Institutional Assessment Profile was specifically developed to assess hospital workers' knowledge, attitudes, and perceptions of caring for elders, as well as the adequacy of the institutional environment to meet hospitalized elders' needs.[41] It is recommended to help identify both the strengths in elder care and the opportunities for improvement.[42]

Structured Geriatric Care Models

For more than 20 years, the concept of hospital-based geriatric assessment and interdisciplinary team care to improve outcomes for hospitalized elders has been implemented in various models. Early studies on the use of geriatric evaluation and geriatric evaluation units demonstrated an impact on reducing disability and nursing home placement.[43–45] Several hospital-based geriatric resource models of care have also demonstrated benefits in promoting evidence-based care for hospitalized elders, including the use of geriatric interdisciplinary team training[46] and the use of a geriatric resource nurse.[47] National programs for geriatric interdisciplinary team training were created in 1997 to enhance the knowledge of caring for elders among a variety of health professions. While evaluation data have demonstrated improvement of geriatric interdisciplinary team trainees, most notably in attitudinal measures,[46] further study on the impact on geriatric care planning is needed.

Several focused models of care designed to prevent functional decline of the hospitalized elderly have demonstrated significant results. The Hospital Elderly Life Program, a structured screening program for hospitalized patients age 70 years and older, concentrates on admission screening of six risk factors: cognitive impairment, sleep deprivation, immobility, dehydration, vision loss, and hearing impairment.[16] More than 1,500 patients were screened, and targeted interventions based on the presence of admission risk factors were instituted. Patients were followed by an interdisciplinary team that included a geriatric nurse specialist, Elderly Life specialists, and geriatricians who worked in conjunction with the patient's primary care nurse to

formulate an individualized plan of care. Use of the program demonstrated significant results: only 14 percent of patients had a decline on ADL scores, compared to a decline in 33 percent of the control group.

Acute Care for Elderly (ACE) units. Models of care incorporate a variety of interventions to promote positive outcomes for the hospitalized elderly. Specific programs have also been tested on specialized units within the hospital setting. These units, termed Acute Care for the Elderly (ACE units), provide dedicated care to the hospitalized elderly.

Originating in the early 1990s, the ACE unit concept has been adopted by organizations as a strategy to provide care to elderly patients during hospitalization.[48–49] ACE units promote a focused model of care that integrates geriatric assessment into medical and nursing care of patients in an interdisciplinary environment.[50] The focus is to provide expert care while simultaneously keeping patients mobile and preventing the loss of normal daily routines.[49] ACE units include specially designed environmental changes to promote activity such as ambulation in hallways, exercise facilities, and social gathering areas.[51] Multidisciplinary teams composed of geriatric physicians; nurses; dietician; social worker; pharmacist; and occupational, speech, and physical therapists regularly discuss the plan of care for each patient.[49] Major components of the ACE unit concept include patient-centered nursing care (daily assessment of functional needs by nursing, nursing-based protocols to improve outcomes, daily rounds by a multidisciplinary team), a prepared environment, planning for discharge, and medical care review.[10, 52]

Another model, designed to improve functional outcomes of acutely ill hospitalized elders, was tested in a randomized control trial with 1,794 patients 70 years of age and older in one unit of a hospital. A number of interventions were implemented under the direction of the primary nurse, including baseline and ongoing assessment of risk factors; following protocols to improve self-care, continence, nutrition, mobility, sleep, skin care, and cognition; conducting daily rounds with a multidisciplinary team; and environmental enhancements such as handrails, uncluttered hallways, large clocks and calendars, elevated toilet seats, and door levers.[29] Results indicated that 21 percent of intervention patients were classified as *much better* in ADL activity abilities, 13 percent as *better*, 50 percent as *unchanged*, 22 percent as *worse*, and 9 percent as *much worse*. In the control group, 13 percent were classified as *much better*, 11 percent as *better*, 54 percent as *unchanged*, 13 percent as *worse*, and 8 percent as *much worse* ($P = 0.0009$). While the program interventions improved functional status in a significant percentage of the patients, the majority of the patients in both the intervention and control groups were unchanged or worse at the time of discharge. At 3 months after discharge, the groups did not differ significantly in terms of ADL or IADL abilities.[29] The results of this study suggested that while targeted interventions can improve functional independence in the hospitalized elderly, some patients will continue to experience functional decline, despite focused interventions.

Research comparing ACE units and standard medical care units has demonstrated positive outcomes, with improvements in ADL function and fewer transfers to nursing home settings after discharge.[29] A randomized controlled study of 1,531 elders age 70 years and older demonstrated that use of an ACE unit improved processes of care and promoted patient and provider satisfaction without increasing hospital length of stay or costs.[51] Additional study on the cost effectiveness of ACE units has demonstrated significant reductions in average length of stay (0.8 day) and a cost savings of $1,490 compared to control patients on two medical-surgical units, a savings that translated to $1.3 million in 9 months[48] as well as no increase in hospital costs.[53]

The NICHE model. An additional model focusing on improving hospital care for the elderly, the Nurses Improving Care of Health System Elders (NICHE) project, was initiated in the early

1990s. The project is a national program focused on promoting evidenced-based care for elders.[42, 54] Resources include best practice protocols, educational materials, nursing care models to replicate, and assessment tools. A unique series of online assessment tools, Try This, is available at www.hartfordign.org/resources/education/tryThis.html. Assessments of the NICHE program indicate that fewer patients were acutely confused at discharge,[55] restraint use was reduced by more than 60 percent, serious injuries related to falls were reduced by 30 percent, there were beginning signs of reduction in the incidence of aspiration pneumonia and urinary tract infection, and patient mobility equipment was standardized.[56] Outcome reports from implementation of NICHE also included increased nursing knowledge of geriatric care, decreased length of stay, and reduced costs.[42, 56–58] The NICHE model of care is currently a voluntary program, and while additional outcomes-based research is needed, implementation of the program components by all hospital settings would facilitate best practices for elder care.

The geriatric resource nurse model is the most widely used NICHE model. In the geriatric resource nurse model, unit-based nurses acquire competency in elder care and improve care by modeling best practices and providing consultation for elder care.[42, 56, 57] Implementation reports highlight anecdotal evidence of benefit, but researched-based outcome evaluations is limited. One study of 173 hospitalized elders demonstrated improvements in outcome measures, including functional and cognitive status from admission to discharge when managed by the geriatric resource nurse model; however, a comparison of a subset of the intervention patients and a control group of patients revealed no differences in patient outcomes.[30] Further research on this model of care for hospitalized elders is required.

Other Measures to Enhance Care for the Hospitalized Elder

Additional resources to promote hospital-based elder care that are evidence based include nursing staff education to enhance geriatric assessment and care, promotion of nursing certification in geriatric care, and promotion of family participation in caring for hospitalized elders.[59–62] Other focused interventions—including geriatric consultation on specific units, comprehensive discharge planning, and nutritional support—have had beneficial effects on clinical outcomes of hospitalization of the elderly.[63, 64] Ongoing initiatives that have the potential for impacting the care of hospitalized elders include strategies for enhancing geriatric content in nursing school curriculum, advanced practice nurse training in geriatric care, centers of geriatric nursing excellence, and geriatric nursing scholar work. Yet, much remains to be learned about not only the causes of functional decline during hospitalization for the elderly, but also the best approaches for comprehensively modifying the hospital care environment to promote best outcomes. As nurse staffing levels have been demonstrated to impact the quality of hospital care,[65] exploration of innovative models of nurse staffing to enhance care for the hospitalized elderly is also needed. In addition, there is limited research on hospital designs to improve functioning for hospitalized elders. Hallway walking is not always encouraged, and hospital hallways are often designed for transport of supplies, equipment, staff, and patients. The effect of environmental designs to enhance functioning of hospital elders, such as designated walking tracts on nursing units with shock-absorbing flooring and railings solely for patient use, require further exploration.

Table 3. Summary of Key Points Based on Research Evidence

- Functional status or the ability to perform self-care and physical needs activities is an important component of independence for the elderly. Maintaining function is central to fostering health and independence in the hospitalized elderly.
- The hospitalized elderly are at risk for decreased mobility and functional decline.
- Hospitalization has been shown to be associated with low mobility and functional disability.
- Comprehensive initial and ongoing geriatric assessments assist in identifying the older adult at risk for decline, enabling timely and targeted implementation strategies.
- Targeting risk factors—cognitive impairment, prehospitalization functional impairment, and low social activity level—that can contribute to functional decline during hospitalization can promote better outcomes for elders.
- Encouraging activity during hospitalization can help to prevent functional decline. Interventions such as structured exercise, progressive resistance strength training, and walking programs have been implemented to target elder care functioning during hospitalization.
- Redesign of the environment and processes of hospital care can improve the quality of the care delivered to the hospitalized elderly.
- Key elements and features of successful intervention programs targeting functional outcomes in the hospitalized elderly include
    - Baseline and ongoing assessment of risk factors
    - Protocols aimed at improving self-care, continence, nutrition, mobility, sleep, skin care, and cognition
    - Daily rounds with a multidisciplinary team
    - Protocols to minimize adverse effects of selected procedures (e.g., urinary catherization) and medications (e.g., sedative-hypnotic agents) and limit the use of mobility restrictors (lines, tubes, and restraints)
    - Environmental enhancements, including handrails, uncluttered hallways, large clocks and calendars, elevated toilet seats, and door levers
    - Encouraging mobilization during hospitalization
- Specialty geriatric nursing care can positively impact elder care in the hospital setting.
- The potential for delayed functional recovery should be considered in discharge planning for hospitalized elders.

Evidence-Based Practice Implications

Table 4 outlines several evidence-based strategies for care of the hospitalized elder. A number of evidence-based practice guidelines that pertain to hospitalized elder care can be used to structure care to promote best practices in a variety of areas, including pain management, strategies for assessing and treating delirium, fall prevention for older adults, prevention of pressure ulcers, and changing the practice of physical restraint use in acute care. The guidelines can be found at www.guideline.gov.

Table 4. Evidence-Based Strategies for Care of the Hospitalized Elder.

- Conduct an institutional assessment of your facility to determine knowledge and awareness of principles of geriatric care and best practices.
- Consider integrating baseline and ongoing assessment of hospitalized elders.
- Integrate established protocols aimed at improving self-care, continence, nutrition, mobility, sleep, skin care, and cognition.
- Conduct daily rounds with a multidisciplinary team.
- Institute protocols to minimize adverse effects of selected procedures (e.g., urinary catherization) and medications (e.g., sedative-hypnotic agents).
- Use environmental enhancements for elder care, including handrails, uncluttered hallways, large clocks and calendars, elevated toilet seats, and door levers.
- Consider participation in best practice models for elder care, including Geriatric Interdisciplinary Team Training (GITT) and Nurses Improving Care of Health System Elders (NICHE).
- Utilize established resources, including geronurseonline (www.geronurseonline), University of Iowa Gerontological Nursing Intervention Research Center resource (http://www.nursing.uiowa.edu/centers/gnirc/protocols.htm), and NICHE online resources (www.hartfordign.org/resources/education/tryThis.html).

A number of important considerations for addressing potential risks for the hospitalized elder are outlined in Table 5.

Table 5. Practice Implications to Avert Potential Risks

Potential Risks for the Hospitalized Elderly	Practice Implication
1. Decreased mobility and functional decline	Conduct comprehensive initial and ongoing geriatric assessment to formulate targeted strategies to enhance mobility levels and functional status, such as structured exercise, progressive resistance strength training, and walking programs.
2. Adverse effects of immobility and bed rest	Incorporate the use of practice guidelines to address potential adverse effects, including prevention of skin breakdown**,** fall prevention, treating delirium, prevention of pressure ulcers, and management of urinary incontinence.
3. Altered nutrition or dehydration	Incorporate the use of practice guidelines to enhance nutritional status and hydration during acute illness.
4. Impaired sleep and rest	Integrate established protocols aimed at improving sleep and rest during hospitalization.
5. Alterations in self-care	Promote participation in activities of daily living; promote normal daily routine activities.
6. Cognitive alterations	Conduct ongoing assessment of cognitive status changes and implementation of measures to address confusion and delirium.

Potential Risks for the Hospitalized Elderly	Practice Implication
7. Complications of acute illness (e.g., infection, aspiration, pneumonia)	Use multidisciplinary care models to address management of acute illness and implementation of prevention measures.

Research Implications

To improve the quality and safety of care for hospitalized elderly patients, the following questions deserve further investigation:

- What interventions are the most effective in enhancing functional status in the hospitalized elderly?
- What is the impact of single-site successful models of care in multiple hospital care settings?
- What is the cost effectiveness of intervention programs aimed at targeting functional decline in the hospitalized elderly?

Future research on reducing functional decline in the hospitalized elderly should target the following significant gaps in research:

- Additional research on the impact of models of care for the hospitalized elderly (including NICHE) is needed to build evidence-based practice recommendations. Most of the existing "evidence" comes from small randomized studies, nonrandomized studies, case studies, and expert opinion.
- Hospital design outcomes research is warranted to further evaluate the impact of redesign interventions in enhancing outcomes for hospitalized elders.
- Most research on interventions targeting functional status during hospitalization of the elderly was conducted at single-site locations. Therefore, it is not clear if the findings can be generalized to other settings. Additional research is needed that focuses on multidisciplinary interventions with larger sample sizes and in multicenter, randomized clinical studies.
- A conceptual model for targeting functional decline in the hospitalized elderly is needed. Factors to be considered include the fact that the elderly are a heterogeneous group—some are frail upon admission and others are robust. The hospitalized elderly come to the hospital with different comorbidities and reasons for admission. Polypharmacy in the elderly needs to also be considered. In addition, the tertiary care environment is not a living environment, creating a dissonance between the goals of restorative care and environmental function.
- While structured models of care focusing on assessment, physical therapy, ADL protocol use, and multidisciplinary team care have demonstrated significant benefits on independence for hospitalized elders, relatively simple interventions such as hallway walking, communal dining, and group therapy need to be further examined.
- Nursing-focused interventions aimed at promoting functional independence for hospitalized elders need further exploration in formal research studies.

Conclusion

This chapter has presented an overview of research and evidence-based practices for elderly care during hospitalization to prevent functional decline. A number of other chapters in this book further address related areas, such as averting patient falls, preventing pressure ulcers, symptom management, and other aspects of care for the hospitalized elder. Continued research and dissemination of best practices will lead to additional strategies that nurses can use to improve the quality of health care and outcomes for hospitalized elders. Assessment of function and targeting interventions during hospitalization are critically important to acute care of older adults.[71] The impact of functional decline on resource utilization and health care costs may further reinforce the need to assess and intervene to prevent functional decline.[72] Additional research on factors influencing functional decline will also provide information for nurses to present to administrators to develop programs to identify and mitigate functional decline in the hospitalized elderly.

Chapter 12. Pressure Ulcers: A Patient Safety Issue

Courtney H. Lyder, Elizabeth A. Ayello

Background

Pressure ulcers remain a major health problem affecting approximately 3 million adults.[1] In 1993, pressure ulcers were noted in 280,000 hospital stays, and 11 years later the number of ulcers was 455,000.[2] The Healthcare Cost and Utilization Project (HCUP) report found from 1993 to 2003 a 63 percent increase in pressure ulcers, but the total number of hospitalizations during this time period increased by only 11 percent. Pressure ulcers are costly, with an average charge per stay of $37,800.[2] In the fourth annual HealthGrades Patient Safety in American Hospitals Study, which reviewed records from about 5,000 hospitals from 2003 to 2005, pressure ulcers had one of the highest occurrence rates, along with failure to rescue and postoperative respiratory failure.[3] Given the aging population, increasingly fragmented care, and nursing shortage, the incidence of pressure ulcers will most likely continue to rise.

Preventing pressure ulcers has been a nursing concern for many years. In fact, Florence Nightingale in 1859 wrote, "If he has a bedsore, it's generally not the fault of the disease, but of the nursing"[4] (p. 8). Others view pressure ulcers as a "visible mark of caregiver sin"[5] (p. 726) associated with poor or nonexistent nursing care.[6] Many clinicians believe that pressure ulcer development is not simply the fault of the nursing care, but rather a failure of the entire heath care system[7]—hence, a breakdown in the cooperation and skill of the entire health care team (nurses, physicians, physical therapists, dietitians, etc.).

Although the prevention of pressure ulcers is a multidisciplinary responsibility, nurses play a major role. In 1992, the U.S. Agency for Healthcare Research and Quality (AHRQ, formerly the Agency for Health Care Policy and Research) published clinical practice guidelines on preventing pressure ulcers.[8] Much of the evidence on preventing pressure ulcers was based on Level 3 evidence, expert opinion, and panel consensus, yet it served as a foundation for providing care. Although the AHRQ document was published 15 years ago, it still serves as the foundation for providing preventive pressure ulcer care and a model for other pressure ulcer guidelines developed afterward. Nurses are encouraged to review these comprehensive guidelines. The document identifies specific processes (e.g., risk assessment, skin care, mechanical loading, patient and staff education, etc.) that, when implemented, could reduce pressure ulcer development, and the literature suggests that following these specific processes of pressure ulcer care will reduce the incidence of ulcers. Research also suggests that when the health care providers are functioning as a team, the incidence rates of pressure ulcers can decrease.[9] Thus, pressure ulcers and their prevention should be considered a patient safety goal.

Incidence, Mortality, and Costs

The incidence rates of pressure ulcers vary greatly with the health care settings. The National Pressure Ulcer Advisory Panel (NPUAP) says the incidence ranges from 0.4 percent to 38 percent in hospitals, from 2.2 percent to 23.9 percent in skilled nursing facilities, and from 0 percent to 17 percent for home health agencies.[10] There is ample evidence that the majority of pressure ulcers

occur relatively early in the admissions process. For patients in the hospital, they can occur within the first 2 weeks.[11] With the increased acuity of elderly patients admitted and decreased lengths of stay in hospital, new data suggest that 15 percent of elderly patients will develop pressure ulcers within the first week of hospitalization.[12] For those elderly residents admitted to long-term care, pressure ulcers are most likely to develop within the first 4 weeks of admission.[13]

Mortality is also associated with pressure ulcers. Several studies noted mortality rates as high as 60 percent for older persons with pressure ulcers within 1 year of hospital discharge.[14, 15] Most often, pressure ulcers do not cause death; rather the pressure ulcer develops after a sequential decline in health status. Thus, the development of pressure ulcers can be a predictor of mortality. Studies further suggested that the development of skin breakdown postsurgery can lead elders to have major functional impairment post surgical procedure.

The cost to treat pressure ulcers can be expensive; the HCUP study reported an average cost of $37,800.[2] Cost data vary greatly, depending on what factors are included or excluded from the economic models (e.g., nursing time, support surfaces). It has been estimated that the cost of treating pressure ulcers is 2.5 times the cost of preventing them.[16] Thus, preventing pressure ulcers should be the goal of all nurses.

Etiology

Pressure ulcers develop when capillaries supplying the skin and subcutaneous tissues are compressed enough to impede perfusion, leading ultimately to tissue necrosis. Since 1930, we have understood that normal blood pressure within capillaries ranges from 20 to 40mm Hg; 32mm Hg is considered the average.[17] Thus, keeping the external pressure less than 32 mm Hg should be sufficient to prevent the development of pressure ulcers. However, capillary blood pressure may be less than 32 mm Hg in critically ill patients due to hemodynamic instability and comorbid conditions; thus, even lower applied pressures may be sufficient to induce ulceration in this group of patients. Pressure ulcers can develop within 2 to 6 hours.[18, 19] Therefore, the key to preventing pressure ulcers is to accurately identify at-risk individuals quickly, so that preventive measures may be implemented.

Risk Factors

More than 100 risk factors of pressure ulcers have been identified in the literature. Some physiological (intrinsic) and nonphysiological (extrinsic) risk factors that may place adults at risk for pressure ulcer development include diabetes mellitus, peripheral vascular disease, cerebral vascular accident, sepsis, and hypotension.[20] A hypothesis exists that these physiological risk factors place the patients at risk due to impairment of the microcirculation system. Microcirculation is controlled in part by sympathetic vasoconstrictor impulses from the brain and secretions from localized endothelial cells. Since neural and endothelial control of blood flow is impaired during an illness state, the patient may be more susceptible to ischemic organ damage (e.g., pressure ulcers).[21]

Additional risk factors that have been correlated with pressure ulcer development are age of 70 years and older, current smoking history, dry skin, low body mass index, impaired mobility, altered mental status (i.e., confusion), urinary and fecal incontinence, malnutrition, physical restraints, malignancy, history of pressure ulcers, and white race.[22–25] Although researchers have noted that the white race is a predictor of pressure ulcers, the small number of nonwhite patients in

most pressure ulcer studies makes this finding questionable. The few studies that have included sufficient numbers of black people for analysis purposes have found that blacks suffer more severe pressure ulcers than nonblacks.[26, 27] Only one nursing study found that blacks had a higher incidence rate of pressure ulcer than whites.[28] In a study funded by AHRQ using the New York State Inpatient Data Set 1998–2000, Fiscella and colleagues[29] found that African Americans were more likely to develop pressure ulcers than other races in hospitals. Moreover, a 2004 study investigating black/white differences in pressure ulcer incidence found that after controlling for eight resident characteristics and three facility characteristics, race was significantly associated with pressure ulcer incidence (hazard ratio comparing blacks with whites = 1.31, 95% confidence interval = 1.02–1.66).[30]

Risk Assessment

What tool and how often a pressure ulcer risk assessment should be done are key questions in preventing pressure ulcers. Due to the number of risk factors identified in the literature, nurses have found the use of risk assessment tools helpful adjuncts to aid in the identification of patients who may be at high risk. Most health care institutions that use pressure ulcer risk assessment tools use either the Braden Scale or Norton Scale, with the Braden scale being the most widely used in the United States. The Braden Scale is designed for use with adults and consists of 6 subscales: sensory perception, moisture, activity, mobility, nutrition, and friction and shear.[31] It is based on the conceptual schema of linking the above clinical situations to the intensity and duration of pressure or tissue tolerance for pressure.[32] The copyrighted tool is available at http://www.bradenscale.com.braden.pdf. The scores on this scale range from 6 (high risk) to 23 (low risk), with 18 being the cut score for onset of pressure ulcer risk. Research has shown that hospital nurses could accurately determine pressure ulcer risk 75.6 percent of the time after an interactive learning session on the Braden scale.[33] Nurses were best at identifying persons at the highest and lowest levels of risk and had the most difficultly with patients with mild levels of risk (scores of 15–18).[34]

The Norton Scale was developed in the United Kingdom and consists of five subscales: physical condition, mental condition, activity, mobility, and incontinence.[35] The total score ranges from 5 (high risk) to 20 (low risk).

The Braden Scale and Norton Scale have been shown to have good sensitivity (83 percent to 100 percent, and 73 percent to 92 percent, respectively) and specificity (64 percent to 77 percent, and 61 percent to 94 percent, respectively), but have poor positive predictive value (around 40 percent and 20 percent, respectively).[36] The Norton and Braden scales show a 0.73 Kappa statistic agreement among at-risk patients, with the Norton Scale tending to classify patients at risk when the Braden scale classifies them as not at risk. The net effect of poor positive predictive value means that many patients who will not develop pressure ulcers may receive expensive and unnecessary treatment. Moreover, optimal cutoff scores have not been developed for each care setting (e.g., medical intensive care versus operating room). Thus, nurses still need to use their clinical judgment in employing preventive pressure ulcer care. A recent systematic review of risk assessment scales found that the Braden Scale had the optimal validation and the best sensitivity/specificity balance (57.1 percent/67.5 percent) when compared to the Norton Scale (46.8 percent/61.8 percent) and Waterlow Scale (82.4 percent/27.4 percent).[37] It should be noted that the Waterlow skill is a pressure ulcer prediction tool used primarily in Europe.

In recent years, several new prediction tools have been developed (FRAGMMENT Score and

Schoonhoven Prediction Rule); however, these tools lack sufficient evidence to evaluate their predictive validity.[38, 39] Thus, the use of a validated pressure ulcer risk assessment tool like the Braden Scale should be used, given the fair research-based evidence. The U.S. Centers for Medicare and Medicaid Services (CMS) recommends that nurses consider all risk factors independent of the scores obtained on any validated pressure ulcer prediction scales because all factors are not found on any one tool.[40]

The usefulness of clinical informatics to assess and prevent pressure ulcers has been explored. A quality improvement study involving 91 long-term care facilities evaluated the usefulness of Web-based reports alerting nursing staff to a resident's potential risk for pressure ulcers.[41] Only one-third of long-term care facilities used the Web-based reports regularly to identify at-risk patients. Several key characteristics of facilities that were high users emerged:

- Administrative level and nursing staff buy-in and support
- Development of an actual process integrating the risk reports into ongoing quality improvement processes
- Having "facility champions" to keep the effort focused and on track

There is no agreement on how frequently risk assessment should be done. There is general consensus from most pressure ulcer clinical guidelines to do a risk assessment on admission, at discharge, and whenever the patient's clinical condition changes. The appropriate interval for routine reassessment remains unclear. Studies by Bergstrom and Braden[42, 43] found that in a skilled nursing facility, 80 percent of pressure ulcers develop within 2 weeks of admission and 96 percent develop within 3 weeks of admission. The Institute for Healthcare Improvement has recently recommended that in hospitalized patients, pressure ulcer risk assessment be done every 24 hours[44] rather than the previous suggestion of every 48 hours.[45]

Implementing a Prevention Plan

Preventing pressure ulcers can be nursing intensive. The challenge is more difficult when there is nursing staff turnover and shortages. Studies have suggested that pressure ulcer development can be directly affected by the number of registered nurses and time spent at the bedside.[46, 47] In contrast, however, one recent study suggested that there was no correlation between increasing the nurse-to-patient ratio and the overall incidence of pressure ulcers.[48] Donaldson and colleagues[49] noted that this particular study was limited by the fact that the researchers could not affirm compliance with ratios per shift and per unit at all times. Given that the cost of treatment has been estimated as 2.5 times that of prevention, implementing a pressure ulcer prevention program remains essential.

A growing level of evidence suggests that pressure ulcer prevention can be effective in all health care settings. One study examined the efficacy of an intensive pressure ulcer prevention protocol to decrease the incidence of ulcers in a 77-bed long-term care facility.[50] The pressure ulcer prevention protocol consisted of preventive interventions stratified on risk level, with implementation of support surfaces and turning/repositioning residents. The sample included 132 residents (69 prior to prevention intervention and 63 after prevention intervention). The 6-month incidence rate of pressure ulcers prior to the intensive prevention intervention was 23 percent. For the 6-months after intensive prevention intervention, the pressure ulcer incidence rate was 5 percent. This study demonstrated that significant reductions in the incidence of pressure ulcers are possible to achieve within a rather short period of time (6 months) when facility-specific intensive prevention interventions are used. A subsequent study by the same researchers was undertaken to

evaluate the cost effectiveness of the pressure ulcer prevention protocol after a 3-year period. The implementation of a pressure ulcer prevention protocol showed mixed results. Initial reductions in pressure ulcer incidence were lost over time. However, clinical results of ulcer treatment improved and treatment costs fell during the 3 years.[51]

A more recent nursing study examined the effects of implementing the SOLUTIONS program, which focuses pressure ulcer prevention measures on alleviating risk factors identified by the Braden Scale, in two long-term care facilities.[52] The quasi-experimental study found that after 5 months of implementing the SOLUTIONS program, Facility A (150 beds) experienced an 87 percent reduction in pressure ulcer incidence (from 13.2 percent to 1.7 percent), which was highly significant ($P = 0.02$). Facility B (110 beds) experienced a corresponding 76 percent reduction (from 15 percent to 3.5 percent), which was also highly significant ($P = 0.02$). Gunningberg and colleagues[52] investigated the incidence of pressure ulcers in 1997 and 1999 among patients with hip fractures and found significant reductions in incidence rates (55 percent in 1997 to 29 percent in 1999). The researchers attributed these reductions in pressure ulcer incidence rates to performing systematic risk assessment upon admission, accurately staging pressure ulcers, using pressure-reducing mattresses, and continuing education of staff. Thus, the use of comprehensive prevention programs can significantly reduce the incidence of pressure ulcers in long-term care.

The use of quality improvement models, where systematic processes of care have been implemented have also been shown to reduce overall pressure ulcer incidence. In one study involving 29 nursing homes in three States, representatives of the 29 nursing homes attended a series of workshops, shared best practices, and worked with one-on-one quality improvement mentors over 2 years.[53] This study found that six of eight prevention process measures (based on AHRQ prevention guidelines) significantly improved, with percentage differences between baseline and followup ranging from 11.6 percent to 24.5 percent. Another study using similar methods involving 22 nursing homes found 8 out of 12 processes of care significantly improved.[7] Moreover, the study found that pressure ulcer incidence rates decreased in the nursing homes. Nursing homes with the greatest improvement in quality indicator scores had significantly lower pressure ulcer incidence rates than the facilities with the least improvement in quality indicator scores ($P = 0.03$).

In the acute care setting, several studies have attempted to demonstrate that the implementation of comprehensive pressure ulcer prevention programs can decrease the incidence rates. However, no studies could be found that eliminated pressure ulcers. One large study evaluated the processes of care for hospitalized Medicare patients at risk for pressure ulcer development.[7] This multicenter retrospective cohort study used medical record data to identify 2,425 patients ages 65 and older discharged from acute care hospitals following treatment for pneumonia, cerebral vascular disease, or congestive heart failure. Charts were evaluated for the presence of six recommended pressure ulcer prevention processes of care. This study found that at-risk patients who used pressure-reducing devices, were repositioned every 2 hours, and received nutritional consults were more likely to develop pressure ulcers than those patients who did not receive the preventive interventions. One explanation for this finding may be the amount of time (48 hours) before the preventive measures were implemented. Given the acuity of patients entering hospitals, waiting 48 hours may be too late to begin pressure ulcer prevention interventions. Thus, despite this one study, there is significant research to support that implementing comprehensive pressure ulcer prevention programs reduces the incidence of pressure ulcers.

A key component of research studies that have reported reduction of pressure ulcers is how to

sustain the momentum over time, especially when the facility champion leaves the institution. It is clear from the evidence that maintaining a culture of pressure ulcer prevention in a care setting is an important challenge, one that requires the support of administration and the attention of clinicians.

Skin Care

Although expert opinion maintains that there is a relationship between skin care and pressure ulcer development, there is a paucity of research to support that. How the skin is cleansed may make a difference. One study found that the incidence of Stages I and II pressure ulcers could be reduced by educating the staff and using a body wash and skin protection products.[54]

The majority of skin care recommendations are based on expert opinion and consensus. Intuitively nurses understand that keeping the skin clean and dry will prevent irritants on the skin or excessive moisture that may increase frictional forces leading to skin breakdown. Individualized bathing schedules and use of nondrying products on the skin are also recommended. Moreover, by performing frequent skin assessments, nurses will be able to identify skin breakdown at an early stage, leading to early interventions. Although there is a lack of consensus as to what constitutes a minimal skin assessment, CMS recommends the following five parameters be included: skin temperature, color, turgor, moisture status, and integrity.[40]

The search for the ideal intervention to maintain skin health continues. One study compared hyperoxygenated fatty acid compound versus placebo compound (triisotearin) in acute care and long-term care patients.[55] These researchers found that using hyperoxygenated fatty acid significantly (p-0.006) reduced the incidence of ulcers. Pressure ulcer incidence was lower in an intervention group of acute care patients when topical nicotinate was applied (7.32 percent) compared to lotion with hexachlorophene, squalene, and allantoin in the control group (17.37 percent).[56]

There are several key recommendations to minimize the occurrence of pressure ulcers. Avoid using hot water, and use only mild cleansing agents that minimize irritation and dryness of the skin.[8, 57] Avoid low humidity because it promotes scaling and dryness, which has been associated with pressure ulcer development.[23] During skin care, avoid vigorous massage over reddened, bony prominences because evidence suggest that this leads to deep tissue trauma. Skin care should focus on minimizing exposure of moisture on the skin.[58] Skin breakdown caused by friction may be mitigated by the use of lubricants, protective films (e.g., transparent and skin sealants), protective dressings (e.g., hydrocolloids), and protective padding.

Mechanical Loading

One of the most important preventive measures is decreasing mechanical load. If patients cannot adequately turn or reposition themselves, this may lead to pressure ulcer development. It is critical for nurses to help reduce the mechanical load for patients. This includes frequent turning and repositioning of patients.

Very little research has been published related to optimal turning schedules. The first such nursing study was an observational one that divided older adults into three turning treatment groups (every 2 to 3 hours [n = 32], every 4 hours [n = 27], or turned two to four times/day [n = 41]).[59] These researchers found that older adults turned every 2 to 3 hours had fewer ulcers. This landmark nursing study created the gold standard of turning patients at least every 2 hours. Some

researchers would suggest that critically ill patients should be turned more often. However, one survey study investigating body positioning in intensive care patients found that of 74 patients observed, 49.3 percent were not repositioned for more than 2 hours.[60] Only 2.7 percent of patients had a demonstrated change in body position every 2 hours. A total of 80–90 percent of respondents to the survey agreed that turning every 2 hours was the accepted standard and that it prevented complications, but only 57 percent believed it was being achieved in their intensive care units. A more recent study by DeFloor and colleagues[61] suggests that depending on the support surface used, less-frequent turning may be optimal to prevent pressure ulcers in a long-term care facility. Several nurse researchers investigated the effect of four different turning frequencies (every 2 hours on a standard mattress, every 3 hours on a standard mattress, every 4 hours on a viscoelastic foam mattress, and every 6 hours on a viscoelastic foam mattress). The nurse researchers found that the incidence of early pressure ulcers (Stage I) did not differ in the four groups. However, patients being turned every 4 hours on a viscoelastic foam mattress developed significantly less severe pressure ulcers (Stage II and greater) than the three other groups. Although the results of this study may indicate less turning may be appropriate when using a viscoelastic foam mattress, additional studies are needed to examine optimal turning schedules among different populations. Reddy and colleagues[62] have raised questions about the methodology in the Defloor and colleagues study, leading them to recommend that it may be too soon to abandon the every-2-hours turning schedule in favor of every 4 hours based on this one study. Thus, there is emerging research to support the continued turning of patients at least every 2 hours.

How a patient is positioned may also make a difference. Lateral turns should not exceed 30 degrees.[63, 64] One randomized controlled trial that studied a small sample of 46 elderly patients in the 30-degree-tilt position and the standard 90-degree side-lying position found no significant difference in the development of pressure ulcers between the two groups.[65]

Support Surfaces

The use of support surfaces is an important consideration in pressure redistribution. The concept of pressure redistribution has been embraced by the NPUAP.[66] You can never remove all pressure for a patient. If you reduce pressure on one body part, this will result in increased pressure elsewhere on the body. Hence, the goal is to obtain the best pressure redistribution possible.

A major method of redistributing pressure is the use of support surfaces. Much research has been conducted on the effectiveness of the use of support surfaces in reducing the incidence of pressure ulcers. A comprehensive literature review by Agostini and colleagues[67] found that there was adequate evidence that specially designed support surfaces effectively prevent the development of pressure ulcers. However, a major criticism of the current support surface studies was poor methodologic design. Agostini and colleagues noted that many studies had small sample sizes and unclear standardization protocols, and assessments were not blind.

Reddy and colleagues[62] have provided a systematic review of 49 randomized controlled trials that examined the role of support surfaces in preventing pressure ulcers. No one category of support surface was found to be superior to another; however, use of a support surface was more beneficial than a standard mattress. A prospective study evaluating the clinical effectiveness of three different support surfaces (two dynamic mattress replacement surfaces and one static foam mattress replacement) found that an equal number of patients developed pressure ulcers on each surface (three per surface).[68] The researchers concluded no differences in the support surface effectiveness, yet large differences in the cost. (Dynamic mattress replacements cost

approximately $2,000 per mattress, compared to $240 per mattress for static foam mattress replacements.) Given the similar clinical effectiveness, cost should be considered in determining the support surface.

Four randomized controlled trials evaluated the use of seat cushions in pressure ulcer prevention, and found no difference in ulcer incidence among groups except between foam and gel cushions.[62] Despite the dearth of research that correlates seat cushions and preventing pressure ulcers, expert opinion supports the use of seat cushions.

The CMS has divided support surfaces into three categories for reimbursement purposes.[68] Group 1 devices are those support surfaces that are static, they do not require electricity. Static devices include air, foam (convoluted and solid), gel, and water overlays or mattresses. These devices are ideal when a patient is at low risk for pressure ulcer development. Group 2 devices are powered by electricity or pump and are considered dynamic in nature. These devices include alternating and low-air-loss mattresses. These mattresses are good for patients who are at moderate to high risk for pressure ulcers or have full-thickness pressure ulcers. Group 3 devices, also dynamic, comprises only air-fluidized beds. These beds are electric and contain silicone-coated beads. When air is pumped through the bed, the beads become liquid. These beds are used for patients at very high risk for pressure ulcers. More often they are used for patients with nonhealing full-thickness pressure ulcers or when there are numerous truncal full-thickness pressure ulcers. The NPUAP has suggested new definitions for support surfaces that move away from these categories and divide support surfaces into powered or nonpowered.[69] Whether these new definitions will be embraced by CMS is yet to be determined.

There remains a paucity of research that demonstrates significant differences in the effectiveness of the various classifications of support surfaces in preventing or healing pressure ulcers. Therefore, nurses should select a support surface based on the needs and characteristics of the patient and institution (e.g., ease of use, cost). It is imperative to have the pressure redistribution product (e.g., mattress or cushion) on the surface where the patients are spending most of their time, in bed or a chair. However, being on a pressure-redistributing mattress or cushion does not negate the need for turning or repositioning.

Nutrition

Controversy remains on how best to do nutritional assessment for patients at risk for developing pressure ulcers. The literature differs about the value of serum albumin; some literature reports that low levels are associated with increased risk.[70] While the AHRQ pressure ulcer prevention guideline suggests that a serum albumin of less than 3.5 gm/dl predisposes a patient for increased risk of pressure ulcers, one study reveals that current dietary protein intake is a more independent predictor than this lab value.[8, 42] In the revised Tag F-314 guidance to surveyors in long-term care, CMS recommends that weight loss is an important indicator.[40] Evaluation of the patient's ability to chew and swallow may also be warranted.

The literature is unclear about protein-calorie malnutrition and its association with pressure ulcer development.[70] Reddy and colleagues[62] suggested that the widely held belief of a relationship between nutrition intake and pressure ulcer prevention was not always supported by randomized controlled trials. Some research supported the finding that undernourishment on admission to a health care facility increases a person's likelihood of developing a pressure ulcer. In one prospective study, high-risk patients who were undernourished on admission to the hospital were twice as likely to develop pressure ulcers as adequately nourished patients (17 percent and

9 percent, respectively).[71] In another study, 59 percent of residents were undernourished and 7.3 percent were severely undernourished on admission to a long-term care facility. Pressure ulcers occurred in 65 percent of the severely undernourished residents, while no pressure ulcers developed in the mild-to-moderately undernourished or well-nourished residents.[15]

Reddy and colleagues[62] concluded that nutritional supplementation was beneficial in only one of the five randomized controlled trials reviewed in their systematic analysis of interventions targeted at impaired nutrition for pressure ulcer prevention. Older critically ill patients who had two oral supplements plus the standard hospital diet had lower risk of pressure ulcers compared to those who received only the standard hospital diet.[72]

Empirical evidence is lacking that the use of vitamin and mineral supplements (in the absence of deficiency) actually prevents pressure ulcers.[73] Therefore, oversupplementing patients without protein, vitamin, or mineral deficiencies should be avoided. Before enteral or parental nutrition is used, a critical review of overall goals and wishes of the patient, family, and care team should be considered.[74] Despite the lack of evidence regarding nutritional assessment and intervention, maintaining optimal nutrition continues to be part of best practice.

Management of Pressure Ulcers

When a pressure ulcer develops, nursing's patient safety goal is to assist the health care team in closing the ulcer as quickly as possible. Nursing is also concerned with preventing further ulcer deterioration, keeping the ulcer clean and in moisture balance, preventing infections from developing, and keeping the patient free from pain.

Many aspects of managing pressure ulcers are similar to prevention (mechanical loading, support surfaces, and nutrition). Clearly, the health care team has to address the underlying causes (intrinsic and extrinsic) or the pressure ulcer will not close. In 1994, AHRQ published clinical practice guidelines on treating pressure ulcers.[75] Much of the evidence related to treating pressure ulcers was based on Level C evidence, requiring one or more of the following: one controlled trial, results of at least two case series/descriptive studies in humans, or expert opinion. Although the AHRQ document was published 13 years ago, it provides the foundation for treating pressure ulcers. The document identified specific indices (e.g., wound assessment, managing tissue load, ulcer care, managing bacterial colonization/infection, etc.). The following section supplements this document.

Cleansing

Once the pressure ulcer develops, the ulcer should be cleaned with a nontoxic solution. Cleaning the ulcer removes debris and bacteria from the ulcer bed, factors that may delay ulcer healing.[76] No randomized control studies could be found that demonstrated the optimal frequency or agent for cleansing a pressure ulcer. A Cochrane review of published randomized clinical trials found three studies addressing cleansing of pressure ulcers, but this systematic review produced no good trial evidence to support any particular wound cleansing solution or technique for pressure ulcers.[77] Therefore, this recommendation remains at the expert opinion level. Nurses should use cleansers that do not disrupt or cause trauma to the ulcer.[78] Normal saline (0.9 percent) is usually recommended because it is not cytotoxic to healthy tissue.[79] Although the active ingredients in newer wound cleansers may be noncytotoxic (surfactants), the inert carrier may be

cytotoxic to healthy granulation tissue.[80] Thus, nurses should be cognizant of the ingredients in cleansing agents before using them on pressure ulcers.

Assessment and Staging

The nurse should assess and stage the pressure ulcer at each dressing change. Experts believe that weekly assessments and staging of pressure ulcers will lead to earlier detection of wound infections as well as being a good parameter for gauging of wound healing.[40, 75] There are no universal parameters for assessing a pressure ulcer. Most experts agree that when a pressure ulcer develops its location, size (length, width, and depth), and color of the wound; amount and type of exudate (serous, sangous, pustular); odor; nature and frequency of pain if present (episodic or continuous); color and type of tissue/character of the wound bed, including evidence of healing (e.g., granulation tissue) or necrosis (slough or eschar); and description of wound edges and surrounding tissue (e.g., rolled edges, redness, hardness/induration, maceration) should be assessed and documentd.[75, 81] Upon identifying the ulcer characteristics, the initial stage of the should be completed.

The staging system is one method of summarizing certain characteristics of pressure ulcers, including the extent of tissue damage. Hence, whether the nurse observes the epidermis, dermis, fat, muscle, bone, or joint determines the stage of pressure ulcer. Knowing the appropriate stage aids in determining the management of the pressure ulcer. However, staging of pressure ulcers can vary, because different nurses may observe different tissue types. In a survey of nurses' wound care knowledge, less than 50 percent of new nurses (fewer than 20 years of nursing experience) did not feel confident in consistently identifying all stages of pressure ulcers, as compared to 30 percent of the more experienced nurses (more than 20 years of nursing experience).[82] Achieving consistency in staging will provide optimal pressure ulcer management.

Pressure ulcer staging systems differ, depending on geographic location. The Europeans use a four-stage system.[83] For Grade 1, nonblanchable erythema of intact skin, discoloration of the skin, warmth, edema, and induration or hardness may be used as indicators, particularly on individuals with darker skin. For Grade 2, indicators include partial thickness skin loss involving epidermis, dermis, or both. The ulcer is superficial and presents clinically as an abrasion or blister. Grade 3 includes full thickness skin loss involving damage to or necrosis of subcutaneous tissue that may extend down to, but not through, underlying fascia. Grade 4 includes extensive destruction; tissue necrosis; or damage to muscle, bone, or supporting structures, with or without full thickness skin loss.

The most widely used staging system in the United States was developed in 1989 by the NPUAP.[84] This staging system was modified from Shea's original system.[85] The staging system rates the pressure ulcer from superficial tissue damage (Stage I) to full thickness skin loss involving muscle or bone (Stage IV). If the pressure ulcer is covered with necrotic tissue (eschar), it should be noted as unstageable. In skilled nursing facilities, nurses must stage a pressure ulcer covered with necrotic tissue as Stage IV.[86] In home care and nursing homes, nurses must stage pressure ulcers because staging is linked to reimbursement of medical expenses.

In 2007, the NPUAP revised the staging system to include deep tissue injury, an ulcer often described as a purple or maroon localized area of discolored intact skin or blood-filled blister due to damage of underlying soft tissue from pressure and/or shear.[87] The NPUAP also reclassified blisters and unstageable pressure ulcers. The NPUAP staging definitions were refined with input from an online evaluation of their face validity, accuracy clarity, succinctness, utility, and

discrimination. The new staging system has six stages: suspected deep tissue injury, Stage I, Stage II, Stage III, Stage IV, and Unstageable. Table 1 presents the NPUAP definition, and Table 2 illustrates the differences between the old and new pressure ulcer staging systems.

Table 1. National Pressure Ulcer Definition

	Previous NPUAP Definition	2007 NPUAP Definition	2007 NPUAP Further Descriptions to Accompany Revised Definition
Pressure Ulcer Definition	A localized area of tissue necrosis that develops when soft tissue is compressed between a bony prominence and an external surface for a prolonged period of time.	A pressure ulcer is localized injury to the skin and/or underlying tissue usually over a bony prominence, as a result of pressure, or pressure in combination with shear and/or friction.	A number of contributing or confounding factors are also associated with pressure ulcers; the significance of these factors is yet to be elucidated.

Table 2. National Pressure Ulcer Staging System

Pressure Ulcer Stage	Previous NPUAP Staging Definitions	2007 NPUAP Definitions	2007 NPUAP Descriptions to Accompany Revised Definitions
Deep Tissue Injury	A pressure-related injury to subcutaneous tissues under intact skin. Initially, these lesions have the appearance of a deep bruise, and they may herald the subsequent development of a Stage III–IV pressure ulcer, even with optimal treatment.	Purple or maroon localized area of discolored intact skin or blood-filled blister due to damage of underlying soft tissue from pressure and/or shear.	• The area may be preceded by tissue that is painful, firm, mushy, boggy, warmer, or cooler, as compared to adjacent tissue. • Deep tissue injury may be difficult to detect in individuals with dark skin tones. • The area may rapidly evolve to expose additional layers of tissue, even with optimal treatment.
Stage I	An observable pressure-related alteration of intact skin whose indicators as compared to an adjacent or opposite area on the body may include changes in one or more of the following parameters: skin temperature (warmth or coolness), tissue consistency (firm or boggy feel), sensation (pain, itching), and/or a defined area of persistent redness in lightly pigmented skin; in darker skin tones, the ulcer may appear with persistent red, blue, or purple hues.	Intact skin with nonblanchable redness of a localized area, usually over a bony prominence.	• The area may be painful, firm, soft, warmer, or cooler, as compared to adjacent tissue. • Stage I may be difficult to detect in individuals with dark skin tones. • May indicate at-risk persons (a heralding sign of risk).
Stage II	Partial thickness skin loss involving the epidermis and/or dermis. The ulcer is superficial and presents clinically as an abrasion,	Partial thickness loss of dermis presenting as a shallow open ulcer with a red, pink wound bed without slough. May also present as	Presents as a shiny or dry shallow ulcer without slough or bruising. This stage should not be used to describe skin tears, tape burns, perineal

Pressure Ulcer Stage	**Previous NPUAP Staging Definitions**	**2007 NPUAP Definitions**	**2007 NPUAP Descriptions to Accompany Revised Definitions**
	blister, or shallow crater.	an intact or open/ruptured serum-filled blister.	dermatitis, maceration, or excoriation.
Stage III	Full thickness skin loss involving damage or necrosis of subcutaneous tissue that may extend down to, but not through, underlying fascia. The ulcer presents clinically as a deep crater with or without undermining of adjacent tissue.	Full thickness tissue loss. Subcutaneous fat may be visible, but bone, tendon, or muscle are *not* exposed. Slough may be present but does not obscure the depth of tissue loss. *May* include undermining and tunneling.	• The depth of a Stage III pressure ulcer varies by anatomical location. The bridge of the nose, ear, occiput, and malleolus do not have subcutaneous tissue, and Stage III ulcers can be shallow. In contrast, areas of significant adiposity can develop extremely deep Stage III pressure ulcers. • Bone/tendon is not visible or directly palpable.
Stage IV	Full thickness skin loss with extensive destruction; tissue necrosis; or damage to muscle, bone, or supporting structure (such as tendon, or joint capsule).	Full thickness tissue loss with exposed bone, tendon, or muscle. Slough or eschar may be present on some parts of the wound bed. *Often* includes undermining and tunneling.	• The depth of a Stage IV pressure ulcer varies by anatomical location. The bridge of the nose, ear, occiput, and malleolus do not have subcutaneous tissue, and these ulcers can be shallow. • Stage IV ulcers can extend into muscle and/or supporting structures (e.g., fascia, tendon, or joint capsule), making osteomyelitis likely to occur. • Exposed bone/tendon is visible or directly palpable.
Unstagable		Full thickness tissue loss in which *actual* depth of the ulcer is *completely* obscured by slough (yellow, tan, gray, green, or brown) and/or eschar (tan, brown, or black) in the wound bed.	Until enough slough and/or eschar is removed to expose the base of the wound, the true depth, and therefore stage, cannot be determined. Stable (dry, or adherent, intact without erythema or fluctuance) eschar on the heels serves as the "the body's natural (biological) cover" and should not be removed.

The Stage I pressure ulcer may be more difficult to detect in darkly pigmented skin. A quality improvement study in several nursing homes found that by empowering the nursing assistants with education (skin assessment), use of pen lights to assess darker skin, mirrors, and financial reward, the researchers were able to reduce the Stage I pressure ulcers in residents with darkly pigmented skin.[88] One method for delineating Stage I pressure ulcers in darkly pigmented skin may be the use of high-resolution ultrasound. Although ultrasound is widely used as a safe and cost-effective technique for noninvasive visualization of specific human anatomy, its use for skin assessment is just now available. Ultrasound utilizes the echoes of sound waves to create images of soft tissue anatomy.[89] A probe transmits sound waves into the body. High-frequency ultrasound (20MHZ)

will provide high resolution images of the skin and underlying soft tissue, and because the images are related to tissue density (not pigment), the clinician's assessment ability is enhanced significantly. A recent study strongly suggests that clinicians should consider high-frequency ultrasound as an improved method for identifying and implementing good pressure ulcer preventive care.[90]

The assessment and staging of pressure ulcers remains at the expert opinion level.

Debridement

The presence of necrotic devitalized tissue promotes the growth of pathologic organisms and prevents wounds from healing.[91] Experts believe that debridement is an important step in the overall management of pressure ulcers. No randomized control trials could be found that demonstrated that one debridement technique is superior. Thus, the best method of debridement is determined by the goals of the patient, absence or presence of infection, pain control, amount of devitalized tissue present, and economic considerations for the patient and institution.[92–94] There are five types of debridement: sharp, mechanical, autolytic, enzymatic, and biosurgery.

Sharp debridement (use of scalpel or laser) is probably the most effective type of debridement because of the time involved to remove the devitalized tissue.[95] Sharp debridement should always be considered when the patient is suspected of having cellulites or sepsis.[96] Mechanical debridement uses a nonselective, physical method of removing necrotic tissue and debris from a wound using mechanical force. One common form of mechanical treatment is wet-to-dry gauze to adhere to the necrotic tissue, which is then removed. Upon removal of the gauze dressing, necrotic tissue and wound debris are also removed. The challenge with mechanical debridement is the possibility that healthy granulation tissue may be removed as well, along with the devitalized tissue, thereby delaying wound healing and causing pain. Thus, CMS suggests that this method of debridement be used in limited circumstances.[40]

Autolytic debridement involves the use of semiocclusive (transparent film) and occlusive dressings (hydrocolloids, hydrogels, etc.), which creates an environment for the body's enzymes to break down the necrotic tissue.[97] Enzymatic debridement uses proteolytic enzymes (i.e., papain/urea, collagenase) to remove necrotic tissue.[98] This form of debridement is considered drug therapy; therefore it should be signed on the medication record. Finally, biosurgery (maggot therapy) is another effective and relatively quick method of debridement.[99] This type of debridement is especially effective when sharp debridement is contraindicated due to the exposure of bone, joint, or tendon.[99]

Bacterial Burden

Managing bacterial burden is an important consideration in pressure ulcer care. All pressure ulcers contain a variety of bacteria. Pressure ulcer bacterial contamination should not impair health.[100] Of great concern is when a colony of bacteria reaches 10^5 or 10^6 organisms per gram in the ulcer.[101] At these levels, the pressure ulcer can be considered infected. Healing can be impeded when wounds have high levels of bacteria. Robson and Heggers[101] found in 32 pressure ulcers that spontaneous healing occurred only when the microbial population was controlled.

Experts agree that swab cultures should not be used to determine wound infection.[102] Rather a tissue biopsy should be conducted to determine the qualitative and quantitative assessment of any aerobic and anaerobic organisms present.[103] Clinical signs that the pressure ulcer may be infected

include malodorous, purulent exudate; excessive draining; bleeding in the ulcer; and pain.[104, 105] One study investigating the validity of clinical signs and symptoms used to identify localized chronic wound infections found signs associated with secondary wounds (i.e., serous exudate, delayed healing, discoloration of granulation tissue, friable granulation tissue, pocketing at the base of the wound, foul odor, and wound breakdown) were better predictors of wound infection than the classic signs of infection (i.e., increasing pain, erythema, edema, heat, and purulence).[106] Overall, these researchers concluded that increasing pain and wound breakdown were both sufficient clinical indicators of infected wounds with 100 percent specificity. Thus, when these signs are present, the nurse should seek additional treatments for the patient. This will help to safeguard the patient from further ulcer complications.

The use of oral antibiotics or topical sulfa silverdiazine has also been found to be effective in decreasing the bioburden in the ulcer bed.[107, 108] Treatment using silver-impregnated dressings has been shown to be somewhat effective in decreasing bacterial bioburden load. One in vivo study found that silver-based dressings decreased specific bacteria (e.g., Eschericha coli, Candida albicans, and Staphylococcus aureas).[109] However, a systematic review of the research literature found only three randomized controlled trials covering 847 participants. This Cochrane review determined that based on only three randomized controlled trials, there remains insufficient evidence to recommend the use of silver-containing dressings or topical agents for treatment of infected or contaminated chronic wounds.[110]

The use of antiseptics to reduce wound contamination continues to be a controversial topic. The ideal agent for an infected pressure ulcer would be bactericidal to a wide range of pathogens and noncytotoxic to leukocytres. In vitro studies of 1 percent povidone-iodine have been found to be toxic to fibroblast, but a solution of 0.005% sodium hypochlorite ($P = 0.001$) caused no fibroblast toxicity and was still bactericidal to Staphylococcus aureus.[111] Another common antiseptic with conflicting data is sodium hypochlorite (Dakins solution). Studies suggest that 0.005 percent concentration of sodium hypochlorite to be bactericidal; however, its use can also cause inhibition of fibroblast and neutrophil migration necessary for pressure ulcer healing.[112] Conversely, other in vitro studies suggest that 0.005 percent sodium hypochlorite did not inhibit fibroblasts. McKenna and colleagues examined the use of 0.005 percent sodium hypochlorite, 0.001 percent povidone-iodine, 0.0025 percent acetic acid, and 0.003 percent hydrogen peroxide on various clinical isolates.[111] These researchers found that sodium chlorite significantly inhibited ($P = 0.001$) the growth of all bacteria tested (Staphylococcus aureas, Escherichia coli, Group D enterococci, Pseudomonas aeruginosa, and Bacteroides fragilis) without inhibiting fibroblast activity, whereas povidone-iodine and acetic acid reduced only specific bacteria.

Exudate Management

The use of dressings is a major component in maintaining a moist environment. There are more than 300 different modern wound dressings available to manage pressure ulcers.[113] Most dressings can be broken down into seven classifications: transparent films, foam islands, hydrocolloids, petroleum-based nonadherents, alginates, hydrogels, and gauze. Few randomized controlled studies have been conducted to evaluate the efficacy of dressings within a specific classification. Therefore, no one category of wound dressings (independent of gauze) may be better than another category. Most research evaluating the effects of dressings usually compare gauze (standard) to modern wound dressings (nongauze).[114, 115, 116] These studies are inherently flawed because gauze dressings are not classified as a modern wound dressing; thus equivalent comparisons cannot be

made. The studies usually have small sample sizes; thus inferences can be difficult to make. However, one study investigating wound-healing outcomes using standardized validated protocols found that primarily using nongauze protocols of care matched or surpassed the best previously published results on similar wounds using gauze-based protocols of care, including protocols applying gauze impregnated with growth factors or other agents. Thus, nongauze protocols of care should be used to accelerate pressure ulcer healing.[117]

Nutrition

The use of high-protein diets for patients with protein deficiency is essential to wound healing. One small study (n = 12) has suggested that 1.25 g protein/L/kg/day to 1.50 g protein/L/kg/day is needed to promote wound healing.[118] However, Mulholland and colleagues[119] suggested in a 1943 journal article that as much as 2.0 g protein/L/kg/day is essential for wound healing. To underscore that increasing protein does have a positive effect on wound healing, researchers investigated 28 malnourished patients with a total of 33 truncal pressure ulcers.[120] The researchers found that patients who received the 24-percent protein intake had significant decrease ($P = 0.02$) in truncal pressure ulcer surface area compared to the group on 14-percent protein intake. Clearly, increasing protein stores for patients with pressure ulcers who are malnourished is essential; however, it is unclear from the literature what the optimum protein intake requirement is for patients with pressure ulcers. Most promising: the use of amino acids such as argine, glutamine, and cysteine have been noted to assist in ulcer healing.[121] However, there remains a paucity of data to substantiate these claims; thus their use should be tempered with the overall goals of the patient.

Pain Management

Pressure ulcers can be painful. In particular, patients with Stage IV ulcers can experience significant pain.[122, 123] A cross-sectional study of patients with a mix of chronic wounds found that wound stage was positively related to severity of pain.[123] Moreover, pain catastrophizing was positively related to pain intensity and higher levels of affective distress and depressive symptoms. Hence, the goal of pain management in the patient with pressure ulcers should be to eliminate the cause of pain, to provide analgesia, or both. This goal was supported recently by the World Union of Wound Healing Societies consensus document, *Principles of Best Practice: Minimizing Pain at Wound Dressing-Related Procedures.*[124] Pain at dressing-related procedures can be managed by a combination of accurate assessment, suitable dressing choices, skilled wound management, and individualized analgesic regimens. Dressing removal can potentially cause damage to delicate tissue in the wound and surrounding skin. Thus, clinicians should use multiple methods to address the pressure ulcer pain. This may include using dressing that mitigates pain during dressing changes, such as dressings containing soft-silicone, and administering analgesic prior to dressing changes.

Monitoring Healing

Presently, there are two instruments that are often used to measure the healing of pressure ulcers. The Pressure Ulcer Scale for Healing (PUSH) was developed by the NPUAP in 1997.[125] The PUSH tool is copyrighted and available on NPUAP's Web site.[84] It quantifies the pressure ulcer with respect to surface area, exudate, and type of wound tissue. Using a Likert scale from 1

to 10 for length and width, a Likert scale from 1 to 3 for exudate amount, and a Likert scale from 1 to 4 for tissue type, the nurse can determine whether a pressure ulcer is healing or nonhealing. Each of the three ulcer characteristics is recorded as a subscore, then the subscores are added to obtain the total score. A comparison of total scores measured over time provides an indication of the improvement or deterioration of the pressure ulcer.

Few studies have been published that measure the validity and reliability of the PUSH tool. A study investigating the PUSH tool's content validity found that it had both content validity (P = 0.01) and correlational validity (P = 0.05) to monitor the changing pressure ulcer status.[126] Moreover, a recent prospective study by Gardner and colleagues[106] of 32 pressure ulcers found that 21 ulcers (66 percent) healed during the 6-month study period, and 11 (34 percent) did not heal. The PUSH scores decreased significantly (P = 0.001) over time among the healed ulcers but did not among the unhealed ulcers. Thus, the PUSH tool was shown to be a valid instrument for measuring healing in a clinical setting.

The Bates-Jensen Wound Assessment Tool (BWAT; formerly the Pressure Sore Status Tool, PSST) was developed in 1992 and is also widely used.[127] The BWAT consists of 15 items. The first 2 items are related to location and shape of the ulcer. The remaining 13 items are scored on the basis of descriptors of each item and ranked on a modified Likert scale (1 being the healthiest attribute of the characteristic and 5 being the least healthy attribute of the characteristic). The 13 BWAT characteristics that are scored are size, depth, edges, undermining, necrotic tissue type, necrotic tissue amount, exudate type, exudate amount, skin color surrounding wound, peripheral tissue edema, peripheral tissue induration, granulation tissue, and epithelialization. The 13 item scores are summed to provide a numerical indicator of wound health or degeneration.

There is a paucity of validation studies for the BWAT. However, content validity has been established by a panel of 20 experts. Interrater reliability was established by the use of two wound, ostomy, and continence nurses who independently rated 20 pressure ulcers on 10 patients. Interrrater reliability was established at r = 0.91 for first observation and r = 0.92 for the second observation (P = 0.001).[128] A recent study examined wound-healing outcomes with standardized assessments using the BWAT. Most of the 767 wounds selected to receive the standardized protocols of care were Stage III–IV pressure ulcers (n = 373; mean healing time 62 days). Partial thickness wounds healed faster than same-etiology full thickness wounds.[117] This finding further adds to the validation of the BWAT tool for measuring wound healing.

Adjunctive Therapies

The use of adjunctive therapies is the fastest growing area in pressure ulcer management. Adjunctive therapies include electrical stimulation, hyperbaric oxygen, growth factors and skin equivalents, and negative pressure wound therapy. Except for electrical stimulation, there is a paucity of published research to substantiate the effectiveness of adjunctive therapies in healing pressure ulcers.

Electrical stimulation is the use of electrical current to stimulate a number of cellular processes important to pressure ulcer healing.[129] These processes include increasing the fibroblasts, neutrophil macrophage collagen, DNA synthesis, and increasing the number of receptor sites for specific growth factors.[129] Eight randomized controlled studies were found in the literature. Electrical stimulation appears to be most effective on healing recalcitrant Stages III and IV pressure ulcers.[130] A meta-analysis of 15 studies evaluating the effects of electrical stimulation on the healing of chronic ulcers found that the rate of healing per week was 22 percent for the

electrical stimulation group compared to 9 percent for the control group.[131] Thus, electrical stimulation should be considered for nonhealing pressure ulcers.

Negative pressure wound therapy is widely used, although few randomized controlled trials have been published. This therapy promotes wound healing by applying controlled localized, negative pressure to the wound bed.[132–134] In one prospective study investigating nonhealing pressure ulcers, 24 patients were randomized into two groups (wet-to-moist dressings or vacuum-assisted closure).[133] Those patients receiving negative pressure wound therapy had a 66-percent reduction in wound depth ($P = 0.0001$), compared to the wet-to-moist dressings group, which had a 20-percent wound depth reduction.[133] Much more research is needed on the benefits of negative pressure wound therapy for treating pressure ulcers, but there is emerging evidence that this therapy may be helpful in assisting the healing of pressure ulcers.

The use of growth factors and skin equivalents in the healing of pressure ulcers remains under investigation, although the use of cytokine growth factors (e.g., recombinant platelet-derived growth factor-BB [rhPDGF-BB]) and fibroblast growth factors (bFGF) and skin equivalents have been shown to be effective in diabetic and venous ulcers. Three small randomized controlled trials have suggested that growth factors had beneficial results with pressure ulcers, but the findings warrant further exploration.[135–137] When we learn more about the healing cascade, the appropriate use of growth factors in pressure ulcer treatment may become clearer.

The use of electroceuticals—highly refined electromagnetic fields that can accelerate the body's natural anti-inflammatory response, thereby aiding wounds to heal faster—is showing some promising results. One animal study used a prospective, randomized, double-blind, placebo-controlled design to evaluate the effect of a specific noninvasive radiofrequency-pulsed electromagnetic field signal on tendon tensile strength at 21 days after transection in a rat model.[138] This study found an increase in tensile strength of up to 69 percent (136.4 ± 31.6 kg/cm^2) at the repair site of the rat Achilles' tendon at 3 weeks after transection and repair, compared with the value (80.6 ± 16.6 kg/cm^2) in nonstimulated control animals. Although electroceuticals are promising, additional research is needed to recommend them for pressure ulcer treatment.

The use of therapeutic ultrasound for pressure ulcers has also been explored. A Cochrane review found three published randomized clinical trails using therapeutic ultrasound.[139] It was concluded that there was no evidence of the benefit of ultrasound therapy in the treatment of pressure ulcers. Thus, additional studies are needed before this therapy can be supported.

Evidence-Based Practice Implications

Much progress has been made in identifying patients at risk for pressure ulcers. The use of pressure ulcer prediction tools (e.g., Braden Scale) have led to nursing's sensitivity to earlier preventive measures. Research has shown that using the AHRQ guidelines on pressure ulcer prediction and prevention can lead to decreased incidence of pressure ulcers. Moreover, internalizing these guidelines throughout the health care system can lead to pressure ulcer reductions.

Much progress has been made in understanding effective wound treatments. Treatments range from using traditional therapies (keeping the wound moist, appropriate repositioning, support surfaces, and proper nutrition) to the wise use of adjunctive therapies. Although many studies in pressure ulcer prevention and treatment have small sample sizes, there is a growing body of evidence to suggest that newer wound modalities can be effective in preventing and treating pressure ulcers.

Research Implications

Since the original publications of the AHRQ pressure ulcer prevention and treatment guidelines in 1992 and 1994, some progress has been made in our understanding of pressure ulcer care. Nursing research is needed to address many gaps in our understanding of pressure ulcer prevention and treatment. Many risk factors for pressure ulcer development have been identified; however, a hierarchy of risk factors has not been determined. Thus, research to determine the essential risk factors is still needed. There also remains a dearth of research determining the role that race and ethnicity may have on pressure ulcer development. A small body of research is emerging to suggest that people of color may have an increased risk for pressure ulcer development. Thus, nurses must actively recruit minority participants to further explore this important variable. Another promising area of nursing research is the use of pressure ulcer prediction tools. Although the Braden Scale was originally published nearly two decades ago, it remains the gold standard. As the patient population continues to change, nursing research is needed to develop and validate newer pressure ulcer prediction tools.

There is a paucity of research on the effects of good skin care on pressure ulcer development. Randomized clinical trials are needed to validate specifics aspects of skin care (bathing schedules, cleansing solutions, water temperature, etc.) and their association with pressure ulcer development. Nursing research can also play a major role in closing the knowledge gap regarding optimal turning/repositioning schedules. Emerging research suggests that turning/repositioning every 2 hours may not be necessary when using dynamic support surfaces. However, randomized controlled trials with large numbers of participants are greatly needed. Evidence is still unclear as to whether there are large differences in the effectiveness of various support surfaces (e.g., Group II) to prevent pressure ulcers.

The role of protein-calorie malnutrition and pressure ulcer development remains understudied. Moreover, research into dietary supplements (vitamins, minerals, etc.) in the absence of a dietary deficiency is lacking. Additional nursing studies are needed to investigate whether the use of dietary supplements have any effect on pressure ulcer prevention. Recent nursing studies suggested that a comprehensive approach to prevention can lead to significant decreases in pressure ulcer incidence. However, studies investigating methods to sustain these decreases in pressure ulcer development are greatly needed. Additional research is also needed to further our understanding of risk level and titration of preventive measures

Staging of pressure ulcers remains more of an art than a science. Additional nursing research is needed to determine effective methods of classifying pressure ulcer depth with good validity and reliability. There is also a dearth of nursing research on the optimal solution and frequency for cleansing a pressure ulcer. Moreover, nursing research is needed to determine the optimal method for removing devitalized tissue in a pressure ulcer. No randomized controlled trials could be found that determined the best debridement method for healing pressure ulcers. Nursing research has identified some clinical characteristics of infected pressure ulcers. However, additional research is needed on the most effective method for treating an infected or contaminated pressure ulcer.

Numerous dressings are currently available to manage wound exudate. However, few randomized controlled trials have been conducted to determine optimal dressings within a classification (e.g., hydrocolloid, alginate). Many adjunctive therapies are currently being used, but few have extensive research to substantiate their effectiveness in healing pressure ulcers. Nursing research investigating the role of skin substitutes, growth factors, negative pressure wound therapy, and electroceuticals in healing pressure ulcers is greatly needed. Finally, nursing

research evaluating the cost effectiveness of adjunctive treatments in healing pressure ulcers is warranted, given rising health care costs.

Conclusion

The prevention of pressure ulcers represents a marker of quality of care. Pressure ulcers are a major nurse-sensitive outcome. Hence, nursing care has a major effect on pressure ulcer development and prevention. Prevention of pressure ulcers often involves the use of low technology, but vigilant care is required to address the most consistently reported risk factors for development of pressure ulcers. The literature suggested that not all pressure ulcers can be prevented, but the use of comprehensive pressure ulcer programs can prevent the majority of pressure ulcers. When the pressure ulcer develops, the goals of healing or preventing deterioration and infection are paramount. Randomized controlled trials are needed to determine optimal management strategies dependent on stage and comorbidities/severity of illness. Nursing remains at the forefront of protecting and safeguarding the patient from pressure ulcers.

Search Strategy

The electronic databases MEDLINE® (1980–2007), CINAHL® (1982–2007), and EI Compedex*Plus (1980–2007) were selected for the searches. Evaluations of previous review articles and seminal studies that were published before 1966 were also included. Research conducted worldwide and published in English between the years 1930 and 2007 was included for review. Moreover, studies using descriptive, correlational, longitudinal, and randomized controlled trials were included.

Evidence Table. Pressure Ulcers—Risk, Assessment, and Prevention

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Allman 1986[22]	Pressure ulcer risk factors	Prospective cohort study	Cross-sectional, pressure ulcer development	Hospital, 21 years and older		Hypoalbuminemia, fecal incontinence, and fractures remained significantly and independently associated with having a pressure sore (odds ratios = 3.0, 3.1, and 5.2, respectively).
Allman 1995[14]	Pressure ulcer risk identification	Prospective cohort study	Prospective cohort study, time to in-hospital development of a Stage II or greater pressure ulcer	Urban teaching hospital		Age of 75 years or more, dry skin, nonblanchable erythema (a Stage I pressure ulcer), previous pressure ulcer history, immobility, fecal incontinence, depleted triceps skin fold, lymphopenia (lymphocyte count < 1.50 x 10(9)/L), and decreased body weight (< 58 kg) were significantly associated with pressure ulcer development by univariate Kaplan-Meier survival analyses ($P < 0.05$ by log-rank test).
Anthony 2000[70]	Pressure ulcer prediction	Prospective cohort study	Noncomparative study, pressure ulcer development	Skilled nursing facility, elderly		Serum albumin (low) can be a useful predictor of pressure ulcer development.
Baier 2003[53]	Pressure ulcer prevention	Quality improvement	Prospective cohort study, implementation of AHRQ guidelines and pressure ulcer development	Skilled nursing facilities, quality improvement teams in 29 nursing homes	Quality improvement teams	Six of eight prevention process measures improved significantly, with percent difference between baseline and followup ranging from 11.6% to 24.5%. Three of four treatment process measures improved significantly, with 5.0%, 8.9%, and 25.9% differences between baseline and followup. For each process measure, between 5 and 12 facilities demonstrated significant improvement between baseline and followup, and only 2 or fewer declined for each process measure.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Bates-Jensen 1992[127]	Pressure ulcer healing	Prospective cohort study	Cross-sectional, pressure ulcer healing			The Pressure Sore Status Tool interrater reliability was established at $r = 0.91$ for first observation and $r = 0.92$ for the second observation ($P < 0.001$). Interrater reliability was $r = 0.99$ for rater one and $r = 0.96$ for rater two ($P < 0.001$).
Baumgarten 2003[30]	Pressure ulcer prevalence	Prospective cohort study	Prospective cohort study, pressure ulcer development among newly admitted residents from hospitals, home, or other settings.	Skilled nursing facilities, 65 years and older		Admission from a hospital was significantly associated with pressure ulcer prevalence on admission (OR = 2.2).
Bergstrom 1987[35]	Pressure ulcer prediction	Quality improvement	Prospective cohort study	Acute intensive care unit	The Braden scale score and skin assessment	Twenty-four of 60 consecutively admitted patients developed pressure ulcers with the total score of 16 as the cut-off.
Bergstrom 1992[13]	Pressure ulcer risk identification	Prospective cohort study	Prospective cohort study, pressure ulcer presence or absence	Skilled nursing facility, 65 years and older, 70% female		Best predictors of pressure sore development were the Braden scale score (< 16), diastolic blood pressure, temperature, dietary protein intake, and age.
Bergstrom 1992[42]	Pressure ulcer prevention guidelines	Published guideline	Systematic literature review (Level 11) and consensus reports (Level 16), pressure ulcer prevention	Hospital, skilled nursing facilities, and home care, elderly population		Development of guidelines to prevent pressure ulcers.
Bergstrom 1998[43]	Pressure ulcer prediction	Quality improvement	Prospective cohort study	Tertiary care hospitals, Veterans Administration Medical Centers, and skilled nursing facilities	The Braden scale score and skin assessment	One hundred eight of 843 subjects (12.8%) developed pressure ulcers. Braden scale scores were significantly lower ($P = 0.0001$) in those who acquired pressure ulcers then those who did not. Total score of 18 is the cut-off score for prediction of pressure ulcers.
Berlowitz 1989[24]	Pressure ulcer	Prospective cohort	Cross-sectional,	Skilled nursing		Factors associated with pressure

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
	predictors	study	pressure ulcer development	facility, elderly		ulcer development included altered level of consciousness (OR = 4.1), bed- or chair-bound (OR = 1.9), and hypoalbuminemia (OR = 1.8).
Brandeis 1990[25]	Pressure ulcers and mortality	Retrospective cohort studies	Use of large database, pressure ulcer development and mortality, hospitalization	Skilled nursing facilities, elderly		Pressure ulcers were associated with an increased rate of mortality, but not associated with increased transfers from skilled nursing facilities to hospitals for treatment.
Breslow 1993[120]	Pressure ulcers and dietary protein	Prospective cohort study	Nonrandomized trial, pressure ulcer healing	Skilled nursing facility, patients ages 72 years and older with malnutrition	Dietary supplement	Significant truncal decrease in pressure ulcers sizes when using 24% protein.
Cuddigan 2001[10]	Pressure ulcer incidence	Systematic literature review	Systematic literature review (Level 11), pressure ulcer incidence and prevalence	Hospital, skilled nursing facilities, and home care		Pressure ulcer incidence rates (e.g., hospitals, 0.4% to 38%; skilled nursing facilities, 2.2% to 23.9%; and home care, 0% to 17%).
DeFloor 2004[61]	Pressure ulcers	Prospective cohort study	Randomized controlled trial, pressure ulcer development	Skilled nursing facilities, 60 years and older	Turning every 2, 3, 4, or 6 hours using either standard mattress or viscoelastic foam	The incidence of Stage I pressure ulcers was not different between the groups. However, the incidence of Stage II pressure ulcers and higher in the 4-hour turning group with viscoelastic was 3%, compared with incidence figures in the other groups varying between 14.3% and 24.1%.
Donaldson 2005[48]	Licensed nurse-patient ratios and pressure ulcer development	Retrospective	Cross-sectional, pressure ulcer development	Hospitals, adult, surgical, and definitive-observation units, nurse-patient ratios	Staffing ratios	Impact of mandated nurse-patient ratios did not reveal significant changes in incidence of pressure ulcer development.
Ek 1985[58]	Pressure ulcers and massage	Prospective cohort study	Nonrandomized trial, pressure ulcer development, pressure ulcer development using massage	Hospital, patients older than 60 years with and without cerebral hemorrhage	Massage	The effect of massage over areas at risk for pressure ulcer varies greatly between patients and within patients.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Fuhrer 1993[26]	Pressure ulcer development	Prospective cohort study	Prospective cohort study, pressure ulcer development	Community, patients with spinal cord injury (100 men and 40 women)		Thirty-three percent (n = 46) presented with one or more ulcers of at least Stage I severity when visually examined. Twenty-one individuals had more than one ulcer, the maximum number of ulcers being seven. Of 87 ulcers for which severity ratings were available, 30 (34.5%) were Stage I, 33 (37.9%) were Stage II, and 24 (27.6%) were either Stage III or IV. Individuals with an ulcer exhibited more paralysis and were more dependent on others in activities of daily living. A greater proportion of blacks had more severe ulcers (Stages III and IV) than their white counterparts.
Gardner 1999[131]	Pressure ulcers	Meta-analysis	Nonrandomized trial, pressure ulcer healing		Electrical stimulation	Rate of healing per week was 22% for electrical stimulation samples and 9% for control samples. The net effect of electrical stimulation was 13% per week, an increase of 144% over the control rate.
Guralnik 1988[23]	Pressure ulcer predictors	Retrospective cohort studies	Use of large database, pressure ulcer development	Skilled nursing facilities, 55 years and older		Pressure ulcer development was associated with current smokers, inactivity, poor self-assessed health status, and anemia.
Hellwell 1997[80]	Cytotoxicity evaluation	Prospective cohort study		Polymorphonuclear leukocytes (PMNs)	Ten commercial wound cleaners	The non-antimicrobial wound cleansers had toxicity indexes of 10 to 1,000, while the toxicity indexes of antimicrobial wound cleansers were 10,000.
Horn 2005[47]	Nurse-patient ratios and pressure ulcer development	Retrospective	Cross-sectional, pressure ulcer development	Skilled nursing facility, registered nurse-patient ratios	Staffing ratios	More registered nurse care time per resident was associated with the development of fewer pressure ulcers.
Johnson-Pawlson 1996[46]	Nurse-patient ratios and pressure ulcer development	Retrospective	Cross-sectional, pressure ulcer development	Skilled nursing facility, registered nurse patient ratios	Registered nurse staffing ratios	The ratio of registered nurse to residents is directly related to a measure of quality of care deficiencies.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Kloth 1988[129]	Pressure ulcer healing	Prospective cohort study	Randomized controlled trial, pressure ulcer healing	Skilled nursing facility, patients ages 20 to 89 years, Stage IV pressure ulcers	High voltage monophasic pulsed current	Patients in treatment group healed at a mean rate of 44.8% a week and healed 100% over a mean period of 7.3 weeks. Patients in the control group increased in area an average of 11.6% a week and increased 28.9% over mean period of 7.4 weeks.
Lyder 1998[20]	Pressure ulcer prediction and prevention	Unpublished research	Retrospective cohort study (Level 9), pressure ulcer development	Hospitals, Medicare beneficiaries		The number of risk factors is associated with pressure ulcer development ($P \leq 0.001$). Patients with ≥ three risk factors were associated with an increased incidence (26.3%) of pressure ulcers, in comparison to those with one or two factors ($P = 0.001$).
Lyder 2001[12]	Pressure ulcer prevention	Quality improvement research	Retrospective cohort study (Level 9), pressure ulcer incidence	Hospital, Medicare beneficiaries	AHRQ pressure ulcer prevention guidelines	Hospital compliance with AHRQ prevention guidelines varied greatly for daily skin assessment (94%), risk identification (22.6%), use of pressure-reducing devices (7.5%), nutritional consult (34.3%), and repositioning patient every 2 hours (66.2%).
Lyder 2002[51]	Pressure ulcer prevention	Retrospective and prospective quasi-experimental	Pressure ulcer prevention program	Two long-term care facilities (A = 150 beds, B = 110 beds)	Pressure ulcer prevention program	An 87% decrease in pressure ulcers in facility A (13.2% to 1.7%) and a 76% decrease in pressure ulcers in facility B (15% to 3.5%).
Lyder 2004[7]	Pressure ulcer prevention	Quality improvement research	Retrospective cohort study (Level 9), pressure ulcer development	Hospitals, Medicare beneficiaries	Implement systematic risk assessment, repositioning, support surfaces	Statistically significant increases in the identification of high-risk patients, repositioning of bed-bound or chair-bound patients, nutritional consults in malnourished patients, and staging of acquired Stage II pressure ulcers from baseline and followup medical record abstractions.
Meaume 2005[108]	Silver in chronic wounds	Prospective cohort study	Randomized (stratification according to	13 centers with 99 participants	Silver-releasing hydroalginate	The study suggests that treating wounds with a high risk of infection with silver-releasing hydroalginate

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
			wound type) opened label multicenter comparative two-arm parallel-group		dressing	dressing had a favorable influence on wound prognosis.
Ooka 1995[68]	Support surfaces	Prospective cohort study	A new-product evaluation with convenience sampling	Surgical intensive care unit	Dynamic and static mattresses	All three mattresses were comparable in effectiveness.
Pang 1998[36]	Pressure ulcer risk identification	Prospective cohort study	Prospective cohort study, validity of pressure ulcer prediction scales	Hospital, 21 years and older, pressure ulcer free	Pressure ulcer prediction scales	Both the Norton and Waterlow scales had relatively high sensitivity (81% and 95%, respectively), whereas the Braden Scale had both high sensitivity (91%) and specificity (62%). All three scales had relatively high negative predictive values (>90%), but the Braden Scale had better positive predictive value.
Perneger 2002[38]	Pressure ulcers	Prospective cohort study	Cross-sectional, pressure ulcer development	Teaching hospital, patients older than 60 years		The FRAGMMENT score (sum of friction, age, mobility, mental status) was linearly related to pressure ulcer risk, and its area under the receiver operating characteristic curve (0.80) was higher than for the Norton (0.74; $P = 0.006$) and Braden (0.74; $P = 0.004$) scores.
Reddy 2006[62]	Pressure ulcer prevention	Systematic literature review, pressure ulcers	Systematic literature review	59 randomized controlled trials grouped into three categories		Giving current evidence, use of support surfaces, repositioning, optimizing nutritional status, and hydration of sacral skin are appropriate.
Romanelli 2003[107]	Pressure ulcer infection	Systematic literature review	Systematic literature review			Use of systemic antibiotics in infected pressure ulcers should be based on culture results. Therapy should be specific to isolated pathogens to avoid widespread use of antimicrobial drugs that contribute to the proliferation of drug-resistant organisms.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Rosen 2005[88]	Pressure ulcer prevention	Quality improvement	Prospective cohort study, pressure ulcer development	Skilled nursing facilities, elderly	Staff empowerment, real-time feedback	Empowering staff with real-time feedback led to significant reduction of new pressure ulcers (*P =0.* 05).
Roth 2004[123]	Pressure ulcer and pain	Prospective cohort study	Cross-sectional, pressure ulcer pain			McGill Pain questionnaire was more sensitive to pain experience than a single rating of pain intensity. Moreover, wound stage (larger) was positively related to severity of pain, and pain catastrophizing was positively related to pain intensity.
Schoonhoven 2002[39]	Pressure ulcer risk	Prospective cohort study	Prospective cohort study, pressure ulcer development	Hospitals, patients admitted to surgical, internal, neurological, or geriatric units, 18 years and older		The weekly incidence of patients with pressure ulcers was 6.2% (95% confidence interval 5.2% to 7.2%). The area under the receiver operating characteristic curve was 0.56 (0.51 to 0.61) for the Norton scale, 0.55 (0.49 to 0.60) for the Braden scale, and 0.61 (0.56 to 0.66) for the Waterlow scale; the areas for the subpopulation, excluding patients who received preventive measures without developing pressure ulcers and excluding surgical patients, were 0.71 (0.65 to 0.77), 0.71 (0.64 to 0.78), and 0.68 (0.61 to 0.74), respectively. In this subpopulation, using the recommended cut-off points, the positive predictive value was 7.0% for the Norton, 7.8% for the Braden, and 5.3% for the Waterlow scales.
Stotts 2001[126]	Pressure ulcer healing	Retrospective	Cross-sectional, pressure ulcer healing	Skilled nursing facility		The Pressure Ulcer Scale for Healing tool accounted for 58% to 74% of the wound healing variance over a 10-week period in Study 1, and 40% to 57% of the wound healing variance over a 12-week period in Study 2. Thus the PUSH

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
						tool is a valid and sensitive measure of pressure ulcer healing.
Thomas 1996[15]	Pressure ulcers and mortality	Prospective cohort study	Prospective cohort study, time to death from admission to 1-year posthospital discharge.	Urban teaching hospital		Development of an in-hospital pressure ulcer was associated with greater risk of death at 1 year (59.5% versus 38.2%, *P* = 0.02). However, pressure ulcer development did not remain independently associated with decreased survival after adjusting for other predictors of mortality.
Torra 2005[55]	Hyperoxygenated fatty acid	Prospective cohort study	Double-blind randomized clinical trial	Multicenter	Hyper-oxygenated fatty acid preparation	Pressure ulcer incidence during the study was 7.32% in the intervention group versus 17.37% in the placebo group (*P* = 0.006).
Xakellis 1998[49]	Pressure ulcer prevention	Quality improvement research	Cost-effectiveness evaluation	77-bed long-term care facility	A guideline-based pressure ulcer prevention protocol	Pre-protocol: 16 out of 69 patients developed 26 pressure ulcers. Post-protocol: 3 out of 63 patients developed 5 pressure ulcers.
Xakellis 2001[50]	Pressure ulcer guidelines	Retrospective and prospective quasi-experimental longitudinal	Cost effectiveness of a guideline-based pressure ulcer prevention protocol over time	77-bed long-term care facility	A guideline-based pressure ulcer prevention protocol	Time to ulcer development varied among three groups (log rank = 8.81, *P* = 0.01). Time to ulcer healing (log rank = 9.49, *P* = < 0.01). Cost of treatment decreased (F = 5.5, *P* = < 0.01). Cost of prevention increased (F = 15, *P* = < 0.01).

Chapter 13. Patient Safety and Quality in Home Health Care

Carol Hall Ellenbecker, Linda Samia, Margaret J. Cushman, Kristine Alster

Background

Home health care is a system of care provided by skilled practitioners to patients in their homes under the direction of a physician. Home health care services include nursing care; physical, occupational, and speech-language therapy; and medical social services.[1] The goals of home health care services are to help individuals to improve function and live with greater independence; to promote the client's optimal level of well-being; and to assist the patient to remain at home, avoiding hospitalization or admission to long-term care institutions.[2–4] Physicians may refer patients for home health care services, or the services may be requested by family members or patients.

The Centers for Medicare and Medicaid Services (CMS) estimates that 8,090 home health care agencies in the United States provide care for more than 2.4 million elderly and disabled people annually.[5] To be eligible for Medicare reimbursement, home health care services must be deemed medically necessary by a physician and provided to a home-bound patient. In addition, the care must be provided on an intermittent and noncontinuous basis.[5] Medicare beneficiaries who are in poor health, have low incomes, and are 85 years of age or older have relatively high rates of home health care use.[6] Common diagnoses among home health care patients include circulatory disease (31 percent of patients), heart disease (16 percent), injury and poisoning (15.9 percent), musculoskeletal and connective tissue disease (14.1 percent), and respiratory disease (11.6 percent).[7]

Delivering Health Care in the Home

The home health care environment differs from hospitals and other institutional environments where nurses work. For example, home health care nurses work alone in the field with support resources available from a central office. The nurse-physician work relationship involves less direct physician contact, and the physician relies to a greater degree on the nurse to make assessments and communicate findings. Home health care nurses spend more time on paperwork than hospital nurses and more time dealing with reimbursement issues.[8, 9] Certain distinctive characteristics of the home health care environment influence patient safety and quality of outcomes: the high degree of patient autonomy in the home setting, limited oversight of informal caregivers by professional clinicians, and situational variables unique to each home.

Respect for patient autonomy is valued in hospital-based care. Nonetheless, many decisions are made by clinicians on behalf of hospitalized patients. In home health care, clinicians recognize that the care setting—the home—is the inviolable domain of the patient. Therefore, compared to the hospitalized patient, the home health care patient often has a greater role in determining how and even if certain interventions will be implemented. For example, in a hospital, nurses, physicians, and pharmacists may all play a role in ensuring that the patient receives antibiotics at therapeutically appropriate intervals. At home, however, the patient may

choose to take the medication at irregular times, despite advice about the importance of a regular medication schedule. Thus, interventions to promote patient safety and quality care must account for the fact that patients will sometimes choose to act in ways that are inconsistent with the relevant evidence, and the clinician's best efforts may not result in desired outcomes.

In addition to deliberate choices made by informed and capable patients regarding their care, individual patient variables may also influence home-based outcomes in ways that are different from those patients who are hospitalized. Ellenbecker and colleagues[10, 11] reported that reading skill, cognitive ability, and financial resources all affect the ability of home health care patients to safely manage their medication regimens. Yet, none of these variables may play a meaningful role in the safe administration of medications to hospitalized patients.

In addition to self-care, some home-bound patients receive assistance from family members or other informal caregivers. Professional clinicians have no authority over these caregivers. Further, the home environment and the intermittent nature of professional home health care services may limit the clinician's ability to observe the quality of care that informal caregivers deliver—unlike in the hospital, where care given by support staff may more easily be observed and evaluated. For example, because of limited access to transportation, a husband may decide not to purchase diabetic supplies for his dependent wife. This behavior may not come to the clinician's attention until an adverse event has occurred. Evidence-based interventions are predicated on careful assessment. However, limited opportunity to directly observe the patient and informal caregivers may hinder efforts to quickly determine the etiology of an adverse event. If a home health care patient is found with bruises that the patient can't explain, is the cause a fall, physical abuse, or a blood dyscrasia? In both self-care by patients and care by informal caregivers, safety and quality standards may not be understood or achieved.

Another distinctive characteristic of home health care is that clinicians provide care to each patient in a unique setting. There may be situational variables that present risks to patients that may be difficult or impossible for the clinician to eliminate. Hospitals may have environmental safety departments to monitor air quality and designers/engineers to ensure that the height of stair risers is safe. Home health care clinicians are not likely to have the training or resources to assess and ameliorate such risks to patient safety in the patient's home.

Finally, given the large number of elderly persons who receive care from Medicare-certified home health care agencies, it is reasonable to anticipate that some patients will be in a trajectory of decline. Due to both normal aging and pathological processes that occur more frequently with advancing age, some elderly persons will experience decreasing ability to carry out activities of daily living (ADLs), even when high-quality home health care is provided. Thus, an implicit goal of home health care is to facilitate a supported decline. That is, patients who do not show clinical signs of improvement may nonetheless receive quality care that results in a decelerated decline or increased quality of life. This is consistent with the American Nurses Association's assertion that promoting the patient's optimal level of well-being is a legitimate goal of home health care.[3]

Assessing Quality of Care in the Home

The goals and multidisciplinary nature of home health care services present challenges to quality measurement that differ from those found in a more traditional hospital setting. The CMS mandates reporting of home health care outcome measures. The Outcome-Based Quality Monitoring (OBQM) program monitors, reports, and benchmarks adverse events such as emergent care for injury caused by fall or accident, increased number of pressure ulcers, and substantial decline in three or more ADLs.[5]

Pay for performance, a mechanism that ties a portion of an agency's reimbursement to the delivery of care, is another CMS quality initiative anticipated in the near future.[12] In preparation, quality-improvement organizations and providers are working to identify and develop a set of performance measures proven effective in home care. A 2006 Medicare Payment Advisory Commission report to Congress identified patient safety as an important component of quality and the need to expand quality measures to include process and structural measures. An expanded approach to quality measurement should accomplish the following goals: broaden the patient population being evaluated, expand the types of quality measures, capture aspects of care directly under providers' control, reduce variations in practice, and improve information technology.[13]

In January 2007, the home health community, health care leaders, and quality-improvement organizations launched the Home Health Quality Improvement National Campaign 2007. The campaign focuses on improving the quality of patient care in the home health care setting by providing agencies with monthly best practice intervention tools. The goal is to prevent avoidable hospitalizations for home health care patients. The Home Health Quality Improvement National Campaign uses a multidisciplinary approach to quality improvement that includes key home health, hospital, and physician stakeholders.[14]

Research Evidence

In many respects, home health care clinicians and clinicians working in other settings have similar concerns about patient safety and care quality. For example, patient falls occur both in homes and in hospitals, and some measures aimed at preventing falls are equally applicable to both settings. However, the significant differences between home health care and other types of health care often require interventions tailored to the home health care setting.

This chapter includes an analysis of the evidence on promoting patient safety and health care quality in relation to problems frequently seen in home health care. The following six areas were selected for review:

- Medication management
- Fall prevention
- Unplanned hospital admissions
- Nurse work environment
- Functional outcomes and quality of life
- Wound and pressure ulcer management

Adverse events in these areas could jeopardize achievement of one or more home health care goals.

Medication Management

Nearly one-third of older home health care patients have a potential medication problem or are taking a drug considered inappropriate for older people.[15] Elderly home health care patients are especially vulnerable to adverse events from medication errors; they often take multiple medications for a variety of comorbidities that have been prescribed by more than one provider. The majority of older home health care patients routinely take more than five prescription drugs, and many patients deviate from their prescribed medication regime.[11] The potential of medication errors among the home health care population is greater than in other health care

settings because of the unstructured environment and unique communication challenges in the home health care system.[11]

A search of the literature identified only three studies testing interventions to improve medication management and adherence in home health care patients.[16–18] The studies are summarized in Table 1. All three studies used a controlled experimental design, with random assignment of patients to one or two treatment groups and a control group of usual care. The populations studied were elderly Medicare patients receiving home health care, ranging from 41 to 259 patients.

The interventions tested were patient education delivered by telephone or videophone with nurse followup, education tailored to individual patients, and medication review and collaboration among providers (e.g., nurse, pharmacist, physician) and patient. Specific outcomes included identifying unnecessary and duplicate medication, improving the use of specific categories of medication such as cardiovascular or psychotropic drugs, and identifying the extent of use of nonsteroidal anti-inflammatory drugs (NSAIDs). The effectiveness of the interventions was measured by improved medication management and adherence to drug protocols. Adherence was estimated objectively from medication refill history and medication event monitoring, and subjectively from patient self-report scores on pre- and postintervention questionnaires testing knowledge, understanding of disease, and adherence.

Evidence from these studies suggests that all of the interventions tested were at least somewhat effective. Medication use improved for patients receiving the intervention, while control groups had a significant decline in adherence to drug protocols. The educational interventions were most successful when individually tailored to patients' learning abilities. The interventions were most effective in preventing therapeutic duplication and improving the use of cardiovascular medications, less effective for patients taking psychotropic medication or NSAIDs. Generally, as knowledge scores improved, adherence improved. When more than one intervention was tested, there was generally no difference between the two intervention groups.

Evidence-Based Practice Implications

Nurses must be vigilant for the possibility of medication errors in the home health care setting, recognizing the associated risk factors. Technology provides many opportunities to improve communication with patients, to provide patients with accurate information, to educate them about their medications, and to monitor medication regimes. Paying close attention to at-risk patients is most effective; therefore, accurate documentation and review of medications during each patient encounter is important. The evidence suggests that frequent medication reviews and collaboration with other members of the health care team, especially pharmacists, will help to prevent adverse events associated with poor medication management.

Research Implications

More effective methods are needed to improve medication use in the home health care population. Research should continue to expand the knowledge of factors that contribute to medication errors in home health care and determine what interventions are the most effective in improving medication management in the home.

Table 1. Summary of Evidence Related to Medication Management

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Fulmer 1999[18]	Medication compliance	Randomized controlled trial	Randomized controlled trial. Outcomes: prescribed cardiac medications taken	n = 50 patients, 65 years or older with congestive heart failure, receiving home care or clinic services	1. Daily videophone 2. Regular telephone reminders 3. Control: usual treatment	Control group medication compliance dropped significantly (*P* = .04) over time compared to intervention groups (telephone or videophone). No significant difference between the two intervention groups.
Gates 2005[17]	Medication improvement	Randomized controlled trial	Randomized controlled trial. Outcomes: medication knowledge and adoption of medication list	n = 41 patients from 2 homecare agencies, 2 educational groups	1. Video 2. Tailored to individual	Knowledge improved with education tailored to individual (group 2), Group 2 members were more likely to speak with a provider before purchase of an over-the-counter drug (*P* = .043) and were significantly more likely to keep an updated medication list (*P* = .003).
Meredith 2002[16]	Medication improvement	Randomized controlled trial	Randomized controlled trial: Outcomes: unnecessary therapeutic duplication and inappropriate cardiovascular, psychotropic, and NSAIDs use.	Medicare home health care patients, more than 65 years of age with at least one medication problem, from 2 large urban home care agencies; n = 130 intervention, n = 129 control	1. Medication program to identify potential med problems and collaboration with clinical pharmacist and nurse 2. Control: usual care	Medication use improved for 50% of intervention patients and 38% of control patients (*P* = .051). Intervention effect greatest for therapeutic duplication (*P* = .003), and intervention group improved in use of cardiovascular meds (*P* = .017). There were no differences in the groups for psychotropic medication or NSAID problems.

Fall Prevention

Emergent care for injury caused by falls or accidents at home is one of the most frequently occurring adverse events reported for patients receiving skilled home health care services.[19] Thirty percent of people age 65 and older living in the community fall each year. One in five of these fall incidents requires medical attention.[20] Falls are the leading cause of injury-related death for this population.[21] Among the elderly, Stevens[22] reported direct medical costs in 2000 totaled $179 million for fatal fall-related injuries and $19 billion for nonfatal injuries due to falls.

Although there is strong evidence of effective fall-prevention interventions for the general over-65 population,[20, 23, 24] knowledge of fall prevention in home health care is limited. For the general older population living in the community, evidence suggests that individualized home programs of muscle strengthening and balance retraining; complex multidisciplinary, multifactorial, health/environmental risk factor screening and intervention; home hazard assessment and modification; and medication review and adjustment can all reduce the incidence of falls.[20] However, patients in home health care are often older, sicker, and frailer than the average community-residing older adult, and it is not known if knowledge from other settings is transferable to home health care.

Research studies specific to home health care are predominantly retrospective, descriptive, correlational designs in single agencies, using matched control or randomized control groups to explore patient characteristics and other factors contributing to patient falls.[25–27] Findings suggest that factors related to falls for home health care patients are previous falls, primary diagnosis of depression or anhedonia, use of antipsychotic phenothiazines and tricyclic antidepressants, secondary diagnoses of neurological or cardiovascular disorders, balance problems, frailty, and absence of handrails.[25-27]

A literature review located only three studies testing interventions to prevent falls.[28–30] The studies are summarized in Table 2. All three interventions were quality-improvement programs in single agencies. The findings suggest that risk factor screening and intervention using a valid and reliable instrument and physical therapy aimed at improvement in gait and balance may reduce injury and emergent care for falls. Unfortunately, there is no evidence that the number of falls incurred by the home health care population can be reduced. It may be that improved provider assessments increased the number of falls reported and documented.

Evidence-Based Practice Implications

Home health care providers need to know the risk factors for falls and demonstrate effective assessment and interventions for fall and injury prevention. Falls are generally the result of a complex set of intrinsic patient and extrinsic environmental factors. Use of a fall-prevention program, standardized tools, and an interdisciplinary approach may be effective for reducing fall-related injuries.

Research Implications

There are several limitations in the current evidence on falls in home health care. Most of the research is descriptive, and there are no randomized controlled studies. Findings from small, single-agency quality-improvement projects cannot be generalized. It is not known if predictors for falls in home health care patients are the same as those for other community dwellers over

age 65. Research is needed to expand the knowledge of factors that contribute to falls in this population and to develop effective interventions. Research is also needed to explore factors to prevent injury from falls, as it is likely that the incidence of falls in this population cannot be completely eliminated.

Table 2. Summary of Evidence Related to Fall Prevention

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Bright 2005[28]	Fall prevention/risk reduction	Quality improvement project/research	Observational study without controls. Outcomes: improvement in balance and gait, number of falls, and emergent care for falls or accidents.	Year 1 n = 153 patients and year 2 n = 183 patients age 62 and over and at risk for falls from 1 Midwest home care agency.	Fall prevention/risk reduction program: screening with Tinetti assessment, education, physical therapy intervention, and followup.	Emergent care for injury caused by fall or accident at home decreased from 2.58% to 1.72% within 7 months. Improvement in gait and balance scores from 15.59 to 18.43. There was no change in number of falls in home.
Sperling 2005[30]	Fall prevention (see also medication management)	Quality improvement project/research	Observational study without controls. Outcomes: patient falls.	n = 228 patients 65 years of age or older from a medical-centered home care agency.	Medication management model: medication review and oversight for patients at risk.	The number of reported falls increased, possibly related to increased staff awareness and better reporting.
Yuan and Kelly 2006[29]	Fall prevention/risk and injury reduction	Quality improvement project/research	Observational study without controls. Outcome: rate of falls, injury from falls.	Unknown number of at-risk patients for falls from 1 hospital-based home care agency.	Fall prevention program, multidisciplinary risk assessment with Morse scale, evidence-based guidelines.	Number of patient falls remained relatively stable, but fewer patients were injured in falls.

Unplanned Hospital Admissions

A primary goal of home health care is to discharge the patient to self or family care and avoid subsequent hospitalizations. Unplanned admission to the hospital is an undesirable outcome of home health care that causes problems for patients, caregivers, providers, and payers. Unplanned hospital admissions are associated with complications, morbidity, patient and family stress, and increased costs.[31] An estimated 1,034,034 home health care patients were hospitalized in 2004. The national rate of unplanned hospital admissions for home health care patients has gradually increased from 27 percent in 2000 to 28 percent in 2006,[32] and it is the only publicly reported home health care patient outcome that has never improved at the national level.[33]

Several researchers have explored the characteristics of home health care patients and other factors associated with hospitalization.[31, 34–39] The studies have been predominantly retrospective, descriptive, and correlation designs examining home care populations from single or multiple agencies.[31, 35–38] One study is a prospective study of a random sample of agencies.[39] Evidence suggests that unplanned hospital admissions are due mostly to an acute exacerbation of chronic disease—exacerbations that could be prevented through knowledge of risk factors, provider communication, and careful monitoring.[39] Risk factors associated with unplanned hospital admissions are polypharmacy,[31, 35] length of home health care episode,[34, 36] development of a new problem or worsening primary or secondary diagnosis,[36] wound deterioration and falling accidents,[31] and age.[31, 37] Based on this evidence most experts[31, 37] conclude that 20 to 25 percent of unplanned hospital admissions are preventable. For example, Shaughnessey and colleagues[2] found that agencies actively involved in Outcomes-Based Quality Improvement (OBQI) monitoring reduced their rate of patient hospitalizations when compared to non-OBQI agencies.

The Briggs National Quality Improvement and Hospitalization Reduction Study[33] convened a panel of experts to identity best practice strategies that agencies should implement to prevent unplanned hospitalizations. Recommended best practices included implementing a fall prevention program, front loading visits, management support, 24-hour on-call nursing coverage, medication management, case management, patient/caregiver education, special support services, disease management, positive physician and hospital relationships, data-driven services, safety and risk assessment, and telehealth. These recommendations were not empirically tested, however.

Only eight studies have tested the effectiveness of interventions to prevent unplanned hospital admissions for home health care patients. Five of these studies employed a randomized controlled trial design, and three used a nonrandomized control or comparison group design. The tested interventions consisted primarily of increasing the intensity of care provided through a disease management program, a team management home-based primary care program, a multidisciplinary specialty team intervention, advanced practice nurse (APN) transitional care, telehealth services, and intensive rehabilitative care prior to hospital discharge.[40–43] Most of these interventions were effective or somewhat effective in preventing or delaying hospitalization. Additionally, four of the studies reported lower mean costs or charges for the intervention groups related to lower hospital costs,[40, 42–44] and one study[45] reported higher costs for the intervention group based on the costs of the team-managed primary care intervention.

In these studies, patients with congestive heart failure (CHF) had fewer unplanned hospital admissions and longer survival times prior to first admission[39–42] if they received APN

transitional care, team-managed home-based primary care, or a multidisciplinary specialty team intervention.[40–43] Patients with CHF who received telecare and telephone interventions also had significantly fewer emergency room visits, but no change in hospital admissions.[42] Team-managed home-based primary care has been found to be most effective for people who are severely disabled.[45] Daly and colleagues [44] reported that long-term mechanically ventilated patients who received a disease management program intervention involving APN services and interdisciplinary coordination had significantly fewer mean days of hospitalization.

Results from one nonrandomized controlled study suggest that patients with chronic obstructive pulmonary disease (COPD) who received APN transitional care also experienced fewer unplanned hospital admissions.[46] Intrator and Berg[47] reported that patients hospitalized with hip fractures had fewer unplanned hospital admissions when they received home health care services following inpatient rehabilitation compared with those patients who received inpatient services only. Findings are summarized in Table 3.

Evidence-Based Practice Implications

Evidence suggests that specialized, coordinated, interdisciplinary care has a positive impact on unplanned hospital admissions in select home health care populations. Agencies can identify patient characteristics associated with hospitalization unique to their patient population. High-risk patients may require specialized interventions beyond the traditional scope of home health care services. Targeted interventions using process-of-care analysis and data available from the Outcome and Assessment Information Set (OASIS), within the framework of OBQI, may result in fewer unplanned hospital admissions for home health care patients.

Research Implications

The available evidence suggests that in addition to the use of APNs for care of complex cases, traditional home health care professionals, individually or through interdisciplinary practice, may be effective in preventing unplanned hospital admissions with targeted interventions. Although numerous strategies have been recommended by researchers and other home care experts, most interventions have not been empirically tested. Costs and benefits of the various interventions also need further exploration. The measurement of intervention costs and cost savings from prevented hospitalizations are not well understood. Some patient populations, due to the nature and complexity of advanced disease process, may require more intense and specialized home health care services that will not result in cost savings. On the other hand, use of seemingly more expensive transitional resources, such as APNs, have been proven cost effective, although adoption of such research-based best practices may be impeded by lack of reimbursement and incentives.[48] Research is needed to understand the impact of shifting care and cost to home health care on patient outcomes and home health care industry fiscal status.

Table 3. Summary of Evidence Related to Unplanned Hospital Admission

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Briggs 2006[33]	Hospitalization reduction	Quality improvement project/ consensus report, and retrospective cohort study	Nonexperimental descriptive Outcomes: 15 best practice strategies to prevent hospitalization. Type and percent of agencies implementing best practices.	Convenience sample of 400 agencies with lower-than-average hospitalization rates	Panel consensus on 15 best practice survey of agencies	Best practice strategies: Fall prevention Front loading visits Management support 24-hour on-call nursing coverage Medication management Case management Patient/caregiver education Special support services Disease management Physician relationships Data-driven services Safety and risk assessment Hospital relationships: Discharge staff and EM staff Telehealth. Successful agencies intentionally used one or more of these strategies. Most strategies did not involve extra expense.
Daly 2005[44]	Hospital admission	Randomized controlled trial	Randomized controlled trial. Outcomes: hospitalization rate, duration, and cost effectiveness	Chronically ill, long-term mechanically ventilated patients discharged from academic medical center: n = 231 intervention, n = 103 control	1. Disease management program, care coordination, family support, teaching, from a team of APNs, a geriatrician, and a pulmonologist 2. Usual care	Intervention group had significantly fewer mean days of hospitalization vs. control (P = .03). The average savings per patient in the intervention group was $21,549.

Table 3. Summary of Evidence Related to Unplanned Hospital Admission (continued)

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Hughes 2000[45]	Hospital readmissions (See also Table 5)	Randomized controlled trial	Randomized controlled trial. Outcomes: hospital readmissions and costs over 12 months	Patients with a mean age of 70 years who had 2 or more ADL impairments or a terminal illness, CHF, or COPD. n = 981intervention, n = 985 control	1.Team-managed home-based primary care (HBPC): primary care manager, 24-hour contact for patients, prior approval of hospital admissions 2. Customary Department of Veterans Affairs and private sector care	Team-managed HBPC patients with severe disability experienced a 22% relative decrease in hospital readmissions (*P* = .03) vs. control group at 6 months, but it was not sustained at 12 months. Total mean per-person costs were 6.8% higher in the TM/HBPC group at 6 months ($19,190 vs. $17,971) and 12.1% higher at 12 months ($31,401 vs. $28,008 (*P* = .005).
Intrator and Berg 1998[47]	Hospitalization or nonskilled nursing facility admission	Retrospective cohort study	Observational study with controls. Outcomes: hospitalization and any nonskilled nursing facility admission.	324 patients age 70 or older who had acute hospitalization for hip fracture and were discharged to home after inpatient rehabilitation	1. Inpatient rehabilitation discharge with additional home care services 2. Inpatient rehabilitation with no additional home care	Patients who received additional home health care services (27.2%) were less likely to be hospitalized than those who received rehabilitation only (31.1%); they were also less likely to have a nonskilled nursing facility admission (11.3% vs. 23.3%), and more likely to survive the year with no subsequent Medicare claims (65.6% vs. 55%).

Table 3. Summary of Evidence Related to Unplanned Hospital Admission (continued)

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Jerant 2001[42]	Hospitalization for CHF and cost	Randomized controlled trial	Randomized controlled trial. Outcomes: CHF-related readmission charges and all-cause readmissions, emergency department (ED) visits, and associated charges	CHF patients discharged from 1 large medical center: n = 13 intervention (group 1), n = 12 intervention (group 2), and n = 12 control (group 3)	1. Home telecare 2. Telephone care 3. Usual care	Mean CHF-related readmission charges were 86% lower in the telecare intervention group and 84% lower in the telephone group than in the usual care group. The between-group difference was not statistically significant. Both intervention groups had significantly fewer CHF-related ED visits (*P* = 0.0342) and charges (*P* = 0.0487) than the usual care group. There was no statistically significant difference in all-cause readmissions between groups.
Naylor 2004[40]	Hospitalization (See also Table 5)	Randomized controlled trial	Randomized controlled trial. Outcomes: time to first hospitalization, number of hospitalizations, and costs	Patients age 65 and older from 6 academic and community hospitals, n = 118 intervention and n = 121 control	1. APN transitional care from hospital to home care 2. Routine care (58% received skilled home care services)	First time to readmission was longer for intervention (*P* = .026); intervention group had fewer readmissions at 52 weeks (104 vs. 162, *P* = .047) and lower mean cost ($7,636 vs. $12,481, *P* = .002).
Neff 2003[46]	Hospitalization, acute care, and emergency room visits (See also Table 5)	Nonrandomized controlled trial	Nonrandomized controlled trial. Outcomes: length of stay, hospitalization, emergent care.	Medicare patients age 62 or older, from a large home care agency, with a primary or secondary diagnosis of COPD, n = 39 control and n = 41 intervention	1.Transitional care APN model with pulmonary disease management team 2. Routine home care	Intervention group patients had a shorter length of stay (*P* < .05). Fewer rehospitalizations and acute care visits (*P* < .05) and more remained at home (*P* < .05).

Table 3. Summary of Evidence Related to Unplanned Hospital Admission (continued)

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Rich 1995[43]	Hospitalization (See also Table 5)	Randomized controlled trial	Randomized controlled trial. Outcomes: hospital readmissions and cost.	Patients age 70 and older hospitalized with CHF in a large urban hospital, n = 142 intervention and n = 140 control	1. Intensive multidisciplinary inpatient intervention by specialized geriatric team, discharged with home care and telephone followup by research team member 2. Usual care	Intervention group had greater 90-day survival without readmission (66.9% vs. 54.3% for control; (*P* = .040) and had fewer readmissions for CHF (*P* = .04). Cost of hospital readmissions were higher in control group by an average of $1,058 per patient ($3,236 vs. $2,178, *P* = .03).
Shaughnessy 2002[2]	Hospitalizations (See also Table 5)	Pretest and post-test study	Observational study with control. Outcomes: measures of hospitalizations	2 groups of home care agencies 73 OBQI agencies (263,465 patients) intervention Non-OBQI agencies (248,621 patients) control	1. Clinical and administrative OBQI intervention at demonstration agencies, patient outcome reports for comparison with a reference population 2. Control: usual care	The intervention group had a decline in hospitalizations over a 3 and 4 year period (*P* < .001) with OBQI.

Nurse Work Environment

Evidence from the acute care setting suggests a relationship between nurses' work environment, patient safety, and quality of patient care.[49–51] A positive work environment is one that supports nurse autonomy and control over the work environment, including shared governance or decisionmaking.[52–55] It is an environment with strong and visible nursing leadership, organizational support, peer support, and positive physician collaboration.[53–55]

Research exploring the relationship of the work environment, patient safety, and quality in home health care is in early stages of development. There have been no randomized controlled studies to date. Feldman and colleagues[56] examined the relationship of patient adverse events with characteristics of the nurses' work environment at one very large urban home health care agency. Characteristics of 86 home health care teams within the agency were examined. Researchers reported that adverse events were lower for teams with higher patient volume and visits, fewer weekend admissions, more equitably distributed incentives, and more teamwork. Rates were higher when teams perceived supervisor support for adverse event reporting. This is the first rigorous study to identify organizational factors associated with potential adverse events, and there were limitations. It was a descriptive, correlational study, and the agency involved in the study is not typical of most agencies in the United States as it serves a disproportionately diverse urban population. Several of the findings approached significance only at a probability level (alpha) of 0.10.

Kroposki and Alexander[57] explored the relationships among patient satisfaction, nurse perception of patient outcomes, and organizational structure in a descriptive study. They reported that higher patient satisfaction scores were more likely in home health care agencies where nurses and supervisors had good working relationships, opportunity for shared decisionmaking was present, and formalization of organizational and professional guidelines existed. Limitations of this study included its descriptive, nonrandomized design of multiple agencies from one State and the lack of a reliable and validated tool to measure nurse perception of patient outcomes. Findings are summarized in Table 4.

Evidence-Based Practice Implications

Agencies should consider how characteristics of the work environment may be influencing patient safety and quality outcomes. It is necessary to explore the context of the environment when examining clinicians' practices in an effort to identify necessary system changes.

Research Implications

It is not known what characteristics of the home health care nursing work environment are related to patient safety and quality. Home health care research is needed to investigate the relationship of work environment characteristics, nurse satisfaction, and patient outcomes.

Table 4. Summary of Evidence Related to Nurse Work Environment

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Feldman 2001–2005[56]	Adverse events	Prospective cohort study	Observational study with controls. Outcomes: team-attributable patient adverse events.	51,560 patient care episodes from the largest U.S. home care agency with average age of patient 71 years	86 home care teams Staff perception of work environment, especially aspects of organizational and team culture climate	7% of the 51,560 episodes had an adverse event. Adverse events were lower for teams with higher volume of patient care episodes ($P \leq .05$), higher concentration of visits among staff ($P \leq .10$), fewer weekend admissions ($P \leq .01$), more weekend visits ($P \leq .01$), in noncongregate care setting ($P \leq .10$), and more care provided by nurses without bachelor's or higher education ($P \leq .10$). Adverse events were lower for teams with greater equity in distribution of incentives ($P \leq .10$), more teamwork ($P \leq .10$).
Kroposki and Alexander 2006[57]	Relationship of patient satisfaction, nurse perception of outcomes, and organizational characteristics	Cross-sectional study	Observational study with controls. Outcomes: relationship of nurse perception of outcomes and organizational structure to patient satisfaction.	Convenience sample of 325 patients and 205 nurses from 38 home care agencies in a southeastern State	Evaluation of patient satisfaction, nurse perception of patient outcomes, and organizational structure	Significant correlation between nurses' ability to meet client's psychosocial needs and patient satisfaction ($P < .05$). No other relationships existed between client satisfaction and outcome inventory components. There was a significant positive relationship between organizational attributes and patient satisfaction in agencies with shared decisionmaking and open communication ($P < .05$) and formal rules and procedures ($P < .05$).

Functional Outcomes and Quality of Life

The goal of care provided in the home is to restore or maintain patient physical and mental functioning and quality of life, or to slow the rate of decline to allow the patient to remain at home and avoid institutionalization. Most patients and family members prefer the home environment, when it is feasible. A patient's and family's ability to function independently and safely in the home increases the possibility of the patient remaining there.

Improving patient safety and quality of care by educating and assisting caregivers (families and providers) is an approach tested in several randomized controlled trials. The findings are summarized in Table 5. Archbold and colleagues[58] pilot tested preparedness, enrichment, and predictability (PREP), a formal nursing intervention designed to prepare family caregivers to provide care. While the study had many limitations, preliminary evidence on the effectiveness of the intervention suggests that families benefit from being informed and prepared.

Other researchers have tested interventions to improve nurse providers' knowledge and awareness.[59–61] Intervention studies to educate and inform nurse providers have been conducted in small and large urban and rural home health care settings, with nurses randomly assigned to an intervention group or a control group. The interventions generally provided nurses with additional education, extra resources for patients, and specialized patient information. In one frequently reported study, evidence-based care with specific disease-related information was sent to nurses by "just-in-time" e-mail reminders.[59, 60]

In all cases the interventions improved nurses' performance, which resulted in better patient outcomes. Patients of nurses in these studies showed significant improvement in pain management, quality of life, satisfaction with care, and other variables associated with improved quality of care, including better communication with providers, better medication management, and improved disease symptoms. Nurses' improved performance included increased documentation of critical patient assessments. In the case of "just-in-time" e-mail reminders, the intervention group that had additional clinical and patient resources had better patient outcomes, suggesting that the multifaceted approach or stronger dose of the intervention was more effective.

A number of randomized controlled trials have tested the effectiveness of specific interventions to improve patient safety and quality in disease management,[62, 63] urinary incontinence,[64, 65] level of ADL functioning,[44, 46, 66–68] quality of life, general health outcomes, and patient satisfaction.[44, 46, 59, 62, 66–70] Corbett[63] demonstrated that individualized patient education in foot care for diabetics was effective in improving patients' self-care. Scott and colleagues[62] demonstrated an improvement in quality of life in patients with CHF though a program of patient education and mutual goal setting. Dougherty and colleagues[64] and McDowell and colleagues[65] tested behavioral management interventions to treat urinary incontinence in the elderly and reported positive results based on behavior management interventions of self-monitoring and bladder training. Mann and colleagues[67] tested the introduction of assistive technology (canes, walkers, and bath benches) and changes made to the home environment (adding ramps, lowering cabinets, and removing throw rugs) with populations of frail elderly. These interventions were successful in slowing functional decline in the study patients.

Some of the research evidence suggests more efficient mechanisms for providing care. In exploring the amount of care that is effective, Weaver and colleagues[71] decreased (compared

with usual care) the number of post-hospitalization visits by patients with knee and hip replacements and added one preoperative home visit. No differences in functional ability, quality of life, or level of satisfaction between those patients receiving usual care (more visits) and those receiving the intervention (fewer postoperative visits and one preoperative visit) were found. Several studies have examined the use of technology in patient functioning and independence. Johnston and colleagues[69] tested real-time video nursing visits and found no difference in patient outcomes or level of satisfaction with usual care or care enhanced by video technology.

A number of randomized controlled trials have tested the outcomes of interventions based on the specialty of the provider combined with different models of care management, or interventions based solely on different models of care management.[44, 46, 65, 70, 71] Research examining the effect of APN providers on the quality of patient care suggests they have a positive effect. In two studies testing the transitional care model, APN-directed teams delivered care to patients with COPD[46] and CHF[70] and found improvements in the group in the transitional care model. Patients experienced fewer depressive symptoms and an increase in functional abilities when compared with patients receiving usual care.[46, 70] Patients in these studies also needed fewer nursing visits, had fewer unplanned hospital admissions, and had fewer acute care visits. A nurse practitioner's urinary incontinence behavioral therapy was effective in decreasing the number of patients' urinary incontinence accidents.[65] The Veterans Affairs Team-Managed Home-Based Primary Care was an add-on to care routinely provided in the Veterans Affairs Home-Based Primary Care program.[44] The added component emphasized continuity of care and team management with a primary care manager, 24-hour on-call nursing availability for patients, prior approval of hospital admissions, and team participation in discharge planning. The investigators found significant improvements in quality of life, functioning, pain management, and general health outcomes for terminally ill patients in this study, and an increase in satisfaction for nonterminally ill patients and family caregivers.

However, mixed results have been obtained from the research to date on the effectiveness of models of care management.[66, 68] Some intervention models have been less effective than others. The interventions are usually an add-on to routine care, and their effectiveness has been determined by a comparison to a control group of usual or routine home health care. An intervention model that does not appear to be effective is the Health Outcomes Management and Evaluation model tested by Feldman and colleagues[66] This model adds a consumer-oriented patient self-care guide and training to improve nurses' teaching and support skills. Study results showed no difference in patient quality of life or satisfaction. Tinetti and colleagues[68] compared the outcomes of a systematic, multicomponent rehabilitation program, including therapies for physical and functional impairments, to the outcomes from usual home-based rehabilitation care. No differences were found between the two groups.

Evidence-Based Practice Implications

The preceding discussion suggests that working closely with and supporting family caregivers is, and will continue to be, an important aspect of helping patients to remain in their homes. It also suggests that nurses' effectiveness in working with patients can be enhanced if nurses are supported in their work. Support can be provided by electronic communication, reminders of protocols, disease-specific educational materials for patients, and working with APN colleagues to serve as clinical experts for staff. Home health care nurses are relatively isolated in the field, and any mechanism to improve communication with supervisors in the office and with other providers will assist nurses in their practice. Incorporating the use of

remote technology to substitute for some in-person visits can improve access to home health care staff for patients and caregivers.[69]

Specific patient interventions can be helpful in improving patient health and quality of life. Interventions of individualized education and disease-specific programs, such as a behavioral management program for urinary incontinence or educational programs for foot care, should be incorporated into practice. The rate of a patient's functional decline can be slowed and costs reduced through a systematic approach to providing assistive technology and environmental interventions to frail elderly patients in their homes. A patient's need for these interventions can be determined with a comprehensive assessment and continued monitoring.

Research Implications

Evidence of the outcomes of health care provided in the home is limited; there are very few controlled experiments on which providers can base their practice. Research is limited in the areas of composition, duration, and amount of home health care services needed to ensure patient safety and quality. Research is needed to determine effective interventions to improve, maintain, or slow the decline of functioning in the home health care population.

More research is also needed to determine mechanisms to keep nurses informed and supported. Providing communication and support is a challenge when providers are geographically dispersed and spend most of their time in the field. Remote technology has the potential to reduce costs: it can substitute for some in-person visits, and it can improve access to home health care staff for patients and caregivers.

Table 5. Summary of Evidence Related to Functional Outcomes and Quality of Life

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Archbold 1995[58]	Family preparedness	Quasi-experimental retrospective without a control group	Nonrandom trial. Outcomes: care effectiveness scale, indicating greater preparedness, enrichment, and predictability.	Caregiver families referred to home care agency: n = 11 intervention and n = 11 standard home care	1. Nursing interventions, designed to increase preparedness (PR), enrichment (E), and predictability (P) in families providing care to older people. 2. Comparison	Intervention (PREP) group one standard deviation higher than the control group (*P* < .05), rated their assistance from PREP nurses significantly higher (*P* < .01); had lower mean hospital costs ($2,775) versus comparison group ($6,929).
Corbett 2003[63]	Diabetic foot care	Randomized controlled trial, pre/post-test	Randomized controlled trial pre/post test. Outcomes: patient self-report knowledge.	40 home care patients with diabetes from 1 home care agency, 2 groups	1. Intervention: individualized education about proper foot care 2. Control	The educational intervention improved patient's knowledge, confidence, and reported foot care behaviors.
Dougherty 2002[64]	Urinary incontinence	Randomized controlled trial	Randomized controlled trial Outcomes: severity and episodes of urine loss—frequency, interval, and quality of life.	218 older women from 7 rural counties in north Florida	1.Behavior management program—self-monitoring and bladder training 2. Control	Intervention group incontinence severity decreased by 61%. Control group incontinence severity increased by 184%.

Table 5. Summary of Evidence Related to Functional Outcomes and Quality of Life (continued)

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Feldman 2004[66]	Quality of life and patient satisfaction with care	Randomized controlled trial	Random assignment of nurses. Outcomes: service use and quality of life, satisfaction with care.	371 patients with CHF and 205 nurses from a large, urban, nonprofit home care agency	1. Formal nurse protocol of "Health Outcomes Management & Evaluation," patient self-care guide, and nurse training in teaching and support skills 2. Usual care	No difference in physician visit, patient mortality, quality of life, or patient satisfaction.
Feldman 2005[60]	Functional status, quality of life, and service use (see also Table 3)	Randomized controlled trial	Randomized controlled trial Outcome: clinical, functional, and quality of life status.	1,242 patients from a large, urban, nonprofit home care agency: 390 basic 404 augmented 448 control	1. Nurse e-mails highlighting clinical recom-mendations 2 Augmented: e-mails and additional clinician and patient resources 3. Usual care	Both intervention groups demonstrated improved patient clinical and functional outcomes (symptoms, physical limitations, quality of life, and social limitations) ($P \leq .05$). Both intervention groups demonstrated better management of medications ($P \leq .05$) Intervention group 1 scored higher on quality of life relative to control ($P \leq .05$).

Table 5. Summary of Evidence Related to Functional Outcomes and Quality of Life (continued)

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Hughes 2000[45]	Functional ability, quality of life, patient satisfaction, and cost (see also Table 3)	Randomized controlled trial	Randomized controlled trial. Patient functional status, patient and caregiver HR-QoL and satisfaction, caregiver burden, hospital readmissions, and costs over 12 months.	1,966 patients average age of 70 with 2 or more ADL impairments or terminally ill, CHF or COPD 981intervention 985 control	1. Home-Based Primary Care: with team manager, 24-hour contact, prior approval readmissions, and team discharge planning 2. Home-Based Primary Care VA and private sector care	Significant improvements were seen in terminal intervention group (TM/HBPC) patients in HR-QoL scales of emotional role function, social function, bodily pain, mental health, vitality, and general health. TM/HBPC nonterminal patients had significant increases of 5 to 10 points in 5 of 6 satisfaction-with-care scales. The caregivers of terminal patients in the TM/HBPC group improved significantly in HR-QoL measures. Caregivers of nonterminal patients improved significantly in QoL measures and reported reduced caregiver burden (*P* = .008).
Johnston 2000[69]	Quality of patient care and cost	Quasi-experimental study with random assignment	Randomized controlled trial. Outcomes: medication compliance, knowledge of disease, self-care ability, service use, patient satisfaction, and costs.	212 patients with CHF, COPD, cerebral vascular accident, cancer, diabetes, anxiety, or need for wound care	1. Routine care and video visits, nurses and patients interact in real time, included equipment for assessing cardiopulmonary status 2. Routine care	No differences in the intervention or control groups in quality indicators, patient satisfaction, or use. No health care cost savings realized.

Table 5. Summary of Evidence Related to Functional Outcomes and Quality of Life (continued)

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Mann 1999[67]	Functional ability (independence), quality of life (pain reduction), and costs	Randomized controlled trial	Randomized controlled trial. Functioning and pain, measured with valid and reliable instruments; health care costs.	Frail elderly persons referred from community agencies, hospitals, and home care agencies in New York State: n = 52 intervention, n = 52 control	1.Usual care, assistive technology, (canes, walkers, etc.), and environmental interventions (ramps, removal of rugs, etc.) 2. Usual care control	Both groups showed significant decline in functional motor score, with a significantly greater decline for the control group. Pain scores were significantly higher for the control group. Treatment group expended more costs than the control group. Control group had significantly more expenditures for institutional care and significantly greater expenditures for nurse visits and case manager visits.
McDonald 2005[59]	Quality of life (pain management) through provider behavior change	Randomized controlled trial	Randomized controlled trial. Outcome measure: Estimate of treatment effect on nurse-documented care practices and patient's pain management.	Nurses, from a large, urban, nonprofit home care agency: n = 121 basic, n = 97 augmented, and n = 118 control	1. Basic group – nurse e-mails highlighting clinical recom-mendations 2 Augmented group – additional clinician and patient resources 3. Usual care	Patients in augmented intervention improved significantly over the control in ratings of pain intensity at its worse (P = 0.05). Patients in basic intervention had better ratings of pain intensity on average (P < 0.05). In both intervention groups, evidence of nurse assessment increased.

Table 5. Summary of Evidence Related to Functional Outcomes and Quality of Life (continued)

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
McDowell 1999[65]	Functional ability (urinary continence)	Prospective, randomized controlled clinical trial with cross-over design	Randomized controlled trial, observational study with controls. Outcomes: bladder diaries, urinary accidents	Home health care patients ages 60 and older with urinary incontinence: n = 53 intervention, n = 52 control	1. Nurse practitioner delivered behavioral therapy of biofeedback-assisted pelvic floor muscle training, urge and stress strategies, and bladder retraining 2. Control	Intervention group had a significantly greater reeducation in urinary accidents per day ($P < .001$). Average number of accidents decreased from 4.0 to 1.7 after treatment ($P < .001$).
Naylor 2004[40]	Mortality, quality of life, and satisfaction	Randomized controlled trial	Randomized controlled clinical trial. Outcomes: patient report, physical and emotional quality of life, functional status, and satisfaction.	Patients 65 years of age or older with CHF discharged from Philadelphia academic and community hospitals: n = 118 intervention, n = 121 control	1.Transitional care intervention – 3-month APN-directed discharge plan and home care followup 2. routine care (1/2 home care)	Intervention had improvement in quality of life ($P < .05$), in functioning ($P < .05$), and in satisfaction ($P < .001$) vs. control group.
Neff 2003[46]	Quality of patient outcomes	Non-randomized trial controlled	Nonrandomized controlled trial. Outcomes: ADLs, IADLs, dyspnea, anxiety, and depression	Medicare patients from a large home care agency: n = 41 urban control group n = 39 rural	1.Transitional Care Model: APN pulmonary disease management team 2. Routine home care	Intervention group experienced fewer depressive feelings ($P < .05$) and better ADL status ($P < .05$). There were no differences in IADLs or dyspnea in the groups.
Scott 2004[62]	Quality of life and mental health	Randomized controlled trial	Randomized controlled trial. Outcomes: Mental Health Inventory and Quality of Life Index.	88 patients with heart failure from 2 nonprofit home care agencies in the Midwest	All got routine care and 1.Mutual goal setting, 2. Supportive educative 3. Placebo	Mutual goal setting group had significantly higher mental health scores ($P = .003$) at 6 months. Mutual goal setting and supportive education groups had significantly higher quality of life ($P = .01$) at 6 months.

Table 5. Summary of Evidence Related to Functional Outcomes and Quality of Life (continued)

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Tinetti 1999[68]	Functional status – self-care ADLs	Randomized controlled trial	Randomized controlled trial. Outcomes: a battery of self-report and performance-based measures of physical and social function.	304 persons age 65 who had undergone surgical repair of a hip fracture at two hospitals in New Haven, CT, from 27 home care agencies	1. Systematic multicomponent rehabilitation strategy addressing both modifiable physical impairments (physical therapy) and ADL disabilities (functional therapy) 2. Usual care	There was no significant difference in the proportion of participants in the two groups who recovered to prefracture levels in self-care ADL at 6 months (71% vs. 75%) or 12 months (74% in both groups), or in home management ADL at 6 months (35% vs. 44%) or 12 months (44% vs. 48%). There also was no difference between the two groups in social activity levels, two timed mobility tasks, balance, or lower extremity strength at either 6 or 12 months. Compared with participants who received usual care, those in the multicomponent rehabilitation program showed slightly greater upper extremity strength at 6 months (P = .04) and a marginally better gait performance (P = .08).
Vallerand 2004[61]	Quality of life (pain management)	Longitudinal, multilevel, randomized controlled trial	Randomized controlled trial. Outcomes: nurse knowledge and attitudes of pain management, patient's self-reported pain level.	Home care nurses: n = 100 intervention, n = 102 control, from 11 home care agencies in Midwest United States 5 intervention 6 control	1. Nurse education program – Power over Pain (POP) 2. Control	Patients of nurses' intervention group self-report worst pain scores decreased significantly (P < 0.04). Nurses' intervention group had significantly improved knowledge, attitudes, and perception of control over pain (P < 0.05).

Table 5. Summary of Evidence Related to Functional Outcomes and Quality of Life (continued)

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Weaver 2003[71]	Functional status and quality of life	Randomized controlled trial	Randomized controlled trial. Outcomes: functional status, lower extremity functioning, health-related quality of life, satisfaction, use, and cost.	136 patients with surgical hip or knee replacements from a hospital home care agency.	1. Pre-op visit by nurse and physical therapist, 9 to 12 post-op home visits 2. Usual protocol with more visits (11 to 47)	There was no difference in functioning, quality of life, or satisfaction. Intervention group costs were 55% lower than control (due to fewer visits).

Wound and Pressure Ulcer Management

Adverse wound events are monitored under the OBQM program. Emergent care for wound infections, deteriorating wound status, and increase in the number of pressure ulcers are monitored and reported as adverse events.[70] The data are used to reflect a change in a patient's health status at two or more times, usually between home health care admission and transfer to a hospital or other health care setting. Data for these outcomes are collected using OASIS-designated intervals. Patient outcome measures related to surgical wounds that are monitored under the OBQI include improvement in the number of surgical wounds and improvement in the status of surgical wounds.[18]

Wound Management

Over a third of home health care patients require treatment for wounds, and nearly 42 percent of those with wounds have multiple wounds. Over 60 percent of wounds seen in home health care are surgical, while just under one-quarter are vascular leg ulcers and another one-quarter are pressure ulcers.[71] Most home health care nurses can accurately identify wound bed and periwound characteristics; the majority (88 percent) of wound treatments have been found to be appropriate.[72] The appropriateness of wound treatments in home health care is significantly related to wound healing. Patients with healing wounds had shorter home health care visits and shorter home health care lengths of stay.[71]

A literature review identified seven studies that tested interventions to improve wound care management in home health care.[73–79] Findings are summarized in Table 6. Three compared effectiveness of various wound treatments. Capasso and Munro[74] found no significant difference in wound closure between amorphous hydrogel dressings and wet-to-dry saline dressings, but costs were found to be significantly higher for the saline dressings due to the need for more nursing visits. Kerstein and Gahtan[76] found the percentage of venous leg ulcers healed using hydrocolloidal dressings was six times higher than with saline gauze dressings and nearly four times greater using an Unna boot; the hydrocolloidal dressings were most cost-effective. Use of negative pressure wound therapy resulted in successful closure of 43 percent of wounds that failed to respond to previous treatment.[78]

Four studies reported positive outcomes from interventions to improve and support home health care nurse practice.[73, 75, 77, 79] Use of telemedicine to provide consultation with wound management experts resulted in improved healing rates, decreased healing time, and decreased home visits and hospitalizations related to wounds.[73, 77] Fellows and Crestodina[75] studied the rate of bacterial contamination of normal saline solutions prepared from distilled water and table salt, a practice common for wound care in the home, and found refrigerated solutions essentially growth-free at 4 weeks. A quality improvement project reported a reduction in adverse events through structured nurse education, introduction of protocols, and competency review.[79]

Pressure Ulcer Management

Rodriques and Megie[80] found that 37 percent of wounds in home health care patients were pressure ulcers, with a mean wound duration of nearly 27 months. Nearly 1 in 10 patients admitted to home health care had pressure ulcers and approximately one-third were at risk of developing new ulcers; yet according to one study, only 27 percent of patients with existing

ulcers and 14 percent of those at risk were receiving appropriate pressure-reducing treatment.[81] Incontinence, limitations in ADLs, mobility impairment, skin drainage, recent fractures, anemia, use of oxygen, and recent institutional discharge were associated with pressure ulcer development.[81, 82] Guidelines from the Wound, Ostomy and Continence Nurses Society[83] call for an initial risk assessment for pressure ulcers of all patients on admission to home health care, and reassessment every visit thereafter, using a validated risk assessment tool. However, one study found that only 21 percent of agencies used a validated tool such as the Braden Scale[84] to identify patients at risk, nearly 8 percent performed no assessments on admission, and only 33 percent used risk prediction or pressure ulcer prevention protocols.[85] Just over half of agencies reported routine skin inspections by nurses of at-risk patients.

A literature review resulted in identification of five studies relating to pressure ulcer management in home health care. The findings are summarized in Table 7. Three studies were randomized controlled trials testing interventions to improve pressure ulcer healing.[86–88] One intervention tested the use of air-fluidized bed therapy with services of a nurse specialist;[87] a second intervention used noncontact normothermic wound therapy.[88] Both resulted in significant improvement in wound healing compared to conventional moist dressings. Overall healing rates were similar for polymer hydrogel and hydrocolloidal dressings, although debridement performance of the hydrogel dressing resulted in more favorable clinical evaluation.[86]

The remaining two studies evaluated the use of the Braden Scale for prediction of pressure ulcer risk in home health care patients, with mixed results. Ramundo[89] reported that the Braden Scale had validity in identifying at-risk patients, but limited predictive ability, while Bergquist[82] found that the summative score of the scale was significantly associated with pressure ulcer development. All subscale scores except nutrition were significantly and negatively associated with pressure ulcer development.

Evidence-Based Practice Implications

When compared with wet-to-dry or moist saline dressings, most wound treatments tested showed greater effectiveness or lower cost. Home health care nurses should be knowledgeable in the use of the full range of existing and emerging wound products, practices, and treatments and demonstrate skill in accurate wound assessment and staging. Provision of structured resources, expert consultation, and competency testing for home health care nurses can improve home health care wound management. Nurses must be knowledgeable in risk factors for pressure ulcer development and relevant preventive measures; they must assess every patient using a valid and reliable instrument, such as the Braden Scale, on admission to home health care and regularly thereafter.

Research Implications

Relatively little is known about the most effective practices for wound care in the home health care setting. Although studies have compared different treatments for wounds, the most efficacious treatments for different wounds are unknown in the presence of various risk factors found in the home health care setting. Randomized controlled clinical trials exist comparing different pressure ulcer treatments in the home, with the exception of care of other types of wounds. Promising findings from studies with small sample sizes should be replicated with larger samples and diverse populations.

Table 6. Summary of Evidence Related to Wound Management

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Capasso and Munro 2003[74]	Wound management, treatment, and cost	Retrospective cohort study	Observational study with control (Level 4) Outcomes: wound size, predominant tissue type, type of exudates; cost of treatment.	Patients 25 years of age or more with superficial wounds without undermined areas: 1. Arterial surgical wound dehiscence or 2. Nonhealing arterial or diabetic ulcerations In 3 home care agencies, n = 25 intervention, n = 25 control	1. Amorphous hydrogel dressings 2. Control wet-to-dry normal saline gauze dressings	No significant difference found in the rate of wound closure between the two types of dressings (*P* = .66). Costs were significantly higher (*P*= .006) for control ($3,774) than for the intervention dressings ($2,634) due to significantly higher numbers of required nursing visits (*P* = .003). There was no significant difference in the cost of wound care supplies.
Fellows and Crestodina 2006[75]	Wound management, treatment, and cost	Nonrandomized trial	Nonrandomized trial. Outcomes: bacterial growth on agar-agar plate (Level 2)	7 1-gallon jugs of normal saline prepared from distilled water with 8 tsp of table salt added	Saline solutions were tested for bacterial growth at 1-week intervals for 4 weeks or until growth appeared. 1. Researcher prepared, nonrefrigerated (2) 2. Researcher prepared, refrigerated (2) 3. Patient prepared, refrigerated (3)	Researcher-prepared, nonrefrigerated saline preparations showed bacterial growth in 2 weeks compared to refrigerated solutions, which remained bacteria-free at 4 weeks. Two patient-prepared, refrigerated solutions remained bacteria-free at 4 weeks, while the third showed trace growth.

Table 6. Summary of Evidence Related to Wound Management (continued)

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Kerstein and Gahtan 2000[76]	Wound management, treatment, and cost	Nonrandomized controlled trial	Nonrandomized trial. Outcomes: complete wound healing, recurrence, and cost of treatment.	81 patients with venous ulcers, 47 in a home care agency and 34 seen in a physician's office n = 32 intervention (group 1) n = 33 intervention (group 2) n = 16 intervention (group 3)	1. Hydrocolloidal dressing and compression hosiery 2. Unna's boot 3. Saline gauze dressing and compression hosiery	13% of ulcers in the first intervention group did not heal or recur, compared to 21% of ulcers in the second intervention group and 88% percent in the third group. Hydrocolloid dressings were more cost effective than Unna's boot or saline-gauze dressings. No difference was found between home care or physician's office outcomes. Patients preferred home care, but costs were higher.
Kobza and Scheurich 2000[77]	Wound management, provider support	Nonrandomized controlled trial	Nonrandomized controlled trial. Outcomes: healing rates, average weeks to healing, average visits per wound patient, condition on discharge from home health.	76 patients ages 28 to 94 with Stage III or IV pressure ulcer, diabetic foot ulcer, venous stasis ulcer, or with orders for twice-daily dressing change (191 wounds), urban and suburban hospital-based home care agencies	Two-way in-home video visit via telemedicine for wound specialist with home health nurse present to evaluate wound and recommend treatment Baseline retrospective patient sample per agency	Intervention resulted in improved healing rates for all wounds except Stage III pressure ulcers; decreased average healing time for all wound categories; 58% discharges with wounds healed/ healing compared to baseline control of 37%; decreased average number of home health visits to 33 from 60 per patient; and a decreased number of hospitalizations related to wound complications of 6% with intervention from 18% at baseline.

Table 6. Summary of Evidence Related to Wound Management (continued)

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Philbeck 1999[78]	Wound management, treatment	Nonrandomized controlled trial	Nonrandomized controlled trial. Outcomes: reduction in wound area over time, wound volume, and healing rate; cost of treatment	1,032 Medicare home care patients with 1,170 wounds failing to respond to previous intervention; 989 wounds over 30 days old, 566 were Stage III or IV pressure ulcers	Negative pressure wound therapy	498 (43%) of wounds resulted in successful closure with intervention; 145 (12%) showed no improvement. Intervention averaged 57 days and resulted in average reduction of wound area and volume.
Sturkey 2005[79]	Wound management, provider support	Quality improvement project	Observational study comparing pre- and postintervention. Outcomes: OASIS Adverse Event Outcome Reports "Emergent Care for Wound Infection/ Deteriorating Wound Status"; number of visits required for wound care; State survey and JCAHO/Medicare survey observed breaches in infection-control practices.	One home care agency, Georgia	Educational program including best practice video and skills laboratory; education on wound care staging, healing and appropriate protocols; observation of actual practice in home using competency skills checklist; certification in negative wound pressure therapy	Adverse Event Outcome Reports, Emergent Care for Wound Infection/ Deteriorating Wound Status improved from 1.83% to 1.09%, compared to a national average of 1.27%; decreased average visits for wound patients by 30%; achieved no breaches observed during State or JCAHO survey visits.

Table 7. Summary of Evidence Related to Pressure Ulcer Management

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Berquist 2001[82]	Pressure ulcer management, prediction	Retrospective cohort study.	Retrospective cohort study without controls. Outcome measure: development of Stage I to IV pressure ulcers or no ulcer development.	1,684 patients age 60 years or older without pressure ulcers on admission, with documented Braden Scale scores, one large Midwestern urban home care agency	None	Braden Scale summative scores were significantly lower for subjects who developed pressure ulcers than subjects remaining free of pressure ulcers ($P <$ .01). All subscale scores except nutrition were significantly and negatively associated with pressure ulcer development ($P <$ .01), but only the summative score remained significantly associated on completion of a backward stepwise procedure ($P <$ .001).
Motta 1999[86]	Pressure ulcer management, treatment	Randomized controlled trial	Randomized controlled trial. Outcomes: healing rate, debridement using Bates-Jensen Pressure Sore Status Tool	Home care patients with Stage II or III pressure ulcer, in home care setting: n = 5 intervention (group 1), n = 5 intervention (group 2)	1. Polymer hydrogel dressing 2. Hydrocolloidal dressing	The overall healing rate for the two groups was similar. Intervention 1 had more favorable overall clinical evaluation based largely on its autolytic debridement effect.
Ramundo 1995[89]	Pressure ulcer management, prediction	Prospective cohort study	Observational study with control. Outcomes: Braden Scale scores, development of pressure ulcers	48 newly admitted patients free of skin breakdown who were unable to leave bed or chair, one suburban, community-based home health care agency	None	7 patients (17%) developed pressure ulcers; Braden Scale scores ranged from 11 to 22. At a score of 18, sensitivity of the tool was 100%; however, specificity was only 34%, indicating that the scale has validity in identifying patients at risk, but has limited predictive ability in home health care.

Table 7. Summary of Evidence Related to Pressure Ulcer Management (continued)

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design & Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Strauss 1991[87]	Pressure ulcer management, treatment	Randomized controlled trial	Randomized controlled trial. Outcomes: wound status, inpatient hospital days, inpatient hospital charges, Medicare DRG, and physician payments.	Patients with Stage III or IV pressure ulcers and severely limited mobility, in home care setting: n = 47 intervention, n = 50 control	36 weeks of treatment, either 1. Air-fluidized bed therapy with services of a visiting nurse specialist, or 2. Control – conventional therapies	A higher proportion of intervention patients were classified as improved without statistical significance. Intervention patients spent significantly fewer days in the hospital (11.4 vs. 25.5 days, $P < .01$) and used significantly fewer total inpatient resources ($P < .05$). Total inpatient and outpatient resource utilization was lower, but not significant.
Whitney 2001[88]	Pressure ulcer management, treatment	Randomized controlled trial	Randomized controlled trial. Outcomes: wound healing and periwound temperature changes, measured using valid, reliable instruments.	Patients, age 18 or older with Stage III or IV pressure ulcers in primary care, home care, acute care, or long-term care facilities: n = 15 intervention, n = 14 control	1. Noncontact normothermic wound therapy 2. Control – moist dressings	The intervention group healed significantly faster (P =.01), and average periwound temperature increased significantly (P = .001).

Conclusion

Home health care clinicians seek to provide high quality, safe care in ways that honor patient autonomy and accommodate the individual characteristics of each patient's home and family. Falls, declining functional abilities, pressure ulcers and nonhealing wounds, and adverse events related to medication administration all have the potential to result in unplanned hospital admissions. Such hospitalizations undermine the achievement of important home health care goals: keeping patients at home and promoting optimal well-being. Nevertheless, the unique characteristics of home health care may make it difficult to use—or necessary to alter—interventions that have been shown to be effective in other settings. Therefore, research on effective practices, conducted in home health care settings, is necessary to support excellent and evidence-based care.

In reviewing the extant studies, the authors of this chapter found useful evidence in all selected areas. However, the number of studies was few and many questions remain. Replications of investigations originally conducted in health care settings other than the home, and studies considering home health care-specific issues are needed to support evidence-based clinical decisions. The available evidence suggests that the work environment in which home health care nurses practice may indirectly influence patient outcomes in many areas, and that technology can be used to support positive patient outcomes. Thus, studies that link nurse-related variables to improved care safety and quality are needed, as well as studies that focus directly on patients. The demographics of an aging society will sustain the trend toward home-based care. Home health care practices grounded in careful research will sustain the patients and the clinicians who serve them. Given the focused review of evidence-based studies comprising this chapter, many informative sources of use to the practicing home health care nurse are omitted. Table 8 lists additional key resources.

Search Strategy

The literature review for this chapter focused on identifying evidence-based practices that supported the goals of home health care: to promote independent functioning; to remain at home, avoiding hospital or nursing home admission; and to achieve optimal well-being. The search was conducted using multiple variations of key terms informed by the characteristics of home health care described at the beginning of this chapter, adverse events used in the OBQM,[5] goals of the Home Health Quality Improvement National Campaign 2007,[14] and the nurse-sensitive quality indicators developed by the American Nurses Association.[15] The Cumulative Index to Nursing & Allied Health, Cochrane Library, Medline, and ProQuest Nursing & Allied Health databases were searched, as well as the grey literature and government Web sites, including the CMS and Agency for Healthcare Research and Quality. Hand searches were conducted of the reference lists of retrieved articles. Search limitations were English language, United States or Canada, peer-reviewed journals or scholarly literature, published between 1990 and the first quarter of 2007. Studies cited in the evidence table were accepted for review using the following inclusion criteria:

- The study was published between 1990 and the first quarter of 2007, inclusive.
- The research was conducted in the United States or Canada.
- The study included an intervention that directly or indirectly influenced a patient outcome.
- The intervention took place under the auspices of a home health care agency.
- Subjects in the study had to be home health care patients (not community-residing or outpatient ambulatory) and 18 years of age or greater.

Chapter 14. Supporting Family Caregivers in Providing Care

Susan C. Reinhard, Barbara Given, Nirvana Huhtala Petlick, Ann Bemis

Background

Most patients have families that are providing some level of care and support. In the case of older adults and people with chronic disabilities of all ages, this "informal care" can be substantial in scope, intensity, and duration. Family caregiving raises safety issues in two ways that should concern nurses in all settings. First, caregivers are sometimes referred to as "secondary patients," who need and deserve protection and guidance. Research supporting this caregiver-as-client perspective focuses on ways to protect family caregivers' health and safety, because their caregiving demands place them at high risk for injury and adverse events. Second, family caregivers are unpaid providers who often need help to learn how to become competent, safe volunteer workers who can better protect their family members (i.e., the care recipients) from harm.

This chapter summarizes patient safety and quality evidence from both of these perspectives. The focus is on the adult caregiver who provides care and support primarily for adults with chronic illnesses and chronic health problems. The focus is not on those with developmental disabilities. In the first section, we discuss the evidence for protecting the caregiver from harm. The second section addresses research aimed at protecting the care recipient from an ill-prepared family caregiver.

Caregivers as Clients

For centuries, family members have provided care and support to each other during times of illness. What makes a family member a "family caregiver"? Who are these family caregivers, what do they do, and what harm do they face? What does the research tell us about ways to assess the needs of these hidden patients and evidence-based interventions to prevent or reduce potential injury and harm? This section answers these questions and highlights the need for nurses to proactively approach family caregivers as clients who need their support in their own right.

Description of Caregiver Population

The terms *family caregiver* and *informal caregiver* refer to an unpaid family member, friend, or neighbor who provides care to an individual who has an acute or chronic condition and needs assistance to manage a variety of tasks, from bathing, dressing, and taking medications to tube feeding and ventilator care. Recent surveys estimate there are 44 million caregivers over the age of 18 years (approximately one in every five adults).[1] The economic value of their unpaid work has been estimated at $257 billion in 2000 dollars.[2] Most caregivers are women who handle time-consuming and difficult tasks like personal care.[3] But at least 40 percent of caregivers are men,[3] a growing trend demonstrated by a 50 percent increase in male caregivers between 1984

and 1994.[4] These male caregivers are becoming more involved in complex tasks like managing finances and arranging care, as well as direct assistance with more personal care.[5] Nurses are likely to see many of these caregivers, although many of them will not identify themselves as a caregiver.

Those caring for someone 50 years or older are 47 years old—on average—and working at least part-time.[1] If they are providing care to an elder who is 65 years or older, they are, on average, 63 years old themselves and caring for a spouse; one-third of these caregivers are in fair to poor health themselves.[6] In many cases, they are alone in this work. About two out of three older care recipients get help from only one unpaid caregiver.[7] In the last decade, the proportion of older persons with disabilities who rely solely on family care has increased dramatically—nearly two-thirds of older adults who need help get no help from formal sources.[4]

Caregiver Responsibilities

Caregivers spend a substantial amount of time interacting with their care recipients, while providing care in a wide range of activities. Nurses have a limited view of this interaction. Caregiving can last for a short period of postacute care, especially after a hospitalization, to more than 40 years of ongoing care for a person with chronic care needs. On average, informal caregivers devote 4.3 years to this work.[8] Four out of 10 caregivers spend 5 or more years providing support, and 2 out of 10 have spent a decade or more of their lives caring for their family member.[9] This is a day-in, day-out responsibility. More than half of family caregivers provide 8 hours of care or more every week, and one in five provides more than 40 hours per week.[1]

Most researchers in the caregiving field conceptualize the care that family members give as assistance with activities of daily living (ADLs) and instrumental activities of daily living (IADLs). But those concepts do not adequately capture the complexity and stressfulness of caregiving.[9] Assistance with bathing does not capture bathing a person who is resisting a bath.[10, 11] Helping with medications does not adequately capture the hassles of medication administration,[12] especially when the care recipient is receiving multiple medications several times a day, including injections, inhalers, eye drops, and crushed tablets. The need to make decisions on behalf of family members who are unable to do so is stressful, as this is contrary to the caregivers' normal role, and they are concerned that the decisions are correct. Supervising people with dementia and observing for early signs of problems, such as medication side effects, are serious responsibilities as family members are often unable to interpret the meaning or the urgency. The medical technology that is now part of home care and the frustrations of navigating the health care system for help of any kind is not even part of the ADL/IADL measures.[13] Being responsible for medical and nursing procedures like managing urinary catheters, skin care around a central line, gastrostomy tube feedings, and ventilators is anxiety provoking for the novice nursing student, but is becoming routine family care of persons with chronic illnesses living at home.

Family caregivers often feel unprepared to provide care, have inadequate knowledge to deliver proper care, and receive little guidance from the formal health care providers.[14-16] Nurses and family caregivers rarely agree about specific needs or problems during hospital admission or discharge,[17] in part because nurses are often unaware of the strengths and weaknesses of both the patient and caregiver. Due to inadequate knowledge and skill, family caregivers may be unfamiliar with the type of care they must provide or the amount of care needed. Family caregivers may not know when they need community resources, and then may not know how to

access and best utilize available resources.[18] As a result, caregivers often neglect their own health care needs in order to assist their family member, causing deterioration in the caregiver's health and well-being.[19-21]

Caregivers get very little help from health care professionals in managing their tasks and the emotional demands of caregiving. Among the greatest challenges for family caregivers is interacting with nurses and other professionals in the hospital setting, and a rough crossing back home, as the patient is "discharged to family."[22] Naylor's review[23] of nearly 100 studies published between 1985 and 2001 confirms that breakdowns in care during the transition from hospital to home result in negative outcomes. Health professionals in emergency departments and inpatient hospital settings do not adequately determine the after-care needs of older patients when they are being discharged.

Effective discharge planning is impeded by gaps in communication between the hospital and community interface, such as illegible discharge summaries and delays in sending information to the physician.[24] Focus groups of caregivers found that they experience their family member's discharge from the hospital as an abrupt and upsetting event because the hospital staff did not prepare them for the technical and emotional challenges ahead of them. Many caregivers felt abandoned at a critical time, and none of the focus group participants had been referred by any health care professional in the hospital to community-based organizations for emotional support—or any other kind of support.[22]

Hazards of Caregiving

Health professionals' lack of explicit attention to caregivers is a serious gap in health care in light of the more than two decades of research that documents the potential hazards of family caregiving. Caregivers are hidden patients themselves, with serious adverse physical and mental health consequences from their physically and emotionally demanding work as caregivers and reduced attention to their own health and health care.

Declines in physical health and premature death among caregivers in general have been reported.[21, 25] Given and colleagues[18, 19] and Kurtz and colleagues[26] found that family caregivers experience significant negative physical consequences as the patient's illness progresses. Elderly spouses who experience stressful caregiving demands have a 63 percent higher mortality rate than their noncaregiver age-peers.[21] Most recently, research documents that elderly husbands and wives caring for spouses who have been hospitalized for serious illnesses face an increased risk of dying prematurely themselves.[27]

Declines in caregiver health have been particularly associated with caregivers who perceive themselves as burdened.[21] Caregiver burden and strain have been related to the caregiver's own poor health status, increased health-risk behaviors (such as smoking), and higher use of prescription drugs.[28] Researchers have reported that caregivers are at risk for fatigue and sleep disturbances,[29] lower immune functioning,[30, 31] altered response to influenza shots,[32] slower wound healing,[33] increased insulin levels and blood pressure,[34, 35] altered lipid profiles,[36] and higher risks for cardiovascular disease.[37]

Burton and colleagues[38] examined the relationships between provision of care by family members and their health behaviors and health maintenance. These researchers found that, with a high level of caregiving activities, the odds of the caregiver not getting rest, not having time to exercise, and actually not recuperating from illness were also high. In addition, caregivers were more likely to forget to take their prescriptions for their own chronic illnesses. Providing care poses a threat to the overall health of caregivers, which can compromise their ability to continue

to be caregivers. If caregivers are to continue to be able to provide care, relief from the distress and demands of maintaining the required care must be considered.

Both highly negative and highly positive consequences of providing care may exist simultaneously.[39] It is plausible that positive consequences, such as rewards and satisfaction, may buffer the negative effects of caregiving. Positive aspects of caregiving are important,[40-42] some researchers are now using a caregiver rewards scale to better understand caregivers' experiences.[41, 42] Other researchers are exploring the positive aspects of care as the mutuality between the patient and caregiver develops.[40] Archbold and colleagues[40] demonstrated that mutuality and preparedness did reduce some of the strain on the caregiver. Picot and colleagues[41, 42] worked primarily with African American caregivers and found that the rewards perceived by caregivers were more important than coping. A specific Picot Caregiver Reward Scale of 25 items exists and has been widely used to show that both rewards and costs can exist in the same care situation.

Caregivers who attempt to balance caregiving with their other activities, such as work, family, and leisure, may find it difficult to focus on the positive aspects of caregiving and often experience more negative reactions, such as an increased sense of burden.[43-45] Regardless of amount of care provided, caregivers may become increasingly more distressed if they are unable to participate in valued activities and interests.[46] More than half of adult children who provide parent care are employed.[7] Caregiving responsibilities can have a negative effect on work roles as caregivers adapt employment obligations to manage and meet care demands.[47, 48] Caregivers who are employed report missed days, interruptions at work, leaves of absence, and reduced productivity because of their caregiving obligations. They have difficulty maintaining work roles while assisting family members.[46] On the other hand, employment provides some caregivers respite from ongoing care activities and serves as a buffer to distress.[49-51]

Low personal and household incomes and limited financial resources can result in increased caregiver risk for negative outcomes, particularly if there are substantial out-of-pocket costs for care recipient needs.[45] Caregivers who are unemployed or have low incomes may experience more distress because they may have fewer resources to meet care demands. Overall, financial concerns cause particular distress for caregivers during long treatment periods,[52, 53] as resources become depleted. Higher-income families, with greater financial resources to purchase needed care, might not become as distressed or burdened as those with limited resources.[54]

Caregiver burden and depressive symptoms are the most common negative outcomes of providing care for the elderly and chronically ill.[20, 55, 56] Caregiver burden is defined as the negative reaction to the impact of providing care on the caregiver's social, occupational, and personal roles[57] and appears to be a precursor to depressive symptoms.[58] Whether the caregiver develops negative outcomes seems to be directly related to the care recipient's inability to perform ADLs, either due to physical limitations or cognitive status.[51] If the care recipient wanders (associated with Alzheimer's disease) or displays unsafe behavior, the caregiver has to be alert and on call for supervision 24 hours per day. The constant concern for managing disruptive behaviors (such as turning on stoves, walking into the street, taking too many pills, yelling, screaming, or cursing) also affects the caregivers negatively.

Care recipients' functional, cognitive, and emotional status predicts caregiver burden and depression,[58-62] which may be manifested in feelings of loneliness and isolation, fearfulness, and being easily bothered, as the demands of caregiving limit their personal time.[58] Care recipient behavior such as screaming, yelling, swearing, and threatening are associated with increased

caregiver clinical depression.[63] Caregiver depression may also have a somatic component, such as anorexia, fatigue, exhaustion, and insomnia.[64]

Caregivers may suffer severe fluctuations in sleep patterns over time, which may affect depression[65] and exacerbate symptoms of chronic illnesses. Pain management is an intractable problem for caregivers that results in substantial caregiver distress, as caregivers assist with both nonpharmacologic and pharmacologic pain-management strategies.[66-68]

Research Evidence: Interventions for Caregivers as Clients

The literature provides substantial evidence that caregivers are hidden patients in need of protection from physical and emotional harm. Interventions directed to the family caregiver should serve two purposes (see Evidence Table). First, interventions can support the caregiver as client, directly reducing caregiver distress and the overall impact on their health and well-being. In this intervention approach, the caregiver is the recipient of the direct benefit and the patient benefits only secondarily. Second, interventions can be aimed to help make the caregiver become more competent and confident, providing safe and effective care to the patient, which can indirectly reduce caregiver distress by reducing their load or increasing their sense of certainty and control. In this section, we focus on the research evidence supporting caregivers as clients.

Despite the importance of information and support to help family caregivers, studies on interventions to increase support for family caregivers have lagged far behind those provided for patients. A focus on the family as a part of the patient's therapeutic plan of care is largely absent from interventional research and from general clinical practice as well. Few randomized clinical trials of educational interventions directed toward family caregivers have been conducted or published, and there is limited research to inform us about skills training for caregivers to prevent back injuries, infection, and other potential risks inherent in the caregiver situation.

Interventions To Reduce Burden and Distress

Recent meta-analyses of caregiver interventions found mixed results, which are important to note. Multicomponent interventions, rather than single interventions like support groups or education, significantly reduced burden.[69, 70] Other interventions found no reductions in burden, but significant improvements in caregiver knowledge and delayed nursing home admission for care recipients.[71] Sorenson and colleagues[72] found that interventions aimed at individual caregivers were more effective in improving caregiver well-being than group interventions, although group interventions were more effective in improving care-recipient symptoms. Reasons for this are unclear. The effectiveness of caregiver interventions lasts approximately 7 months. Few studies are funded for long-term followup.

Comprehensive counseling sessions for spouses caring for a person with dementia help reduce depression.[73] Counseling appeared to be effective in improving the quality of life for caregivers of stroke survivors.[74] However, even a simple one-to-one telephone call may be effective in helping the caregiver as client. An automated, interactive voice-response telephone support system for caregivers reduced burden for those caregivers with a lower sense of control over their situation.[75] Davis and colleagues[76] found an unexpected reduction in burden and distress for caregivers receiving friendly, socially supportive phone calls that provided some respite from caregiving, even without in-home caregiver skills training. Home visits and enhanced social support also can help reduce caregiver depression.[77, 78]

Zarit and colleagues[79] used a quasi-experimental design to demonstrate that caregivers who used adult day care services for their relatives with dementia had significantly lower levels of caregiver stress, anger, and depression after 3 months of this respite care than a control group of similar caregivers who did not obtain this intervention. Sorenson and colleagues[72] also found that respite/day care interventions effectively reduced caregiver depression and increased well-being.

Interventions To Improve Competence and Confidence

Smeenk and colleagues[80] investigated the quality of life of family caregivers who received a home care intervention that consisted of a specialist nurse coordinator, a 24-hour nurse telephone service with access to a home care team, a collaborative home care dossier and case file, and care protocols. The care dossier was used to assist with communication and coordination between caregivers and health professionals. The dossier included the lists of the patient's caregivers, discharge reports, nursing home case transfer reports, medication lists, and multidisciplinary reports. From these reports, specific patient intervention approaches were developed. The intervention significantly improved caregiver quality of life at 1 week and 4 weeks after discharge from the hospital.

Houts and colleagues[81] describe a prescriptive program that is based on research on problem-solving training and therapy. Designed to empower family members to moderate caregiver stress, the Prepared Family Caregiver model is summarized in the acronym COPE (Creativity, Optimism, Planning, and Expert information). COPE teaches caregivers how to design and carry out plans that focus on medical and psychosocial problems that are coordinated with care plans of health professionals. Although proponents of this program assert it has positive outcomes for caregivers, a formal evaluation of COPE was not found.

Teaching caregivers how to manage specific patient problems can improve the caregiver's well-being. For example, not being able to sleep at night is a serious problem for caregivers of people with Alzheimer's disease, as the caregivers become fatigued and exhausted, which can have an adverse effect on both the physical and emotional health of the caregiver. Teaching them how to improve their family members' nighttime insomnia through daily walks and exposure to light can improve sleep time for both the caregiver and care recipient.[82] Even caregivers providing end-of-life care can benefit from structured interventions. McMillan and colleagues[83] found that a skills and coping training intervention with family caregivers of hospice patients improved the caregivers' quality of life.

Caregivers as Providers

Twenty-five years of research have documented that the work of family caregiving can be stressful. That stress can adversely harm both the caregiver and the care recipient. This section addresses research aimed at protecting the care recipient from an ill-prepared or emotionally stressed family caregiver. It describes the link between the work of caregiving and patient harm, and examines interventions that aim to make the caregiver a better worker and less likely to harm the patient.

The Potential for Harm

Caregivers can place their family members at risk in two ways, and both situations are preventable. First, despite their good intentions and hard work, if caregivers do not have the knowledge and skills to perform their work, they may unintentionally harm their loved one. This risk for injury is directly related to lack of knowledge and competence, which can be improved through caregiver education and support. For example, a recent study confirmed that patients had many negative outcomes when untrained informal caregivers managed their home enteral nutrition or tube feeding.[84] Problems included tube displacement, tube clogging, infection, and dehydration—all of which can lead to a stressful caregiving situation and hospital readmission.

A second concern is that the demanding work of caregiving can put caregivers at risk of engaging in harmful behaviors toward their care recipients, particularly among caregivers of persons with cognitive impairments.[85] Depressed caregivers are more likely to harm their spouses. Caregivers who are at risk of depression while caring for spouses with significant cognitive or physical impairments are more likely to engage in neglect or abusive behaviors, such as screaming and yelling, threatening to abandon or use physical force, withholding food, hitting, or handling roughly.[63]

In general, family members may be challenged to find the capacity or ability to provide care, but Fulmer[86] found that caregivers who were in poor health or from low-income or dysfunctional situations might have the most limited capacity to provide needed care. They also might not understand the standard for quality and might not provide the level of care that is needed.

The risk of elder abuse. The presence of dementia and cognitive behavioral problems put the care recipient at risk for abusive behaviors by the caregiver.[86, 87] Neglect may also occur, including neglect of nutrition and access to food, unmanaged pain, urinary incontinence, and falls. Caregiver neglect may occur because the dementia patient is unable to communicate and the caregiver is unable to understand or know how to deal with nutritional intake and pain management. Mittelman and colleagues[88, 89] found that counseling and support for caregivers who face disruptive behaviors from their ill family members will decrease their stress over their multiyear caregiving responsibility.

Medication errors. With regard to caregiver knowledge and skills, an important example of the potential to harm the patient is caregivers' administration of medications. A substantial number of community-dwelling elders do not recall receiving any instructions on taking their medications.[90] They often rely on family members for help in taking them. Travis and colleagues[12] found that caregivers manage between one and 14 medications on a daily basis, have difficulty keeping so many prescriptions filled, and often miss doses due to their work schedules. Their responsibility to monitor for adverse or toxic effects in family members who are not capable of reporting problems themselves is important in preventing dehydration brought on by vomiting and diarrhea, and even more serious emergency situations. Caregivers need education to recognize both classic and atypical adverse drug effects they may see as their family member's condition changes, and help in developing the critical thinking skills that would enable them to manage these potential problems.

Neglect and family conflict. The caregiver's perception of the care situation is crucial in understanding the potential for harm. The amount of "bother" the caregiver perceives in relation to the patient's symptoms affects the caregiving context. Caregivers bothered by symptoms tend to inaccurately assess patients' symptoms, particularly patients' pain and patients' ability to care for self.[91-93]

Neglect is more common when the caregiver is depressed or distressed. It interferes with the person's ability to make observations and to identify needs or provide social stimulation for their ill family member. When caregivers themselves are distressed, burdened, or depressed, they might leave elders alone for long periods of time, ignore them, or fail to provide any companionship or interaction.[86] Annerstedt and colleagues report on the breaking point of caregivers providing care for patients with dementia.[59] When caregivers have a high level of burden, care becomes inadequate. The amount of care demands and time per week, impaired sense of own identity, clinical fluctuations in the patient, and nocturnal deterioration in the patient predict the caregiver breaking point.

When there is family conflict, there is less assistance to the patient. Bourgeois and colleagues[94] looked at the consequences of disagreement between primary and secondary caregivers and found divergence in perceptions. There was, however, more agreement on patient behaviors and caregiver strain. Primary caregivers with pessimistic secondary caregivers were less distressed than those with optimistic ones. Given and Given[18] found that secondary caregivers left the care situation over time and only returned with increased physical care needs. Caregivers may also relinquish caregiving when they are unsuccessful in maintaining a relationship or when the care becomes difficult, such as when the care recipient loses cognitive function. Conflicts can also occur with unfulfilled or mismatched aid. Negative interactions with kin include despairing comments on caregiving, caregiver health status, and criticisms of care decisions.[95, 96]

Research Evidence: Interventions for Caregivers as Providers

Interventions designed to help the caregiver become a more competent and confident provider are important to ensure that the patient receives safe and effective care. These interventions are aimed at: preventing abuse and neglect, and improving the caregiver's knowledge and skills; supporting caregivers with early identification of patient problems and managing patient care; developing psychomotor skills training for the safe administration of medications and use of equipment; and enhancing emotional and coping skills to deal with the caregiver's anger and frustration. In these situations, interventions, such as role playing and rehearsal, are designed to help the caregiver better understand how to communicate with the care recipient and manage negative reactions, or remove the care recipient from a dangerous caregiving situation. A focus on the former may help prevent the latter. All of these interventions can strengthen caregivers' competence and reduce harm to the patients under their care.

Strengthening Caregiver Competence

Strengthening caregivers' competence and confidence improves their *mastery*, defined as the amount of control that a person feels over the forces that are impinging upon him or her.[97] Caregivers with higher levels of mastery of the care situation have more positive responses to providing care[98, 99] because they perceive themselves as able to meet care demands.[100, 101] Caregiver mastery can reduce caregiver distress by influencing the availability of healthy problem-coping strategies to meet care demands.[102, 103] The control associated with caregiver mastery is also associated with a lower stress response and more positive health-related behaviors among caregivers.[104]

Caregivers require knowledge, skills, and judgment to carry out the tasks of care for patients, and research has shown that caregivers who feel prepared to deliver care (i.e., have the knowledge and skills needed) have less burden.[15] Providing care takes into account the following dimensions: (a) the nature of the tasks; (b) the frequency with which tasks are performed; (c) the hours of care provided each day; (d) the skills, knowledge, and abilities of caregivers to perform tasks; (e) the extent to which tasks can be made routine, and thus incorporated into daily schedules; and (f) the support received from other family members. Caring for patients ranges from providing direct care, performing complex monitoring tasks (e.g., monitoring blood sugar, titrating narcotic dosages for pain), interpreting patient symptoms (e.g., determining the fever level to report to a health care provider), assisting with decisionmaking, and providing emotional support and comfort. Each type of involvement demands different skills and knowledge, organizational capacities (e.g., obtaining needed community services or ordering the best wheelchair), role demands, and social and psychological strengths from family members.[16, 104, 105] Each of these is a potential area of concern for patient safety and caregiver distress.

Developing Task-Specific and Problem-Solving Skills

Despite the overall lack of interventional research with caregivers, there is some evidence that interventions designed to improve specific caregiving tasks are helpful. For example, Ferrell and colleagues[106] examined the impact of pain education on family caregivers who were providing care to elderly patients with cancer. The pain education program included pain assessment, pharmacologic interventions, and nonpharmacologic interventions. The pain education program helped improve caregivers' knowledge and attitudes about managing their family members' pain. Other researchers have found that interventions to build skills and problem-solving abilities help caregivers of persons with Alzheimer's disease by decreasing negative behavior in those they care for.[107] Weekly telephone interventions to help caregivers of stroke survivors problem-solve led to reduced depression.[108]

Another example of specific training found nurse-initiated interventions to teach older adults and their caregivers about safe medication administration resulted in significant improvements in the ability to name prescribed medications and their administration schedules correctly.[109] This knowledge base is essential for caregiver competence and patient safety.

Several interventions have been aimed at assisting caregivers to develop problem-solving skills. For example, Toseland and colleagues[110] and Blanchard and colleagues[111] implemented a randomized trial (Coping with Cancer) using a psychosocial intervention aimed at spouses of cancer patients. A six-session problem-solving intervention was designed to help spouses cope with the stress of caring for their partners. Intervention components included support, problem-solving, and coping skills. There was little change over time with respect to caregivers' levels of depression, perhaps because the level of caregiving activities was low. This kind of problem-solving training may be more critical for caregivers who spend more time providing care.

Psycho-Educational Interventions

The majority of intervention studies for caregivers have utilized a psycho-educational intervention. That is, the intervention emphasizes both the provision of information and a psychological/counseling approach to decrease caregiver distress. Although not explicated as such, these interventions aim to address caregivers as both clients and providers.

A randomized clinical trial designed to test the effects of a psycho-educational intervention for caregivers and patients with newly diagnosed cancer who had recently initiated chemotherapy had a positive effect on reducing caregiver depression.[112] Four months after attending a psycho-educational caregiver cancer education program that addressed symptom management, psychosocial support, and resource identification, the number of caregivers who reported being well informed and confident about caregiving increased.[113]

Training caregivers in a multiracial primary care setting about specific ways to manage behavioral disturbances appears promising.[114] Anger and depression management interventions decreased anger, hostility, and depression and improved the caregiver's sense of control.[115] Caregivers received moderate support from an AlzOnline's Positive Caregiving classes, in part because they felt an increased sense of control over their caregiving situation.[116] An intervention to teach management of behavioral problems and basic activities of living left caregivers feeling less upset and more capable of managing difficult behaviors.[100] Similar findings were demonstrated for a portable CD-ROM training program for caregivers of people with dementia.[117]

Navigating the Service Delivery System

Family members must interact with the health care system to obtain information, services, and equipment, as well as to negotiate with family and friends to enlist and mobilize support. Interventions to increase caregivers' knowledge about community services and how to access them can increase their sense of competence and reduce depression.[118] Caregivers' involvement in direct and indirect care changes over time, in response to the stage of illness and treatment, and caregivers must be able to adapt to changes in the amount, level, and intensity of care demands. Given and colleagues[19] describe that it was not the amount of care itself, but the change in care demands (either increased or decreased) that resulted in caregiver distress. Change requires constant adaptation and adjustment by the caregivers, which translates into adapting to different schedules, changing routines, and accommodating other roles for which family caregivers are responsible.

One of the most essential aspects of navigating the system is finding home- and community-based services, and determining what private and public programs might be available. The public sector side is particularly complex. People who are very frail and below or close to the poverty line can receive home care under Medicaid. Much of this care is provided through a home health agency. Through the authority of section 1915(c) of the Social Security Act, States can request Federal permission to provide a range of services, which may include respite service for family caregivers. Benefits vary by State, but research documents an increasing trend in the numbers of people served and dollars spent in Medicaid home- and community-based care. In addition, policymakers are facing pressure to increase these services to address the unmet needs of patients and their families.[119] A study examining the benefits and costs of home- and community-based services in Florida[120] found that people receiving these services had been diagnosed with at least three chronic health conditions and needed help with three or more ADLs and seven IADLs. With services, they were able to avoid institutionalization despite this high level of needs. Other research has shown that the presence of a caregiver can reduce nursing home stay by 3.2 days. These caregivers need help finding services.

Options for arranging flexible services are emerging from Medicaid-funded consumer-directed care programs, which allow people to select and manage paid home care workers, as well as purchase assistive devices or home modifications. The program gives people the

flexibility to adjust the frequency and timing of paid and unpaid services. Benjamin and colleagues examined the services of low-income Medicaid beneficiaries under agency-directed and community-directed services. People who directed their own services had positive outcomes. They were more satisfied with services and had fewer unmet needs.[121] Foster and colleagues[122] assessed the impact of consumer direction on caregiver burden in Arkansas and found that caregivers had greater satisfaction with the care recipient's care and were less worried about safety. Caregivers in the study reported less physical, emotional, and financial strain compared to the control group receiving traditional agency services. Primary informal caregivers who became paid caregivers reported substantial benefit compared to the group receiving agency services.

Evidence-Based Practice Implications

A review of the literature found that society depends on family caregivers to continue providing care for their loved ones, but does little to teach them how to do it and support them in this stressful work. At a minimum, nurses can recognize and respect their efforts, assess their needs, provide concrete instructions on the specific care they are giving (e.g., medication administration, dressing changes, and similar tasks), and refer them to potential sources of ongoing help. Nursing interventions in these areas can help reduce harm to caregivers and the patients they serve.

Respecting the Patient–Family–Professional Triad

The most important practice implication of this review of caregiving research evidence is that nurses can meaningfully change the course of caregiving for both the caregiver and care recipient by respecting the role that each has in managing ongoing care beyond the classic boundaries of professional patient care. For example, it is often not easy for the elderly patient in the hospital who is going to need postacute care to accept the need for family help, because they view themselves as independent. Nurses can help shift their views of classic independence as freedom from functional limitations to a context of family care in which giving and receiving assistance does not need to strip away autonomy.[123] It is also important to understand that burdened caregivers can successfully support their family member, but these caregivers may need help to bolster their sense of self-esteem.[124] They want to be part of the decisionmaking team.[125]

Nurses in all practice settings need to partner with patients and their families to move from the traditional nursing context of *doing for* clients in the "expert model of service delivery" to more mutuality in nurse-client relationships.[126] Nurses may need to "enact more empowering partnering approaches" and "reframe their professional image, role, and values"[126] to accomplish this. Listening skills and the ability to interpret body language and verbal communication are essential competencies in all encounters with patients and their family members.[127]

This model is consistent with Dalton's theory of collaborative decisionmaking in nursing practice triads, where the triad comprises the client, the nurse, and the caregiver.[128] In this vision of the caregiving environment, the nurse interacts with and assists not only consumers, but the informal caregiver as well. This kind of collaboration can increase feelings of control over health, the sense of well-being, and compliance with prescribed treatments.

Providing Information

Nurses need to communicate effectively with clients and caregivers to develop cost-effective plans of care and achieve positive client outcomes.[129] Communication is crucial across settings. The emergency room and hospital discharge planning processes, assisted living facility admission process, skilled nursing facility discharge process, and the home health care admission and discharge process are all critical points of interaction where health care professionals, patients, and family caregivers can benefit from respectful, high-quality communication.[130] In the managed care environment, providing concrete care information along with emotional support can help spouses of frail older adults better manage their caregiving situation.[118]

At all points in the patient's disease trajectory, caregivers need information to deal with the patient's care and treatment demands. Nurses and other health care providers should not expect caregivers to be responsible for sorting out relevant information and applying it to the care requirements for their family members. Research documents that caregivers have difficulty obtaining information from health care professionals, particularly physicians and nurses.[131-133] Professionals should be more responsive to patients' and family members' information needs.

It is important to provide information in a clear, understandable way through verbal, written, and electronic methods. Caregivers want concrete information about medications, tests, treatments, and resources. They also want time to have their questions answered. Nurses can provide anticipatory guidance for what the caregiver can expect.[134] This kind of information can relieve caregivers' distress arising from uncertainties about their ill family members' disease and treatment status and the care they may need.[135, 136] For example, teaching caregivers how to manage pain and other symptoms benefits both the patient and the caregiver. Caregivers who report more confidence in managing symptoms report less depression, anxiety, and fatigue.[137]

Caregiver Assessment

Given caregivers' essential role in caring for their family members and the hazards they face in doing so, their needs and capacities to provide care should be carefully assessed.[138] This assessment should focus on the caregiver as both client and provider before health professionals can assume caregivers are able to provide competent care without harming themselves or their family member.

Assessing the home and family care situation is important in identifying risk factors for elder abuse and neglect. Heath and colleagues[87] found that in-home geriatric assessments are needed to determine the risk for and occurrence of elder care recipient mistreatment. Fulmer's research[86] documents the need for interdisciplinary teams in emergency rooms to screen for elder neglect, with attention to risk factors associated with caregiver and elder vulnerability, such as the elder's cognitive and functional status and depression. Health care professionals who conduct detailed assessments of the caregiving situation through separate conversations with the patient and the caregiver are better prepared to provide guidance and collaborate with the family to prevent abuse and neglect.

Assessing the needs of older people living in the community is a prerequisite for helping caregivers find resources and adhere to a comprehensive plan of care. Outpatient geriatric evaluation and management can reduce caregiver burden, particularly for those who are less experienced caregivers.[139]

Linking Caregivers to Resources

Caregivers need adequate resources to assure minimization of risk to the patient.[140] To reduce the rough crossing that family caregivers experience as they navigate the discharge from hospital to home, there is a clear need to develop referral criteria and guidelines, accurate documentation, and prompt referral to continuing care professionals.[24] More case management programs may be useful to help ease this transition, promote safe and effective hospital discharges, and support caregivers in their ongoing, posthospital care. Nurses, preferably those trained in gerontological nursing, have a key role in case management for frail older people.[141]

Linking caregivers to resources throughout the disease trajectory is important because caregivers are often unaware that there are support services available to help them. A recent study of caregivers of people with Alzheimer's disease found that 75 percent had unmet needs, yet only 9 percent had used respite services and only 11 percent had participated in support groups.[142] Extending nursing care beyond the hospital boundary, nurses can help caregivers mobilize supportive resources in their natural network as well as formal services.[143]

Research Implications

Taken as a whole, interventions to improve caregiver outcomes have been varied. Intervention studies have typically been descriptive in nature, used small convenience samples, and have not included comparison groups. In addition, many studies have limited their samples to patients with only a single diagnosis. In the future, randomized trials are needed to substantiate the role of similar programs in enhancing caregiver skills and minimizing caregiver distress.

The majority of studies have focused on a single construct of the care situation (i.e., examining the correlation between the caregiver-patient relationship and caregiver burden). Researchers have given limited attention to the nature of the knowledge and skills of the caregiver, and to personality factors or dispositions of caregivers.[144, 145] Most of the intervention studies did not consider potential confounding or risk variables, such as prior family relationships, cultural variation, caregiver health status, stage of disease, hours of care, or competing caregiver role demands. In addition, little detail was provided about the intervention design. Finally, few studies described the nature of care tasks of the caregiver, so we are unaware whether caregivers were effectively managing symptoms, providing emotional support, providing direct care, monitoring patient status, or performing a combination of these tasks.

Recommendations for Future Research

Since much of the caregiving research remains descriptive, there are many gaps in the evidence-based research to promote patient safety and quality care for caregivers as secondary patients and caregivers as providers to vulnerable patients. To advance our knowledge in this field, we recommend several strategies for future research.

Because caregiving is a day-in, day-out role that fluctuates as the needs of the care recipient change, it is not well understood through cross-sectional research designs. It is essential that descriptive and longitudinal designs be employed to follow the care requirements over the course of the illness trajectory. Longitudinal research to date has uniform intervals between observations such as 3, 6, or 9 months, without concern for treatment protocol or stage of disease

or care demands. Further studies should take into consideration other time points that may better reflect the disease trajectory, such as time of initial diagnosis, protocols alterations, and points of disease exacerbation or decline. A special focus on safety, risk for negative outcomes, and adverse effects for both the caregiver and care recipient should be noted.

Key variables to include in these studies are the type and stage of the disease and the treatments because they will be related to the types of continuing therapy. These various therapies will be related to the needs of the patient and assistance with self-care, as well as the patient's ability to perform other customary daily activities. Are the demands on the caregiver such that they jeopardize his or her health? We also need larger population-based studies so we can have heterogeneous samples related to diagnosis, stage of disease, caregiver distress, care provided, patient impairment, and duration of care as they relate to caregivers' ability to provide safe care without jeopardizing their own well-being.

Research that uses carefully selected inception cohorts is needed so that variation in care demands can be understood. We will be in a far better position to describe how the course of the disease and associated treatment influence caregivers' responses if we start with inception cohorts of those caregivers beginning with initial treatment and proceeding through palliative care. Adverse patient care and caregiver situations, such as medication errors, falls, and subsequent hospitalizations, can be noted over time.

We need studies that target caregivers that are from minority and economically disadvantaged groups if we are to better understand their own needs and interventions to support them in providing safe care. Furthermore, focus on variations or adaptations needed to minimize caregiver distress related to ethnic, racial, cultural, or socioeconomic diversity is needed. We know very little about the distress and resource limitations of various vulnerable groups and the acceptability of various types of interventions to ethnically and racially diverse populations.

We need to investigate the interplay between the formal and informal systems of care for the ongoing needs of patients as well as caregivers. More research needs to be conducted that focuses on how family influences care-related decisions and the impact to clinically significant processes of care and/or client outcomes. There is very little research to suggest how variations in caregiver contact with the formal health care system interacts with the amount and types of responsibilities faced by family caregivers. Can prepared caregivers contribute to the quality of patient clinical outcomes as well as patient safety? What does competent and appropriate family care contribute to patient clinical outcomes? How does it affect cost and care utilization?

Future research should identify and test patient- and family-directed interventions and chart their impact upon the quality of care outcomes for patients. In addition, interventions should report the cost of care, as well as the cost of utilization of services. What are the costs of negative outcomes that result when safety and neglect or abuse are involved?

Interventions that can demonstrate improved patient outcomes are particularly essential to building a high-quality system of continuing care. Caregivers who face conflicts in competing demands related to caring for children, spouse, or parent and to maintaining their work roles are particularly threatened by and vulnerable to the demands for continuing home care. More appropriate home care and home care support (resulting in caregivers who are prepared to care and have adequate formal support) may lead to fewer patient or caregiver hospital readmissions, fewer interruptions in treatment cycles, shorter periods of work loss, and better patient and caregiver mental health. Quality of care and patient safety are concerns.

We need to design and test interventions to assist patients and their families to increase their preparedness to deal with the overall care process, to deal with both the direct and indirect care

demands. How do we increase their sense of control and mastery of their care situation? Future intervention studies should utilize multidisciplinary, randomized clinical trials (including physicians) to determine the unique contribution of educational programs versus social support versus psychological support on caregiver outcomes and patient outcomes.

Future studies should explore whether health care professionals can assist the caregiver to build effective buffers against being overwhelmed and distressed. Interventions that assist the caregiver to engage in activities that promote their own health should be carried out to identify strategies of health promotion. Research questions should address whether or not caregiver distress (i.e., depression and burden) affects caregiver decisionmaking and judgment about patient care, and to examine caregiver behavior and choices and the subsequent quality of care. Do these have a negative impact on the patient or on themselves?

Examining caregiver distress as it relates to quality of care is absent from the literature. Research is needed to understand the *quality* of care that family members provide and then determine how that care impacts the overall therapeutic plan and patient clinical outcomes.

Longitudinal studies of caregivers are needed to explore the complex interactions of caregiver physical health and mental health, and how self-care and health-promotion practices of the caregiver are altered. Exploration is needed of which self-care practices (i.e., nutrition, exercise, sleep, stress management, preventive and promotive health care) can influence caregiver distress and physical health status so that caregivers can continue to provide quality and positive care.

To better understand the effects of care on family caregivers and on patient outcomes, caregiver roles, responsibilities, knowledge, and skills need to be more rigorously explored and defined. For instance, what do caregivers do well? What do caregivers not do well? In what areas are the patient outcomes most likely to be compromised? In what areas is patient safety most in jeopardy? What areas cause caregivers more distress? Once these questions are answered, we can target interventions at those who are at risk and intervene early in the care situation, rather than late.

Finally, interventions must recognize professional or formal caregivers and family caregivers as partners in health care—partners who offer unique and vital skills and resources—and engage them in the entire plan of care. Such interventions are critical as we increase the focus on outcomes of care and as providers are paid for outcomes performance. Family members as partners are critical.

Conclusion

Family caregivers are critical partners in the plan of care for patients with chronic illnesses. Nurses should be concerned with several issues that affect patient safety and quality of care as the reliance on family caregiving grows. Improvement can be obtained through communication and caregiver support to strengthen caregiver competency and teach caregivers new skills that will enhance patient safety. Previous interventions and studies have shown improved caregiver outcomes when nurses are involved, but more research is needed. There is more to be learned about the effect of family caregivers on patient outcomes and areas of concern for patient safety. Nurses continue to play an important role in helping family caregivers become more confident and competent providers as they engage in the health care process.

Search Strategy

The research cited is a comprehensive but not exhaustive review of the caregiver literature. The literature search for this paper was done in the databases MEDLINE, CINAHL, and PsycINFO using variations of the terms "caregiver" and "long-term care" or "home care services," combined with other terms relating to patient safety and nursing practice. Other terms employed included "case management," "education and training," "medication," and "risk management." The search was limited to articles written in English, but not limited to the United States.

The search terms applied were usually kept very broad, and keyword searches were frequently employed more often than searches that relied upon the use of controlled descriptors, as the topics of patient and caregiver safety, which are often intertwined, are difficult to isolate through clearly defined identifiers. As a result, search results were large, and relevance was frequently determined through the reading and review of abstracts of large sets of retrieved publications. Relevant articles for this review were not always indexed using terms relating to nursing; the *potential* involvement of the nurse as a contributor to *improved* patient and caregiver safety was a determinant for inclusion. Some articles discussed the professional health care team in general terms, while others focused on the specific role of a nurse serving as a factor in *safe family caregiving*. The broad search strategies delivered high retrieval levels and the need to distill relevant evidence.

Evidence Table: Supporting Family Caregivers in Providing Care

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design and Outcome Measures	Study Setting & Study Population	Study Intervention	Key Finding(s)
Acton & Kang 2001[69]	Care burden	Meta-analysis	Various meta-analysis (Level 1) Effect sizes calculated; studies were grouped by intervention category; pooled effect size calculated for each intervention category (Level 3)	24 reports testing 27 treatments for adults with dementia.	Various educational	Multicomponent interventions have a small significant effect on burden. No effect on burden from support group, education, psycho-education, counseling, and respite.
Austrom 2004[114]	Nonpharmacologic methods, such as this collaborative stepped-care management intervention program, are the intervention of choice for behavioral disturbances, which can add to caregiver burden and affect quality of care.	Randomized controlled trial	Randomized controlled trial (Level 2). Questionnaires were periodically administered to evaluate frequency of behavioral disturbances in patients as well as a measure of the caregiver's reaction (Memory and Behavior Problems Checklist), and measure of severity of the caregivers depression (Patient Health Questionaire-9). (Level 3)	Minority Alzheimer's patients, who were less likely to visit specialty clinics, may find interventions more accessible if they were delivered through primary care clinics. Intervention of three basic components: (1) comprehensive screening and diagnosis protocol, (2) multidisciplinary team approach to care coordinated by a geriatric nurse practitioner, and (3) proactive longitudinal tracking system.	All participants receive Alzheimer caregiver guides, educational interventions, and specific protocols for common behavioral disturbances. Treatment group then received treatment recommendations for specific behavioral disturbances from a clinical treatment team of geriatric nurse practitioner, social psychologist, geriatrician, geriatric psychiatrist.	Study is ongoing. Preliminary data indicate that program is well received by patients, caregivers, and primary care physicians. Subjects are attending voluntary meetings more frequently than those not in the program.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design and Outcome Measures	Study Setting & Study Population	Study Intervention	Key Finding(s)
Beach 2005[63]	Threatening behavior, verbal abuse	Convenience sample (descriptive)	Structured interviews (Level 5) Care recipients reports of harmful caregiver behavior, screaming, yelling swearing, threatening (Level 3)	265 caregiver/care recipient dyads	None	Harmful caregivers were associated with greater recipient ADL needs; spouse's greater caregiver cognitive physical symptoms; caregiver at risk for clinical depression.
Bowles 2003[146]	Home care referral can lead to better care	Noncompara-tive	Interviews with content analysis (Level 5) Identify patterns clinicians used when gathering information, determine information essential to discharge referral decisions, and explore why patients in need may not be referred for service (Level 3)	Patients discharged without home care referrals were presented as case studies to nurses, social workers, physicians, and discharge planners. Observations were recorded.	None	Three themes describe why patients may not receive referrals: (1) patient characteristics, (2) workload, and (3) staffing, educational issues.
Brodaty 2003[73]	Psychological distress in caregivers	Meta-analysis	Meta-analysis (Level 1) Various psychological morbidity and benefits (Level 3)	30 studies	34 interventions	Significant improvement in caregiver distress and caregiver knowledge. No improvement in caregiver burden.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design and Outcome Measures	Study Setting & Study Population	Study Intervention	Key Finding(s)
Brown 2006[126]	Changing the home care nursing approach from the expert model of service delivery to a more client-centered empowering model can optimize the potential for improved interactions and understandings between the nurse and consumer, and greater professional autonomy for the nurse.	Non-comparative (interpretive phenomeno-logical using hermeneutic analysis)	Holistic interpretation of nurses' experiences through analysis of interviews (Level 5) Identified concepts were noted and categorized until themes and patterns emerged. Participant review and peer review of findings assured authenticity of data. (Level 4)	Purposeful sample consisting of 8 registered nurses who had in-depth experience in the flexible client-driven delivery approach, identified by a key informant within the home care program (Canada). Employed maximum variation sampling regarding age, education, experience in in-home nursing.	None	While interpretive research findings are not generalizable, this study identified pitfalls and suggests potential ways that nurses can implement practice change. Several barriers exist that impede nurses from evolving to a client-centered service model: system level (governmental financial), organizational (centralized allocation and control of service delivery), personal (remuneration, workload, working conditions). Home care nurses revealed a tendency to seek direction of physicians and managers rather than to exert professional autonomy within the scope of professional nursing practice. Empowering partnering approaches in nursing fosters sharing power to optimize the potential for nurse and client. Nurses may have to reframe their professional image, role, and values to enact this interaction.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design and Outcome Measures	Study Setting & Study Population	Study Intervention	Key Finding(s)
Burton 1997[38]	High-level caregiving can increase odds of insufficient rest and exercise, and poorer outcomes while recovering from illness or threats to health.	Cross-sectional (descriptive)	Caregivers compared to noncaregivers (Level 4) Structure interviews in their home (Level 3)	Health effects study. 434 caregivers with a control matched 385.	None	Being a high-level caregiver increased odds of not getting rest, not having time to exercise, and not recuperating from illness and forgetting to take prescription meds when compared to noncaregivers.
Cameron 2006[99]	Complex rehabilitation has negative health outcome on caregivers.	Cross-sectional	Survey (Level 4) Identify aspects of the caregiver's emotional distress and psychological well-being; compare health-related quality of life of informal caregivers. Evaluated outcomes by CESD, postaffect scale SF36 (MO5). (Level 3)	Informal caregivers matched age and gender of ARD survivors.	None	Caregivers had more emotional distress, more lifestyle interference, lower misery. Caring for ARD survivors with more depression, poorer overall health quality compared to age and gender matched group lasted 2 years.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design and Outcome Measures	Study Setting & Study Population	Study Intervention	Key Finding(s)
Campbell 2004[137]	Caregiver strain and burden	Cross-sectional (survey description)	Descriptive cross-sectional (Level 4) Quality of life, self-efficacy, mood (Level 3)	Age mean 57.6, intimate partners of patients with prostate cancer.	None	Caregiver self-efficacy was associated with both partner mood and caregiver strain. Caregiver self-efficacy scores were negatively correlated with partner depression, anxiety, and fatigue subscale scores since partners who reported greater overall confidence in assisting patients with symptom control also reported less depression, anxiety, and fatigue. The total self-efficacy score was negatively associated with strain. Increased self-efficacy in the caregiver led to better adjustment to the symptoms and increased mental health of the patient.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design and Outcome Measures	Study Setting & Study Population	Study Intervention	Key Finding(s)
Coon 2003[115]	Anger and depression	Cross-sectional	Survey (Level 4) Anger, depression coping intervention (Level 3)	Female caregivers age 50+, older community dwelling, 169 females; psycho-educational and skill building, 2-hour workshops for 8 consecutive weeks followed by two booster sessions at 1-month intervals for 3 months. Two options: anger management or depression management, intervention study, R(2/CT) 3-4 months.	Psycho-educational small group over 3-4 months.	Anger and depression management interventions decreased anger, hostility, and depression and improved self-efficacy at 3 months. Anger management improved coping skills. RCT, effective. Self-efficacy impaired in both groups. Pretreatment depressive symptoms moderated intervention.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design and Outcome Measures	Study Setting & Study Population	Study Intervention	Key Finding(s)
Crist 2005[123]	Understanding how care recipients feel about the care they receive and the level of autonomy that they retain while under care may facilitate better understanding between caregivers and recipients, and result in less anxiety and better relationships.	Non-comparative (hermeneutic interpretive phenomeno-logical)	Exploration of shared meanings through multiple, open-ended, in-depth interviews, observation (Level 5) 2-5 interviews were conducted with each elder. A 3-member investigator team co-constructed an emergent interpretation of the narratives within the specific context. (Level 4)	Convenience sample of 9 elders (5 women, 4 men) in urban and rural areas of the Pacific Northwest, recruited from three home health agencies, one adult day center, one neurological clinic. Elders were 65 or older and had an identified family member who provided assistance with at least one ADL.	None	Elders can incorporate family care into their lives while still viewing themselves as autonomous. Gerontological nurses, who traditionally measure independence as the level of a client's functional ability, may shift to understand the recipient's view of autonomy and independence is constructed independently and individually. Positive relationships between elders and caregivers resulted in personal growth; a positive family care context facilitated recipients' willingness to incorporate receiving family care into their lives.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design and Outcome Measures	Study Setting & Study Population	Study Intervention	Key Finding(s)
Christakis 2006[27]	The hospitalization of a spouse with a serious illness may be associated with an increase in the risk of death of a partner.	Retrospective cohort	Cohort compiled from data in Medicare claims forms. (Level 4) Two statistical methods were applied (Cox regression and fixed-effects) to estimate the relationship between the hospitalization of a spouse and the subsequent death of the partner, while controlling for all constant characteristics of the spouses and their environment. (Level 1)	518,240 couples who were enrolled in Medicare in 1993, 65 years of age or older	None	Serious spousal illness and spousal death appear to be independently associated with the risk of death of the partner. Hospitalization for various diseases may differentially affect partners. Implications: training and assistance of spouses who serve as caregivers can lower costs and improve the health of patients and partners. Such interventions might decrease mortality among partners. Interventions may be more useful in certain diseases, such as stroke or dementia.
Dalton 2005[129]	Quality of care can be improved when client-caregiver-nurse (triad) communication occurs; caregivers can better understand care plans; coalition decisions within triads may increase the possibility that client interests are maintained.	Non-comparative (ethnographic, content analysis); exploratory	Observation, recording, and transcription of triad interactions. (Level 5) Qualitative and quantitative analysis of frequencies of different types of decisions and decisionmaking situations. (Level 4)	12 client-caregiver-nurse triads admitted for the first time to home health care agencies in suburban New England during 1994	None	Coalitions (two members of a triad acting together) form during triadic interactions; of 157 decisionmaking situations evaluated, coalitions formed in just 8 (5%). Decisions were organized into program decisions, operational decisions, and agenda decisions. Two of the roles (advocate and passive participant) that can be assumed by a third person were evident.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design and Outcome Measures	Study Setting & Study Population	Study Intervention	Key Finding(s)
Dalton 2003[128]	An understanding of triad interaction and how coalitions are formed in clinical settings may enhance the effectiveness of clinicians' communication with clients and family caregivers and facilitate positive client, caregiver, and nurse outcomes.	Systematic literature review (theory generation)	Literature review (Level 1) Theory generation (Level 4)	None	None	The theory of collaborative decision-making in nursing practice for a triad provides a framework for studying the effects of collaborative decision-making among nurses, family caregivers, and clients.
Davis 2004[76]	Telephone-based psycho-educational interventions may provide relief from the burden, distress, and depression suffered by caregivers who are not able to, or do not wish to, seek help from sources that require that they leave their home.	Three-group pretest and post-test (repeated measures design with randomization to treatment group)	Each of three groups of caregiver-recipient dyads received 12 weekly sessions of training by in-home contacts; training by telephone contacts; and friendly, socially supportive phone calls. (Level 2) Caregiver self-reported outcome measures: burden, distress, depression, social support, and life satisfaction. (Level 4)	71 caregiver-care recipient dyads were recruited from geriatric clinics and home care agencies in central Alabama, and were randomized into three groups.	Caregivers in telephone and in-home groups were trained in problem-solving, caregiver appraisal of behavior problems, written behavioral programs for managing specific problems, and strategies for handling affective responses to difficult caregiving strategies.	An unexpected reduction in caregiver burden and distress was observed in those receiving only friendly phone calls, possibly because the calls provided caregiver respite. Only the in-home training group experienced significant burden and caregiver distress reduction. Caregiver groups did not differ significantly on caregiver depression. Despite differences in contact time with the three different groups, they were all similar in satisfaction levels.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design and Outcome Measures	Study Setting & Study Population	Study Intervention	Key Finding(s)
Dunnion & Kelly 2005[24]	Improvements in planned discharge strategies (a multidisciplinary approach to developing referral guidelines, staff training, and dissemination of information) of elders from emergency room to home can lead to improved quality and continuity of care for the older person.	Cross-sectional (interviews) of 5 groups of health care professionals	Standardized questionnaires (Level 3) Quantitative data were analyzed with SPSS, and qualitative data were content analyzed. (Level 4)	Emergency department in a 320-bed rural general hospital in the Republic of Ireland. Purposeful sample (excluded psychiatric nurses, social workers, physiotherapists) of nursing and medical staff in the emergency room, totaling 222. 135 questionnaires were returned and 131 were analyzed.	None	Findings added support to others that found that in general, health professionals in the emergency department do not adequately determine the aftercare needs of older patients when they are being discharged. Effective discharge planning is impeded by gaps in communication between the hospital and community interface, such as illegible discharge summaries and delays in sending information to the general practice physician. There is a lack of synchrony between hospital and community nurses in relation to the level of communication between the two sectors. The liaison nurse role may help to improve communication links and channels between the primary and secondary interface. There is a clear need to develop referral criteria and guidelines, accurate documentation, and prompt referral to continuing care professionals.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design and Outcome Measures	Study Setting & Study Population	Study Intervention	Key Finding(s)
Ferrell 1995[106]	Pain management can affect quality of life and caregiver burden.	Cross-sectional	Quasi-experimental (Level 3) Quality of life and caregiver burden; physical and psychological impact of family caregiving and pain management (Level 3)	50 family caregivers of patients experiencing cancer-related pain from two California medical centers	Pain education program: pain assessment, pharmacologic interventions, and nonpharmacologic interventions	The pain education program was effective in improving knowledge and attitudes regarding pain management. Pain management is a priority for nurses, and use of interventions such as structured pain education improves quality-of-life outcomes for patients and their caregivers.
Fortinsky 2001[130]	The quality of interaction in the health care triad is likely to influence health-related outcomes of family caregivers, persons with dementia, and primary care physicians. The consequences of dementia care communication and practice are most significant when dementia patients are entering or leaving a new health care setting.	Systematic literature review	Literature review (Level 1) Summarization of knowledge base (Level 4)	None	None	Interactions in medical encounters involving dementia care are not optimal from the perspectives of family caregivers or physicians. Physicians are willing to share ongoing management of dementia patients and their families with other organizations in the community. Older persons with dementia, even though physically present during triadic encounters, are unlikely to be involved as active participants in dialogs and decisionmaking regarding diagnosis and management of dementia symptoms.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design and Outcome Measures	Study Setting & Study Population	Study Intervention	Key Finding(s)
Fulmer 2005[147]	Elder mistreatment is an enormous social problem, which emergency departments may help identify.	Cross-sectional	Older adults screened and recruited from emergency rooms (Level 3) Elder and caregiver cognitive status, functional status, depression level, health status; demographics; perceived social support; childhood support; personality. Relationship between measured variables and neglect-assessment team's diagnosis of neglect (Level 3)	165 subjects, 70 years or older, English/Spanish speaking, Mini-Mental Status Exam score of 18 or more, using a paid or unpaid caregiver 20 hours per week or more. Recruited from four urban emergency departments in New York and Tampa.	None	Older adults who are diagnosed as neglected are sicker, have fewer financial resources, and have less help in the home. There is a relationship between self-reported childhood trauma and later-life neglect, which may be considered normative by these elders. Personality traits may be indicators of neglect.
Gitlin 2001[100]	Upset family caregivers	Randomized controlled trial	Intervention RCT (Level 2) Behavioral problems, ADL, IADL, caregiver well-being, self-efficacy, and being upset (Level 4)	171 families of dementia patients; five 90-minute home visits by occupational therapists	Focusing on education and environmental modification every other week over 3 months; occupational therapists	Spouses reported reduced upset; women reported improved self-efficacy in managing behaviors; minority women reported improved self-efficacy in managing functional dependency.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design and Outcome Measures	Study Setting & Study Population	Study Intervention	Key Finding(s)
Gitlin 2003[70]	Burden among dementia caregiver	Meta-analysis	Meta-analysis (Level 1) Pooled parameter estimates of nine active conditions compared with six control conditions of the Resources for Enhancing Alzheimer's Caregiver Research (REACH) project. Associations of caregiver characteristics and outcomes were examined statistically. (Level 3)	Homes of patients with dementia, multisite study	Consulting education, support, skill building, home visits, problem-solving; 6 months.	Active interventions are superior to control on caregiver burden. Active interventions superior to control for women, those with lower education. Family therapy and computer technology intervention impacted depression. Active better for Hispanics, nonspouses.
Gitlin 2005[107]	Negative behavior in patients with dementia	Randomized controlled trial	Randomized controlled trial (Level 2) Behavior problem checklist, Says ADL, task management affect (Level 4)	127 caregivers, 6 months	Skill building, education, problem-solving, and technical skills. Active—five 90-minute home visits and one phone session over 6 months. Maintenance—one home visit and three phone sessions over the next 6 months.	Decreased days assisting with ADLs at 6 months, no difference at 12 months. Decreased upset with memory-related behaviors at 6 months, no difference at 12 months. Improved affect at 6 months, none at 12 months. Decreased memory behavioral occurrences in patients at 6 and 12 months.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design and Outcome Measures	Study Setting & Study Population	Study Intervention	Key Finding(s)
Glueckauf 2004[116]	Caregivers of persons with dementia typically experience emotional, physical, and psychosocial deterioration due to the extreme demands of providing home care without support.	Single-group pretest-post-test	Telephone interviews with caregivers to assess effects of the Positive Caregiving classes (Level 5) Survey instruments for dependent measures were: Steffen et al.'s Caregiver Self-Efficacy scale,[148] Parke et al.'s Stress-Related Growth Scale,[149] Lawton et al.'s Caregiver Appraisal Inventory[150] (Level 3)	21 caregivers of individuals with progressive dementia who had completed the AlzOnline's Positive Caregiving program	Series of six 45-minute interactive (PC- or telephone-based) Positive Caregiving sessions, every 2-3 weeks over a 16-week period	Moderate support was obtained for the effectiveness of AlzOnline's Positive Caregiving classes; significant increases in self-efficacy, concomitant decreases in subjective caregiving burden, little or no change in stress-related growth and positive caregiving appraisals, or perceptions of time burden in providing caregiving assistance.
Grant 2002[108]	Caregiver depression and burden	Randomized controlled trial	Randomized 3-group design (Level 2) Social problem-solving (Level 4)	45 stroke caregivers	Problem-solving: (1) 3-hour home visit with RN, (2) weekly phone calls by RN for 1 month, (3) phone calls by RN every 2 weeks for 1.5 months.	Improved problem-solving skills, preparedness, vitality, social functioning, mental health, and role limitations related to emotional problems. Less depression. No significant difference in burden.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design and Outcome Measures	Study Setting & Study Population	Study Intervention	Key Finding(s)
Greenberger & Litwin 2003[124]	Caregiver burden "is liable to diminish the caregiver's ability to provide quality care."	Cross-sectional (interviews)	Structured in-home interview schedule (Level 3) Variables measured: background, personal and social resources, burden measures, feelings of caregiver competence, adherence facilitation, measured with multiple instruments (Level 3)	240 Jewish primary informal caregivers, randomly recruited using records of recently discharged dependent older patients, caring for recipients over the age of 65, who lacked at least one functional ability delineated by ADLs or assessing motor functions necessary for independence in IADLs, and with at least one chronic illness.	None (interaction only)	Operationalizes facilitation of care recipients' adherence to prescribed care regimens in informal caregiving. Shows positive association between caregiver burden and adherence facilitation; burdened caregivers can be successful informal caregivers; and efforts to bolster caregivers' self-esteem and social support may be more effective in assuring quality care than attempts to relieve their sense of burden.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design and Outcome Measures	Study Setting & Study Population	Study Intervention	Key Finding(s)
Griffiths 2004[109]	Persons over 65 years old represent a significant percentage of medication-related admissions to hospitals. Community nurses can play a role in managing the administration of medicines and the monitoring of their effects on patients. Community nurses can play a unique role in the "medication team" (i.e., doctors, pharmacists, nurses, consumers) in a multidisciplinary approach to quality use of medicines.	Pretest-post-test with a cross-sectional survey	Survey (Level 3) Participants living at home and receiving community nursing care were assessed for knowledge of and ability to manage medication regimes. A nurse-initiated intervention was developed that included referral pathways to physicians and/or pharmacist medication review. (Level 3)	111 participants over age 65, taking oral medications and having regular community nursing visits, were surveyed. Recruited from case-load of Australian community nurses. A subgroup of 24 participants with diminished knowledge of medications were administered a followup in-depth survey.	Various interventions, including client education, referral paths to physicians and pharmacists, provision of administrative support systems.	After invention, participants showed improvement in their ability to manage medications (alteration in use of compliance aids) and demonstrated increased knowledge about their medications. Clients showed significant improvement in the ability to correctly name their medications and schedules correctly; clients did not experience reduction in the complexity of the regimes. Community nurses can successfully work within the boundaries of a multidisciplinary team to provide interventions within their professional scope of practice.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design and Outcome Measures	Study Setting & Study Population	Study Intervention	Key Finding(s)
Hallberg & Kristensson 2004[141]	Preventive case/care management interventions for community-dwelling frail older people may result in better quality of life, fewer emergency medical calls, and a reduction in hospital admissions.	Systematic literature review	Systematic review (Level 1) Three areas of outcome were targeted, though not at the same time: health care consumption, in some cases transformed into costs; quality of care; and patient's health and ability. (Level 4)	A literature review produced 26 papers that related to the topic. Articles discussing a particular group of diseases were excluded, as the focus was on the needs of frail older people with complex needs. Criterion for inclusion of older people in the programs was either having a chronic disease combined with receiving care from at least two professionals or nonprofessional caregivers and living independently in the community.	Case management interventions included traditional tasks (case finding, assessing, planning, implementation, coordination and monitoring, and evaluation of options); comprehensive (outreach, client assessment, advocacy, etc.); extensive (medication and symptom management, caregiver and family supportive counseling).	Case management includes a range of interventions, but the core of the intervention is a task-focused approach, with parallel functions added (interagency coordination, bereavement counseling) depending on the individual's situation. The effect of case management interventions studied showed a range of outcomes. The content of case management needs to be expanded and influenced more by a salutogenic, rehabilitative, and family-oriented health care approach. Nurses, preferably trained in gerontological nursing, have a key role in case management for frail older people. Nurses as case managers, along with a geriatric team, can solve difficult problems. Case management has not been standardized and usually does not take a deliberate preventive and/or rehabilitative approach, using psycho-educative interventions focusing on self-care activities, risk prevention, disease management, community involvement, and functional ability.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design and Outcome Measures	Study Setting & Study Population	Study Intervention	Key Finding(s)
Heath 2005[151]	Assessment of prevalence of remediable health conditions from in-home geriatric assessments of referred adult protective services. Elder mistreatment has a significant impact on mortality of victims.	Retrospective cohort study	Assessments were conducted with referred elders by a nurse-practitioner-geriatric physician team, including a detailed medical and functional history, physical exam. (Level 5) Classifications of mistreatment (neglect, financial exploitation, abuse) were employed from the NJ State Dept. of Health and Senior Services as independent variables. Descriptive statistical analysis. (Level 3)	211 adult protective services referred to the Linking Geriatrics With Adult Protective Services program in central New Jersey.	None	The predominance of neglect among the subjects is consistent with the known national distribution of various forms of elder mistreatment. A high level of dementia and depression was also consistent with that found in neglected populations.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design and Outcome Measures	Study Setting & Study Population	Study Intervention	Key Finding(s)
Hellstrom 2004[152]	While health problems can reduce quality of life (QoL), dependency on others may also influence how people perceive their QoL. Understanding how living with health-related assistance at home affects peoples' lives can inform what nursing care should focus upon.	Cross-sectional (survey)	Survey (Level 3) Comparison of people 75 years and older, living at home and receiving help with daily living, with those without such help, with regard to sociodemographic data, self-reported illness, health problems, and QoL (Level 3)	1248 subjects (448 receiving help; 793 not receiving help; age stratified randomized sample) responded to a mailed survey in a southern Swedish municipality.	None	Although symptoms of health-related problems did determine QoL, it was specific symptoms and living conditions that predicted low QoL. Therefore, it is especially important to focus on these symptoms in nursing care. The transition from living independently to receiving help from others probably contributes to a change of values and attitudes about what is important in life. This indicates that an assessment of various symptoms and their importance for each individual is vital. There is a need for thorough assessment and monitoring, e.g. by a nurse, of older people who are living at home and who are restricted in their resources in handling daily living.
Heinrich 2003[25]	Support to caregivers of dementia patients; guidance from health personnel.	Non-comparative	Secondary analysis interviews (Level 4) Interview focus groups analysis (Level 3)	Interviews of 20 women who were caregivers and new data from 8 volunteers; 62 interviews total for analyses.	None	Wanted mutuality in decisionmaking with staff and partnership and empowerment. Community resources use was the experience they described. Struggled with personnel.

Hepburn 2003[117]	Caregiver well-being, burden, emotional enmeshment	Changing practice projects	Training program descriptive field study (Level 6) Well-being, burden, goal setting. Burden CESD competence. (Level 4)	140 caregivers, 40% spouses, 47% adult, children	Manual, CD-ROM, workshops for caregivers	Improved reaction to caregiver behavior burden, emotional enmeshment changed, descriptive, increased skill, knowledge, confidence.
Houts 1996[81]	Establishment of a prescriptive problem-solving model for family members who care for patients at home can help caregivers develop and carry out orderly plans that address both medical and psychosocial problems and coordinate with care plans of health professionals.	Published guidelines	Proposal of a model for problem-solving in caregiving (Level 6) No outcome measures (Level 4)	None	None	The role of caregivers needs to be restructured to ensure they become effective members of the health care team. This requires educational materials and training programs.
Jang 2004[73]	Depression diminishes response to helping patient.	Randomized controlled trial	Spouse caregiver, AD patients, RCT (Level 2) Counseling, neuroticism, depression (Level 3)	160 in each group; caregivers, spouses caring for patient with dementia	Enhanced psychosocial care or usual care. Comprehensive, counseling sessions, counseling support and consultation (2), and family (4) sessions, then weekly groups 4 months later with ad hoc individual sessions as needed—usual care group.	Caregivers low in neuroticism responded with declining levels of depression, caregiver's height in neuroticism maintained baseline level of depression.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design and Outcome Measures	Study Setting & Study Population	Study Intervention	Key Finding(s)
Kozachik 2001[112]	With a shift to outpatient cancer care and increased responsibilities placed on family members, a greater potential exists for depressive symptoms to arise in a family caregiver.	Randomized controlled trial	Convenience sampling. Control dyads and experimental group that received Cancer Care intervention. (Level 2) Equivalence of groups at baseline; comparison of caregiver depression; impact of patient depression, patient symptoms, caregiver exposure to supportive nursing intervention on caregiver depression (Level 1)	120 caregiver/patient dyads. Caregivers of newly diagnosed cancer patients. Patients were from two Midwestern cancer treatment sites.	Nursing intervention of symptom monitoring/ management, education, emotional support, coordination of services, caregiver preparation to care.	Baseline caregiver depression and the number of patient symptoms at baseline were significant predictors of caregiver depression at 9 and 24 weeks. However, no main effect of the experimental condition existed on caregiver depression; a nonsignificant relationship was found between the number of interventions and depression scores for caregivers.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design and Outcome Measures	Study Setting & Study Population	Study Intervention	Key Finding(s)
Kurtz 1994[26]	Depression, health impact.	Cross-sectional studies	Descriptive interviews (Level 4) Issues addressed most frequently occurring symptoms, levels of symptom severity, immobility, dependences in ADLs, and depression variance. (Level 3)	Family caregiver experiences at different stages of patient illness, mean age 55, N = 208. Followed for 12 months.	None	Family caregiver variables of depression, impact on health, impact on schedule, and assistance with ADLs were correlated significantly with all patient variables. Family caregivers of elder patients were less depressed and perceived less impact of their schedules. As stage levels of depression progressed, there was a greater impact on caregivers' health and schedule, and increased involvement in assisting their patients with ADLs, closely mirroring the increasing progression with levels of the patient variables. As increased demands on the family caregiver occurred during the later stage of illness, physical and emotional support for the family caregiver did not occur.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design and Outcome Measures	Study Setting & Study Population	Study Intervention	Key Finding(s)
Mahoney 2003[75]	Caregiver bother and depression anxiety	Randomized controlled trial	Multisite randomized trial (Level 2) Bother, anxiety, depression mastery (Level 4)	100 AD caregivers, 50 in usual care and 49 in technology group	Year-long access to an automated interactive voice response system. Provided stress monitoring, counseling system, voice mail links to AD experts, voice mail telephone support group, and a distraction call for care recipients.	Improved caregiver bother and depression for those with lower mastery at baseline. Improved caregiver burden for wives. Affected bother, anxiety, and depression. Benefit from technology.
McCurry 2005[82]	Caregiver sleep	Randomized controlled trials (for caregiver)	Randomized trial (Level 2) 36 Community Developing CESD, Cornell Depression Scale. Problem checklist - Pittsburg Sleep Index (Level 3)	36 dyads who had a sleep problem	Sleep hygiene, daily walking, daily light exposure (over 3 weeks), written materials, principles of sleep hygiene, control group, general instructions	Improve percent sleep time and total sleep time, fewer waking periods per hour at post-test and 6 months, used actigraph. Effective, MR, control patients spent more time in bed.
McMillan 2006[83]	Mastery burden	Randomized controlled trial three-group design	Randomized controlled trial (Level 2) Coping burden mastery (Level 3)	354 family caregivers with patients with terminal cancer. Three interventions: (1) standard hospice care, (2) hospice care plus three supportive visits, (3) hospice care plus problem-solving training	Coping skills	Improved family coping. Improved caregiver QoL, reduced task burden.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design and Outcome Measures	Study Setting & Study Population	Study Intervention	Key Finding(s)
Mailey 2002[153]	The nurse's role of educating client's about their health care is an important component of quality care and can be key to successfully coping with a disastrous event.	Changing practice projects/ research	Theory application (Level 6) Neal Theory of Home Health Nursing (Level 4)	None	None	After determining which of Neal's stages (dependence, moderate dependence, autonomy, or collaborator) a nurse occupies, an agency can provide the appropriate resources (training, checklists, supervision, mentoring) the nurse needs (and can communicate to the caregiver) to function effectively in a disaster.
Miller 2006[85]	Caregivers' harmful behavior toward patients	Non-comparative	Descriptive (Level 5). Onetime measures; amount of care provided CO, depression (Level 3)	180 caregiver-care recipient dyads.	None	Compromised cognitive status in 39%; caregiver probably affects the quality of care.
Mittelman 2004[88]	Prevent negative responses to patients' troublesome behaviors	Randomized controlled trial	Randomized controlled trial (Level 2) Problem behavior checklist (Level 3)	406 spouses, caregivers.	Counseling and support and usual care counseling for 4 months, then support groups and ad hoc counseling.	Caregiver distress decreased over time from year 1 to year 4. RCT, effective

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design and Outcome Measures	Study Setting & Study Population	Study Intervention	Key Finding(s)
Mittelman 2004[89]	Fewer depressive symptoms	Randomized controlled trial	Randomized controlled trial (Level 2) Geriatric depression scale (Level 3)	406 spouses, caregivers of dementia patients.	Counseling sessions; individual (2) and family (4) sessions, then weekly groups 4 months later with ad hoc individual sessions as needed.	No difference in depression at 4 months, but significant differences at all other points up to 3 years after enrollment.
Metlay 2005[90]	In the outpatient setting, patients and their caregivers play a critical role in ensuring the safe use of medical therapies. Knowledge of the causes of medication errors can inform the design of medication-taking interventions.	Cross-sectional	Prospective cohort study (Level 4) Telephone interviews. Demographic characteristics of survey participants were compared to characteristics of nonparticipants in the PACE program. Five groups were identified for sampling by medication use. Interview responses to specific medication information and medication organization questions were compared across drug categories using chi-square tests (Level 3).	4,955 Pennsylvania Pharmacy Assistance Contract for the Elderly (PACE) members (65 years and older) who were taking warfarin, digoxin, and phenytoin (half of whom lived home alone)	None	Almost one-third of subjects reported not receiving any instructions on the use of their medications. Approximately 40% used no organizational system to adhere to medication regimens. A substantial proportion of older adults on high-risk medications do not recall receiving instructions for the use of their medications and do not take advantage of existing systems for organizing medication regimens.

Naylor 2000[154]	Identification of problems experienced by elders who were hospitalized and discharged to home.	Noncompara-tive	Content analysis of patient records by advanced practice nurses (Level 5) Problems encountered by discharged elders, interventions used by advanced practice nurses with patients, linkages between patient problems and advanced practice nurse interventions (Level 3)	Sample records obtained from 124 intervention group patients in a large randomized clinical trial.	None	Most problems experienced were either psychological in nature or related to health behaviors. The majority of interventions for both study groups could be linked to problems of circulation and discharge planning.
Naylor 2000[155]	An effective hospital discharge process can contribute to reduced costs and more positive care outcomes for caregivers and their patients at home.	Systematic literature review	Systematic review (Level 1) Development of a transitional care model (Level 6)	None	None	This program of research has increased an understanding of the differential effects of the model on elders with medical versus surgical cardiac conditions, the profile of elders at risk for poor outcomes, predictors of caregiver burden, the unique needs of elders and the contributions of advanced practice nurses in meeting these needs, and decisionmaking regarding home care referrals.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design and Outcome Measures	Study Setting & Study Population	Study Intervention	Key Finding(s)
Naylor 2004[156]	Patients and caregivers report substantial numbers of unmet needs resulting from inadequate discharge procedures.	Randomized controlled trial	Two randomized groups (Level 2) Time to first rehospitalization or death, number of rehospitalizations, quality of life, functional status, costs, satisfaction with care (Level 3)	Six Philadelphia academic and community hospitals. 239 patients ages 65 and older and hospitalized with heart failure.	3-month advanced practice nurse-directed discharge planning and home followup protocol.	Time to first readmission or death was longer in intervention patients. For intervention patients, only short-term improvements were demonstrated in overall quality of life, physical dimension of quality of life, and patient satisfaction.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design and Outcome Measures	Study Setting & Study Population	Study Intervention	Key Finding(s)
Ohman 2004[127]	Establishment of a close relationship between district nurses and people with serious chronic illness and their close relatives can increase the health personnel's possibility to alleviate and console those suffering illness, and can be useful for reflection of care interventions, in education and supervision of district nurses.	Non-comparative	Phenomenological hermeneutic (Level 5) Interviews with a narrative approach; interpretation of text in three phases: naïve understanding, structural analysis, interpretation of the text as a whole (Level 3)	Sweden. Purposive sample of 10 female district nurses, between ages 50 and 62 with work experience of 2–20 years.	None	The meaning of district nurses' (DNs) experiences of encounters with people with serious chronic illness and their close relatives at home can be understood as DNs being welcomed into the ill person's privacy, to share intimacy and their understanding of illness. This is expressed in three themes: being in a close relationship, sharing an understanding, weaving a web of protection. Listening was a prerequisite for being able to help and support people. A communicative process (interpretation of body language and verbal communication) has the function of establishing a common environment or shared world of meaning. It is difficult for DNs to escape the close relationship after it is established.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design and Outcome Measures	Study Setting & Study Population	Study Intervention	Key Finding(s)
Pot 2005[157]	Elders receiving professional long-term care (vs. informal or no care) may experience increased stress and increased risk of depressive symptoms.	Time series (longitudinal)	Part of the Longitudinal Aging Study Amsterdam. Linear regression analysis (generalized estimating equations). (Level 4) Survey data gathered in 3,107 face-to-face interviews in respondents' homes, with followup interviews after 3 and 6 additional years. Independent variables used to evaluate the dependent variable of depression were (a) from no or informal care to professional home care, (b) from no or informal care to institutional care, (c) continuing professional home or institutional care, (d) from institutional or professional home care to no or informal care. (Level 3)	The Netherlands. Random, nationally representative age- and gender-stratified sample of adults 55–85 years old.	None	There was an association between professional care utilization and depressive symptoms over time, and between transitions in professional care and changes in depressive symptoms. Older adults with a transition to professional care reported considerably more depressive symptoms compared with those who did not receive professional care. Older adults who had a backward transition, from professional care to no or informal care only, did not show such change in depressive symptoms.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design and Outcome Measures	Study Setting & Study Population	Study Intervention	Key Finding(s)
Rose 2000[17]	Combined knowledge of family caregivers and staff nurses can foster comprehensive and appropriate posthospital care.		Open-ended interviews with content analysis (Level 5) Nurses' perceptions of patients and family caregivers, family caregiver's perception of patients and themselves near admission and discharge from hospital (Level 4)	37 caregivers and 37 nurses who were present for discharge but not admission of patient.	None	Suggests a lack of agreement between staff nurses and family caregivers on health issues related to hospitalized older patients.
Roth 2005[77]	Caregiver depression	Randomized controlled trial	Randomized controlled trial (Level 2) Geriatric depression, satisfaction with social support (Level 3)	406 spouses, caregivers of dementia patients	Individual and family counseling; five 90-minute home visits focusing on education and environmental modification every other week over 3 months. Enhanced social support.	Improved number of support persons, satisfaction with support network, and support persons' assistance with caregiving. Increased satisfaction with social support network mediated a significant proportion of the intervention's impact on caregiver depression.
Schulz & Beach 1999[21]	Caregiving as a risk factor for mortality	Perspective population cohort study with 4.5 years of followup	Survey (Level 4) Morbidity, caregiver strain (Level 3)	Population based, community based	None	Caregivers who were providing care and experienced strain had risks 63% higher than noncaregiving controls. Mental or emotional strain is a risk factor for mortality among elderly spousal caregivers.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design and Outcome Measures	Study Setting & Study Population	Study Intervention	Key Finding(s)
Schulz & Beach 1999[21]	Death of caregiver spouses	Prospective cohort	Survey. Prospective population-based cohort study with 4–5 year followup. (Level 4) Mortality, caregiver strain (Level 2)	392 caregivers and 427 noncaregivers, ages 66–96 living with spouses	None	Asked if they were experiencing caregiver strain after 4 years of followup, participants providing care who had strain reported mortality 63% higher than noncaregiving controls, and caregivers with no strain did not have elevated mortality rates.
Schumacher 1998[158]	Identification of concepts related to doing family caregiving well.	Systematic literature review	Systematic review (Level 1) Concepts organized into those referring to caregivers perceptions of how well they provide care and those that refer to professional assessment of the quality of care (Level 4)	None	None	Two issues that should be addressed to advance research are the perspective taken on doing caregiving well and change over time in doing caregiving well.
Silver 2004[159]	Core competence and care effectiveness	Noncompara-tive	Descriptive study (Level 5) Caregiver competence and effectiveness (Level 3)	Interviews of 30 family caregivers during first 3 months	None	Caregivers provided an average of 19 tasks per day. The tasks included functional, care management and technical, nutrition-related tasks. Low caregiver preparedness was associated with unmet training needs and low self-rated caregiver effectiveness.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design and Outcome Measures	Study Setting & Study Population	Study Intervention	Key Finding(s)
Sit 2004[143]	Family caregivers of stroke patients often do not have the requisite knowledge and skills to provide the extensive care needs of stroke survivors. The demands and stress of caring for the family member can result in the caregiver becoming a "second patient."	Cross-sectional (descriptive)	Family caregivers participated in face-to-face interviews 12 weeks after starting stroke caregiving role at home (Level 5). Interview guide consisted of four sections: demographics, assessment of stroke survivor's current health status, assessment of social support for the subject, caregiver's general health. Regression analysis applied to responses to open-ended questions (Level 3)	Hong Kong. 102 Mandarin or Cantonese-speaking subjects obtained from four rehabilitation hospitals with established stroke rehab units.	None	After 12 weeks, nearly half of the caregivers reported having somatic symptoms and fatigue to the extent that they needed to see a physician. Unmet social support needs were identified as tangible support, including provision of equipment, transportation, financial, respite; informational support, including guidance in health-related care task at home; structural support, including a network of people supplying support. Social support can have a positive impact on caregiver health, and nurses are in an excellent position to advance their practice by offering this professional support by extending nursing care beyond the hospital boundary. Nurses can mobilize supportive resources in the caregiver's natural network or provide a “created” network to supplement the insufficiency of the family caregiver's existing network during the period of stress and transition.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design and Outcome Measures	Study Setting & Study Population	Study Intervention	Key Finding(s)
Smeenk 1998[160]	Patients with complex health care problems being cared for at home are often cared for by numerous professional caregivers. These caregivers may be providing "parallel" vs. "coherent" care, due to communication gaps, which can result in inadequate care for the patient.	Cross-sectional	Direct and professional caregivers of eligible subjects generated reports (Level 3) Costs and time spent providing care was recorded. Professional and direct caregivers completed a questionnaire after patient's demise, asking opinions on various aspects of intervention. (Level 5)	Terminal cancer patients in the Netherlands. Patients were followed until demise.	Transmural home care intervention program: a specialist nurse coordinator managed discharge from hospital and organized home care; 24-hour phone consultation; dossier maintained at home for various caregivers; specific care protocols established.	Patient, direct and professional caregivers showed that the specialist nurse coordinator and the 24-hour phone service were important components of the intervention. Most of time spent by specialist nurse coordinator was spent in contact with patients and families. Physicians were seen as having a limited role.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design and Outcome Measures	Study Setting & Study Population	Study Intervention	Key Finding(s)
Sorensen 2002[72]	Family caregivers of elderly persons with physical ailments and/or dementing illnesses often experience high levels of stress, which can lead to a lowered sense of well-being, feelings of being burdened, depression, compromised physical health, and even premature mortality.	Meta-analysis	A comprehensive literature review and the "ancestry method" (Level 1) Identified 78 eligible studies. Outcome measures were caregiver burden, self-rated depression, subjective well-being, uplifts, ability and knowledge, care receiver outcomes. (Level 4)	For eligible studies: number of intervention sessions ranged from 1 to 180; followups were conducted in 22% of cases; number of participants in the experimental intervention condition ranged from 4–2,268; mean age of caregiver was 62.3; caregivers had been providing care for an average of 4 years with 30 hours/week of care; most studies were conducted with heterogeneous disabilities samples; 60 studies were in North America, 11 in Europe, 7 in Australia.	Psycho-educational, supportive, respite/adult day care, psychotherapy, improvement of care receiver competence, multicomponent	Interventions are, on average, successful in alleviating burden and depression, increasing general subjective well-being, and increasing caregiving ability/knowledge. The majority of these effects persist after an average of 7 months after intervention. Providing psycho-educational interventions, psychotherapy, and a combination of several of these interventions is most effective for improving caregiver well-being in the short term. Individual interventions were more effective at improving caregiver well-being, whereas interventions in groups were more effective at improving care receiver symptoms.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design and Outcome Measures	Study Setting & Study Population	Study Intervention	Key Finding(s)
Steffen 2000[57]	Anger and hostility experienced by caregivers can impact psychosocial functioning.	Randomized controlled trial	Interviews of three groups: wait-list comparison, home-based viewing with weekly phone session, class-based viewing (Level 2) Demographics, self-reported anger intensity, depression, caregiving self-efficacy, telephone contacts (Level 3)	33 caregivers of Alzheimer's patients or other dementing disorder. Recruited through various methods. Provide 5 hours weekly of face-to-face direct care.	8-week psycho-educational video series for anger management, workbook.	Family caregivers may benefit from innovative anger management interventions based on cognitive/behavioral principles and techniques.
Teng 2003[162]	Early supported discharge programs may decrease hospital costs without having a negative effect on patient outcomes.	Randomized controlled trial	Two groups randomized to home intervention or usual care (Level 2) Interviews ascertained self-rated physical health; costs estimated for acute-care hospitalization, outpatient care, and in-home care; caregiver stress (Level 3)	Stroke patients who required rehabilitation services and had a caregiver at home.	4-week, tailor-made home program of rehabilitation and nursing services.	Providing care at home was no more (or less) expensive for those with greater functional limitations than for those with less. Caregivers in the early supported discharger group scored lower on the Burden Index than caregivers with usual care.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design and Outcome Measures	Study Setting & Study Population	Study Intervention	Key Finding(s)
Toseland 2004[118]	Health education programs can help caregivers reduce depression, increase knowledge of community services and how to access them, change caregivers feelings of competence and how they respond to the caregiver situation.	Randomized controlled trial	Two-level randomized controlled trial (Level 2) General Health Questionnaire, Medical Outcome Short Form Health Survey, Social Provisions Scale, psychological well-being, perceived social support, subjective burden (Level 3)	Caregivers of spouse with chronic illness who was a member of a staff model HMO. Minimum score of 7 on Caregiver Strain Index. Care recipients with at least two impairments in ADLs. Total of 105 caregiver-care recipient dyads.	Multicomponent psycho-educational health education program. Consisted of 8 weekly sessions, followed by 10 monthly sessions.	Caregivers reported that by end of 1 year, they felt the health education program helped them learn about community resources and how to access them.
Travis 2000[12]	Improving understanding of how family caregivers deliver complex care can result in better care.	Noncompara-tive	Semistructured, face-to-face interviews (Level 5) Content analysis to capture the shared and idiosyncratic experiences of individuals responsible for all aspects of medication administration. Three categories of medication administration hassles were identified: scheduling logistics, administration procedures, and safety issues. (Level 3)	23 family caregivers providing 122 separate accounts.	None	Primary care providers must continually reevaluate and simplify medication regimens for dependent elderly persons in the care of family members, and the family caregivers must be given adequate training and access to ongoing information support systems to help them perform safe and effective medication administration responsibilities.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design and Outcome Measures	Study Setting & Study Population	Study Intervention	Key Finding(s)
Visser-Meily 2005[74]	Identification of effectiveness of different types of intervention programs for caregivers of stroke patients.	Systematic literature review	Systematic review (Level 1) Four types of support groups identified: providing specialist services, psycho-educational, counseling, and social support by peers; various outcome measures (reduction of depression and burden, improvement of knowledge, satisfaction with care, family functioning, quality of life) (Level 5)	22 studies, a critical review	None	Could not identify sufficient evidence to confirm the efficacy of interventions, but counseling programs appeared to have the most positive outcome.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design and Outcome Measures	Study Setting & Study Population	Study Intervention	Key Finding(s)
Ward-Griffin & McKeever 2000[140]	Quality of care delivered by informal caregiver, contingent upon communication and relationship with nurse	Cross-sectional	Critical ethnography—socialist-feminist perspective (Level 5) 38 in-depth focused interviews (average 75 min. in length) from 23 family caregiver-nurse dyads; data analysis through use of NUD*IST software (Level 3)	Dyads were acquainted 3 months–14 years; sample drawn from three nonprofit, publicly funded community nursing agencies in southwestern Ontario. Average age of nurses was 47 years (one male only); family caregivers' age was 33–82 years (all female); elder care recipients' age was 65–99 years.	None (interaction only)	Relationships between family and professional caregivers appear to be exploitive in nature (economic vs. humanitarian). Family caregivers were contributing more effort toward caring for recipients than nurses, and were not receiving adequate resources to assure minimization of risk to care recipients. Improved communication between formal and informal caregivers may lead to coalition building and collective lobbying for resources, but ultimately a "transformation of the broader political and economic conditions of home care is necessary" for an equitable sharing of caregiving responsibilities.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design and Outcome Measures	Study Setting & Study Population	Study Intervention	Key Finding(s)
Weuve 2000[139]	Outpatient geriatric evaluation and management (GEM) may alleviate caregiver burden, e.g., physical, psychological, social, and economic distress.	Randomized controlled study	Randomized controlled trial (Level 2) Assessed caregiver burden by telephone interview survey, using a Likert scale. Statistical analysis used to compare burden scores of control and treatment group. (Level 3)	568 high-risk older adults living in the community who were fee-for-service Medicare beneficiaries age 70 or older living in or near Ramsey County, Minnesota.	Participants in the control group received all health care from their usual providers; GEM participants were assigned to one of three clinical teams, each composed of a geriatrician, a nurse, a social worker, and a gerontological nurse practitioner for 6 months. GEM participants (outpatient) received counseling from the team until it was determined that the participant had attained GEM goals or was adhering to a comprehensive plan of care. Caregivers were assessed for burden at baseline and 1 year later. Caregivers did not receive a standard intervention, although they received resource referrals.	GEM and control caregivers were similar at baseline. During the 1-year observation period, mean burden scores of GEM caregiver group tended to decline, while mean scores of control tended to increase or decline less substantially. Assignment to GEM was associated with a reduction in the amount of time caregivers devoted to assisting recipients in some specific tasks. Caregivers who were less experienced and less closely related to their care recipients tended to benefit more from GEM.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design and Outcome Measures	Study Setting & Study Population	Study Intervention	Key Finding(s)
Williamson & Shaffer 2001[163]	Potentially harmful behaviors to patients	Non-comparative	Descriptive interviews (Level 5) Caregiver depression (Level 3)	142 caregivers—98 wives, 44 husbands—interviewed	None	Depressed caregivers are more likely to treat spouses in hurtful ways. Premorbid relationships were directly related. If perceived as rewarding, less depression and less harmful behaviors.
Zarit 1998[79]	Family caregivers of dementia patients can suffer overwhelming and uncontrollable stress that can take a toll on emotional health and well-being. Programs can be developed to relieve these negative effects.	Non-randomized trials	Quasi-experimental comparing two groups of primary family caregivers who enrolled relatives in adult day care (Level 3) Caregivers were interviewed at three intervals over 1 year.	Treatment group comprised of caregivers in New Jersey with relatives enrolled in day care; control group was from another state and relatives were not in day care.	Caregivers in treatment group used substantial amounts of day care services.	Use of adult day care by caregivers of dementia patients results in lower levels of caregiving-related stress and better psychological well-being when compared to that of controls.
Zarit 1986[164]	Caregiver burden can affect quality of life and decisions to institutionalize.	Time series	Interviews (Level 5) Caregiver burden, severity of impairment, social support, quality of relationship, placement decision factors (Level 3)	64 caregivers for a spouse with senile dementia, recruited from a clinic offering counseling and support to caregivers, and membership lists from an Alzheimer's disease advocacy group.	None	Severity of the patient's symptoms did not differentiate caregivers who placed relatives from those who did not.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design and Outcome Measures	Study Setting & Study Population	Study Intervention	Key Finding(s)
Zwygart-Stauffacher 2000[134]	It appears that there is a discrepancy between the perceived needs of stroke survivors and their caregivers and those of health professionals. Stroke survivors' and caregivers' perspectives as to their needs are critical if professionals are to identify unmet needs and deliver health care that is truly high quality and client centered.	Cross-sectional	Phase I: Twelve focus group and individual interviews, with 47 stroke survivors, caregivers, and professionals from the community (Level 5) Asked caregiver to rate importance of needs and degree to which need had been met. Factor analysis done on needs of survivors and caregivers. (Level 3)	281 stroke survivors and 223 caregivers completed the mailed survey.	None	For both caregivers and survivors, the most highly rated domain for importance was the need for information. Both survivors and caregivers identified the importance of clear information about medications, tests, and treatments, as well as wanting time for questions to be answered and resources. The nurse is pivotal in activating discharge services and facilitating smooth transition of care across health care settings. The nurse can provide caregivers more information on what they can expect through written, verbal, and electronic means.

Chapter 15. Pediatric Safety and Quality

Susan Lacey, Janis B. Smith, Karen Cox

Background

Pediatric inpatient safety and quality of care are dynamic and complex phenomena. Our intent is to inform the reader about efforts underway by pediatric stakeholders and specialty groups and to understand where credible information can be accessed pertaining to patient safety and quality in the provision of care for the hospitalized child. Over the past several years, pediatric groups have partnered to improve general understanding, reporting, process improvement methodologies, and quality of pediatric inpatient care. These collaborations have created a robust program of projects, benchmarking efforts, and research.

This chapter discusses general findings about safety and quality; major initiatives by agencies, groups, and collaborations; a guide to synthesis documents surrounding quality care and evidence-based practice for specific areas of pediatric care; and recommendations about how we can move pediatric safety and quality forward in practice and in the policy arena.

Patient safety literature and associated findings on adverse events for pediatric patients have been widely disseminated.[1–9] Much of the focus has centered on medication errors—the most frequently reported adverse event for both adult and pediatric patients. Indeed, the Institute of Medicine (IOM) reported that medication errors are the most common, yet preventable, type of harm that can occur within the pediatric population,[10] and Bates[11] reported that when pediatric medication errors occur, these patients have a higher rate of death associated with the error than adult patients.

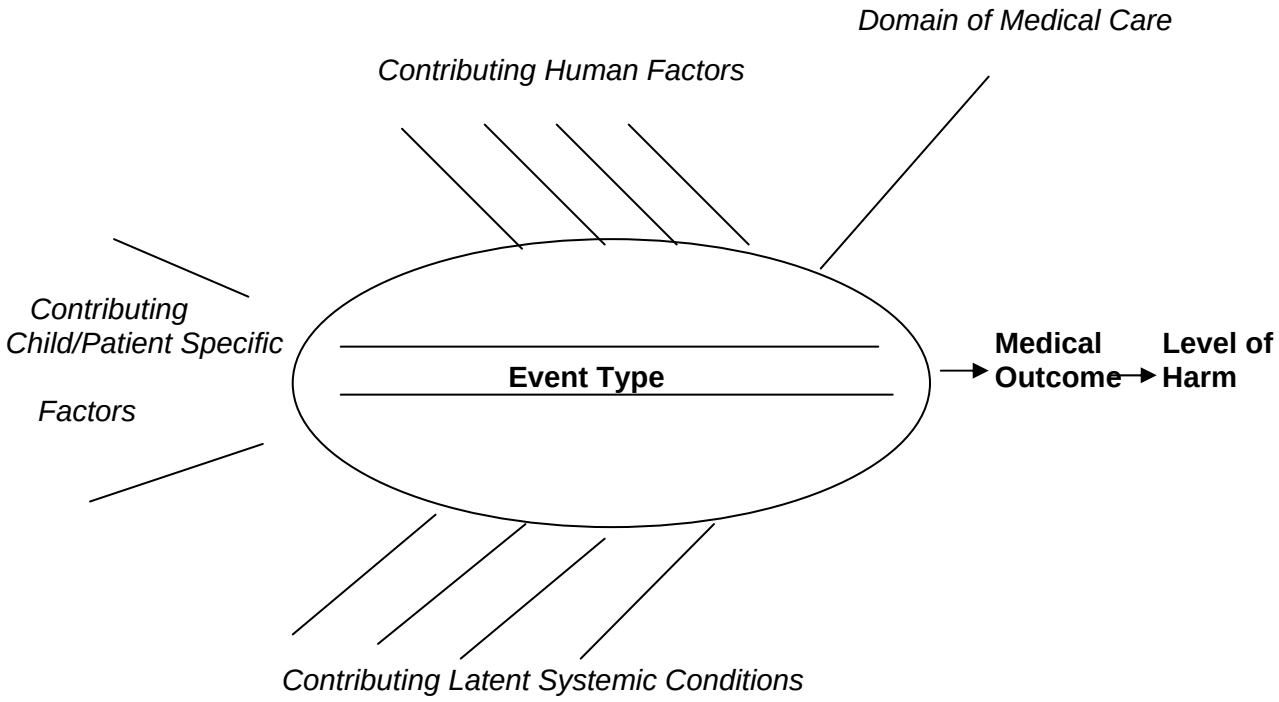
Medication errors, however, are only one potential adverse event for hospitalized children. Slonim and colleagues[4] found 1.86–2.96 medical errors per 100 discharges of hospitalized children. Four distinct challenges confront those conducting research and caring for children.[12] These four related issues are each problematic, but in concert they create a high-risk environment for hospitalized children. Following are the four issues for pediatric patients, summarized from Beal and colleagues:[12]

- Development: As children mature both cognitively and physically, their needs as consumers of health care goods and services change. Therefore, planning a unified approach to pediatric safety and quality is affected by the fluid nature of childhood development.
- Dependency: Hospitalized children, especially those who are very young and/or nonverbal, are dependent on caregivers, parents, or other surrogates to convey key information associated with patient encounters. Even when children can accurately express their needs, they are unlikely to receive the same acknowledgment accorded adult patients. In addition, because children are dependent on their caregivers, their care must be approved by parents or surrogates during all encounters.
- Different epidemiology: Most hospitalized children require acute episodic care, not care for chronic conditions as with adult patients. Planning safety and quality initiatives within a framework of “wellness, interrupted by acute conditions or exacerbations,” presents distinct challenges and requires a new way of thinking.

- Demographics: Children are more likely than other groups to live in poverty and experience racial and ethnic disparities in health care. Children are more dependent on public insurance, such as State Children's Health Insurance Program (SCHIP) and Medicaid.

All quality research is challenged to standardize frameworks and language under which all care providers operate. Each population has unique language and focused areas with no current common language across all specialty areas. Pediatric safety and quality efforts are further challenged as most of the work on patient safety to date has focused on adult patients. There is no standard nomenclature for pediatric patient safety that is widely used. However, a standard framework for classifying pediatric adverse events that offers flexibility has been introduced.[13] The model, seen in Figure 1, allows for analysis and depicts the relationships and interactions of the elements of an event.

Figure 1. Conceptual Model of a Patient Safety Taxonomy



Standardization provides consistency between interdisciplinary teams and can facilitate multisite studies. If these large-scale studies are conducted, the findings could generate large-scale intervention studies conducted with a faster life cycle. More rapid acceptance of efficacious improvement strategies should result.

Leaders in Pediatric Safety and Quality

Agency for Healthcare Research and Quality

The Agency for Healthcare Research and Quality (AHRQ) is the Federal authority for patient safety and quality of care. AHRQ has been a leader in funding safety and quality improvement efforts, synthesizing and disseminating findings to clinicians and the public for more than two decades to stimulate both scientific and policy dialogue. AHRQ has been a leader in pediatric quality and safety. Within the agency, the Children's Health Advisory Group is a resource for AHRQ's senior leaders that helps focus work in key topic areas as the state of the science changes. A focus of AHRQ funding is translational research, which moves scientific findings to health care settings across the care continuum. Projects funded by AHRQ help determine where gaps in safety and quality exist.[14]

AHRQ also sponsors the Health Cost and Utilization Project (HCUP), a family of databases supported by a Federal-State-industry partnership. One of the databases is the Kids Inpatient Database (KID). HCUP is the largest information source of patient encounters in both inpatient and outpatient settings. All HCUP databases contain more than 100 variables linked to patient care, including both clinical and charge data. All patient identifiers are removed to protect patients' confidentiality. The HCUP databases are used by clinicians and health services researchers to investigate care delivery and discover trends in outcomes and costs. They are also used internally at AHRQ for special projects, such as the development of pediatric indicators outlined in the next section.

The initial AHRQ work on pediatric patient safety was conducted by investigators from Johns Hopkins, using the KID database for the year 1997.[4] However, Miller, Elixhauser, and Zhan[5] conducted a more recent review of potential pediatric safety issues by using the previously defined adult indicators. They found that hospitalized children who experienced a patient safety incident, compared with those who did not, had

- Length of stay 2- to 6-fold longer
- Hospital mortality 2- to 18-fold greater
- Hospital charges 2- to 20-fold higher

Another key finding in this initial work demonstrated that severity of illness and type of hospital are directly associated with patient safety incidents, except for birth trauma. Birth trauma was directly associated with African American and Hispanic race, but not type of hospital.

Subsequently, AHRQ sought to develop pediatric quality indicators with the goal to "highlight areas of quality concern and to target areas for further analysis."[15] Nominated peer reviewers from 44 professional clinical organizations joined this effort. Each had to spend the majority of his or her time in direct clinical practice. Development of the PedQIs is the result of Phase I of this work. The complete report, *Measures of Patient Safety Based on Administrative Data: The Patient Safety Indicators*, was published in February 2006.

After rigorous review, 18 pediatric quality indicators were recommended for inclusion in the AHRQ quality measure modules, based on expert input, risk adjustment, and other considerations. Thirteen inpatient indicators are recommended for use at the hospital level, and five are designated area indicators. Inpatient indicators are treatments or conditions with the greatest potential of an adverse event for hospitalized children. Area-level indicators are intended

to measure access to care and have the potential to reduce hospitalization and subsequent untoward events. Table 1 presents the AHRQ pediatric quality indicators.

Table 1. Pediatric and Area-Level Indicators

Pediatric Quality Indicators **Provider-Level Indicators**	**Area-Level Indicators**
Accidental puncture or laceration	Asthma admission rate
Decubitus ulcer	Diabetes short-term complication rate
Foreign body left during procedure	Gastroenteritis admission rate
Iatrogenic pneumothorax in neonates at risk	Perforated appendix admission rate
Iatrogenic pneumothorax in nonneonates	Urinary tract admission rate
Pediatric heart surgery mortality	
Pediatric heart surgery volume	
Postoperative hemorrhage or hematoma	
Postoperative respiratory failure	
Postoperative sepsis	
Postoperative wound dehiscence	
Selected infections due to medical care	

Source: Agency for Healthcare Research and Quality—www.qualityindicators.ahrq.gov.

Phase II of this project will extend the work to include indicators of neonatal care quality. In addition, methodological issues associated with risk adjustment require refinement to reduce variation in coding patient care for future comparison studies. Possible additions to the dataset will address the patient's condition on admission and increase the understanding of how laboratory and pharmacy utilization impact patient outcomes. AHRQ will continue to work with health care providers to refine the area-level indicators to improve outcomes for children receiving outpatient care and reduce the incidence of hospitalization for those defined conditions.

The findings of AHRQ-funded research provide Congress with critical information about patient safety and quality of care for the American people. This work will influence Federal funding for projects related to improving health care safety and quality for children. (See AHRQs' Web site, www.ahrq.gov, for more information.)

National Guideline Clearinghouse and National Quality Measures Clearinghouse

The National Guideline Clearinghouse is a public resource for evidence-based clinical practice guidelines, while the National Quality Measures Clearinghouse is a repository of evidence-based practice measures and measure sets. These entities, both initiatives of AHRQ, offer consumers and clinicians the most recent information about the continuum of care and best practices for all health care recipients. Those which involve the provision of care to children are relevant to this chapter. Although both sources offer comprehensive guides for numerous diseases and disorders for children, there are also specific reports and documents pertinent to pediatric inpatient care. In addition, users are able to search both sites with a high level of specificity; the search for articles can be narrowed to those that are peer reviewed, by authors, by dates, etc.[16, 17]

Collaborations for Pediatric Safety and Quality

Numerous groups are actively engaged in improving pediatric care, quality and safety. Each of these groups has a unique mission and membership. Several recent efforts have these groups

working on joint projects to move things forward within their respective spheres of influence. Table 2 details these groups' missions and how to access their Web sites.

Table 2. Key Web Sites

Organization	Mission	Web Site
The National Association of Children's Hospitals & Related Institutions	Clinical care, research, training, and advocacy	www.childrenshospitals.net
Child Health Corporation of America	Business strategies, safety & quality	www.chca.com
National Initiative for Children's Healthcare Quality	Education and research	www.nichq.org
Neonatal Intensive Care/Quality & Vermont Oxford Network	Quality improvement, safety & cost effectiveness for newborns & families	www.nicq.org
Children's Oncology Group	Cures for childhood cancers, family support	www.childrensoncologygroup.org
Initiative for Pediatric Palliative Care	Education, research & quality improvement	www.ippcweb.org
End-of-Life Nursing Education Consortium	End-of-life education & support	www.aacn.nche.edu/elnec

The National Association of Children's Hospitals and Related Institutions

The National Association of Children's Hospitals and Related Institutions (NACHRI) is a not-for-profit organization of 160 member institutions in the United States, Australia, Canada, Italy, Mexico, and Puerto Rico. It supports and promotes children's health issues through clinical care, research, training, and advocacy. NACHRI works through collaborative efforts to help build measures for inpatient pediatric outcomes and is a key stakeholder in these efforts. In addition, NACHRI staff have led national focus groups to facilitate the understanding of barriers to pediatric patient safety and quality of care. The Web site can be searched for information on improvement efforts either completed or underway.[18]

Child Health Corporation of America

Child Health Corporation of America (CHCA) is a for-profit organization with membership of free-standing pediatric hospitals across the United States. Its mission is to support its membership through improved business strategies, and also through improved safety and quality of care. In fact, CHCA was the lead on the development and adoption of the pediatric core asthma measures, described below, included in the National Quality Forum work.[19]

The National Initiative for Children's Healthcare Quality

As a not-for-profit organization, the National Initiative for Children's Healthcare Quality focuses on education and research and is dedicated solely to improving the quality of health care provided to children. Founded in 1999, the National Initiative's mission is to eliminate the gap between what is and what can be in health care for all children.[20]

The Neonatal Intensive Care/Quality and Vermont Oxford Network

The Neonatal Intensive Care/Quality is a multicenter collaborative working with members of the Vermont Oxford Network, a not-for-profit organization that has as its mission to improve the quality and safety of care for newborn infants and their families through a coordinated program

of research, education, and quality improvement projects.[21] Currently, the Neonatal Intensive Care/Quality collaborative has three primary goals:

1. Achieve measurable improvements in the quality, safety, and efficiency of neonatal intensive care.
2. Develop new resources, tools, and knowledge for quality improvement in neonatal intensive care units.
3. Disseminate this improvement knowledge to the neonatal community.

Children's Oncology Group

The Children's Oncology Group is an international research organization supported in large part by the National Cancer Institute.[22] The National Cancer Institute founded the pediatric cooperative group in 1955. Since then, cure rates for children and adolescents with cancer have risen dramatically, from 10 percent to 70 percent. The Children's Oncology Group includes 500 pediatric cancer specialists from 240 pediatric institutions in the United States, Canada, and Australia. Currently more than 40,000 children, adolescents, and young adults in the United States are treated according to research protocols. A multidisciplinary approach is used, and both curative and supportive care are constantly under investigation. They way in which the Children's Oncology Group collaborates is considered the gold standard for cooperative clinical research because of its ability to pool scientific ideas, research skills, and data. Member institutions can obtain rapid answers to clinical questions of interest and pursue optimal care for pediatric patients diagnosed with cancer.

100,000 Lives Campaign

CHCA, NACHRI, and the National Initiative for Children's Healthcare Quality are partnering to bring resources to the children's health care community as part of the Institute for Healthcare Improvement 100,000 Lives Campaign. The Pediatric Node of the 100,000 Lives Campaign was launched in December 2004.[23] The objective of the campaign was to save 100,000 pediatric lives within 18 months by improving strategies in key areas of care: preventing surgical site and central line infections, preventing ventilator-associated pneumonia, deploying rapid response teams for inpatient settings, and medication reconciliation. A target of 1,600 participating institutions was set, and as of April 2006 there were more than 2,200 organizations engaged in this work.

Pediatric Intensive Care Measures

The Pediatric Intensive Care Measures collaborative is a joint effort of NACHRI; Medical Management Planning, a benchmarking service; and CHCA to develop pediatric core measures.[24] In February 2004, the Pediatric Intensive Care Measures collaborative issued a national call for measures from hospitals and received 51 measures from a variety of sources. An expert panel was created representing a variety of expertise and care models, with panelists from all parts of the Nation. The panel's charge was to rigorously review the measures submitted and determine which should move forward for consideration as standard measures for generalized use.

A key issue that arose immediately was the need for a standardized risk-adjustment methodology that would meet the Joint Commission (formerly the Joint Commission on Accreditation of Healthcare Organizations or JCAHO) requirement to be in the public domain, but that also had been validated in the United States pediatric population. The panel did not identify any single tool to meet these criteria, but noted that risk adjustment was a critical component of any core measure set for pediatric intensive care units (PICUs).

After several months of work by the expert panel, by additional experts who worked in subgroups, and after voting by the children's hospitals, the following potential PICU core measures were identified:

- PICU standardized mortality ratio
- PICU severity-adjusted length of stay
- PICU unplanned readmission rate and review of unplanned readmissions
- PICU pain assessment on admission and PICU periodic pain assessment
- PICU medication safety practice adoption
- PICU central line infection prevention practice adoption

Next steps are continued discussions with all stakeholders to pilot test these measures in a respectable number of PICU settings followed by modification of these measures, if necessary. Because the Joint Commission uses only measures endorsed by the National Quality Forum, discussed in other chapters and below, advocates will seek this endorsement. Ultimately, PICUs would embed these measures in their overall quality improvement programs with institutional improvement strategies.

The National Quality Forum

The mission of the National Quality Forum is to improve the lives of patients by building consensus for quality measurement and reporting. The majority of this work has been done with adult patients. A vigorous collaboration with NACHRI and CHCA was launched to create pediatric measures. This partnership has identified the Children's Asthma Core, which is made up of the following core measures for asthma patients:[25]

1. Return to hospital (i.e., emergency department, observation status, or inpatient admission) with same asthma diagnosis within 7 days following inpatient discharge
2. Return to hospital with same asthma diagnosis within 30 days following inpatient discharge
3. Return to hospital with same asthma diagnosis within 7 days following emergency department or observation stay
4. Use of relievers (drugs used to control exacerbations) for inpatient asthma
5. Use of systemic corticosteroids for inpatient asthma
6. Risk-adjusted length of stay
7. Home management plan of care discussed with patient/caregiver

Development and national pilot testing of these children's asthma core measures was conducted and, as of October 2007, three were selected for inclusion as performance measures for accreditation by the Joint Commission: use of relievers, use of systemic corticosteroids, and home management plan of care.

Resources and dedication are needed to conduct and sustain this level of inquiry. Hospitals are committed to this level of disease-specific investigation and reporting. However, the Joint

Commission's involvement adds an additional level of organizational commitment to provide the necessary resources to collect and report this information consistently over time.

This work is aligned with the National Heart, Lung, and Blood Institute's and the American Academy of Pediatrics's most recent recommendations for pediatric asthma guidelines, which are now under revision. These guidelines include information on best practices with asthma medications as related to symptoms, prevention, and monitoring and controlling asthma.[26] All of this work is an iterative process, and organizations and regulatory bodies continue to modify and revise this work.

Palliative Care

Over the last few decades, a significant body of research has contributed to the science of palliative care. Two key groups have developed best practices and guidelines for individuals and institutions that provide care to dying children: the Initiative for Pediatric Palliative Care (IPPC) and the End-of-Life Nursing Education Consortium.[27, 28]

IPPC is both an education and a quality improvement effort, aimed at enhancing family-centered care for children living with life-threatening conditions. IPPC's comprehensive, interdisciplinary curriculum addresses knowledge, attitudes, and skills that health care professionals need to better serve children and families.

IPPC is a project of the Center for Applied Ethics and Professional Practice, a division of Education Development Center, Inc. The Education Development Center is a nonprofit organization with more than 600 professional staff, working on 300 educational projects throughout the United States and in 27 other countries. Education Development Center is the lead organization in this initiative, working in close collaboration with NACHRI, the Society of Pediatric Nurses (SPN), the Association of Medical Schools Pediatric Department Chairs, and the New York Academy of Medicine.

The IPPC team is composed of nationally renowned educators and clinicians with expertise in pediatric palliative care. IPPC is a broad-based collaborative effort that includes children's hospitals, pediatric units in general hospitals, and hospice or home care programs that serve children living with life-threatening conditions and their families.

The End-of-Life Nursing Education Consortium project is a national education initiative to improve end-of-life care in the United States. The project provides undergraduate and graduate nursing faculty, continuing education providers, staff development educators, pediatric and oncology specialty nurses, and other nurses with training in end-of-life care so they can teach this essential information to nursing students and practicing nurses.

Nurse Staffing and Pediatric Outcomes

An established body of literature links nurse staffing and hours worked with patient outcomes. While the number of nurses providing patient care is recognized as an inadequate measure of nursing care quality, there is hard evidence that nurse staffing is directly related to patient outcomes. Patient death, nosocomial infections, cardiac arrest, and pressure ulcers are linked to inadequate nurse-to-patient ratios.[29, 30] Heavy workloads, nurses' perception that they are unable to carry out their professional role, conflict and other difficult relationships, and unsupportive leadership are identified by the IOM as related to increased risk of errors and accidents, as well as to substance abuse, conflict, increased use of sick time, and workplace

violence.[31] However, most of the research linking nursing workload and outcomes for either patients or nurses has been conducted with adult patients and the nurses who care for them. The following section covers only pediatric patients and nurses.

National Database of Nursing Quality Indicators

The American Nurses Association's National Center for Nursing Quality collects data about nursing care quality reported by nursing units to the National Database of Nursing Quality Indicators.[32] The database provides a data repository for hospitals participating in a national effort to address nursing care safety and quality. The National Database of Nursing Quality Indicators has collected data about nursing care quality for adult patients since 1998. Indicators of pediatric nursing care quality were developed and pilot tested in 2004. Since the fourth quarter of 2004, data about the pain assessment, intervention, and reassessment cycle and peripheral intravenous infiltration have been collected from a national sample of pediatric units and children's hospitals.

These two indicators of pediatric nursing care quality are *sensitive* measures of nursing care. That is, the presence or absence of registered nurses (RNs) impacts the outcome for pediatric patients requiring pain management and/or peripheral administration of intravenous fluids and/or medications. Professional nurses play a key role in successful pain management, especially among pediatric patients unable to verbally describe pain. Astute assessment skills are required to intervene successfully and relieve discomfort.[33] Maintenance of a patient's intravenous access is a clear nursing responsibility. Pediatric patients are at increased risk for intravenous infiltration and for significant complications of infiltration, should it occur.[34, 35]

The characteristics of effective indicators of pediatric nursing care quality include the following:

- Scalable. The indicators are applicable to pediatric patients across a broad range of units and hospitals, in both intensive care and general care settings.
- Feasible. Data collection does not pose undue burden on staff of participating units as the data is available from existing sources, such as the medical record or a quality improvement database, and can be collected in real time.
- Valid and reliable. Indicator measurement within and across participating sites is accurate and consistent over time.

In 2003, Stratton[36] studied the link between pediatric outcomes of interest and nurse staffing. She used administrative data from seven academic, not-for-profit children's hospitals, which included 17 medical/surgical, 5 oncology, and 12 intensive care units, to analyze the correlation between staffing and 5 indicators of quality care identified in the literature as nurse sensitive. Stratton controlled for unit type and patient characteristics. The five indicators were medication administration errors, central line infections, bloodstream infections, intravenous infiltrates, and parent/family complaints. Key findings supported a strong inverse relationship between the proportion of hours of pediatric nursing care delivered on patient care units by RNs and the rate of occurrence of central line and bloodstream infections. Other significant findings included the following:

- A higher percentage of nursing overtime hours was associated with lower parent/family complaint rates.
- A higher percentage of nursing overtime hours and a lower percentage of hours of care from float/agency/traveler RNs were associated with lower bloodstream infection rates.

This work applies nurse staffing to outcomes among pediatric patients and also expands the context of nurse staffing to include "float/travel/agency" nurses and the complex issue of overtime into the research questions. Since maximizing the capability of the nursing workforce is a strategy employed in high-reliability organizations, this work makes an important contribution to pediatric nursing.

The California Nursing Outcomes Coalition Database Project

The California Nursing Outcomes Coalition Database Project, the statewide database that links patient outcomes and nurse staffing, is actively conducting data collection and unit-based benchmarking for pediatric units across the State (N. Donaldson, co-principal investigator, Carolyn Aydin, co-investigator, California Nursing Outcomes Coalition Pediatric Pilot Project, personal communication, July 2006).To date, 66 diverse pediatric units have joined this database. No formal reports have been generated, as this work is in process.

Evidence-Based Pediatric Practice

Evidence-based practice is defined as a systematic approach to clinical decisionmaking to provide the most consistent and best possible care to patients.[37] Evidence-based practices can also be applied to organizational structure and processes. As individuals and organizations seek to provide safe, high-quality care for hospitalized children, tactics to reduce hospital errors are an important beginning point. McFadden, Towell, and Stock[38] systematically reviewed the literature on patient safety and derived a list of seven "critical strategies" for dealing with the challenges of reducing errors and improving patient safety, as well as both internal and external barriers to error-reduction strategies. Following are the evidence-based recommendations for improvement:

1. Create a partnership for safety with all stakeholders—doctors, nurses, administrators, trustees, and patients. Care of children in hospitals necessitates the inclusion of parents or other surrogates among the safety stakeholders.
2. Develop a system for reporting errors that is free of blame. An effective reporting system encourages reporting by being confidential and impartial, and assuring that no retribution for reporting occurs.
3. Foster open discussion of errors and near misses at all levels of the organization to identify risks, define goals, and measure progress in an environment where individuals feel comfortable discussing problems and sharing information and knowledge.
4. Create an organizational culture where patient safety is the top priority and there is an ongoing commitment to address patient safety issues.
5. Provide staff education and training in error-reduction strategies.
6. Systematically analyze the data collected on errors to understand the complex relationships and interactions that are often related to health care errors.
7. Redesign hospital systems and processes (the workplace and the work) to mitigate error so that it is difficult or impossible to make a mistake.

Barriers to the adoption of evidence-based strategies to reduce errors were also identified from the literature. Examples of organizational factors that may function as barriers include lack of support from top administrators, lack of knowledge or understanding of errors, and lack of resources. External barriers to reporting errors include threat of malpractice suits and media

attention to errors. Cost-containment efforts resulting from managed care may reduce staffing to dangerous levels, divert resources from error prevention, or both.[38]

Hospitals are making progress toward adopting strategies that improve patient safety, McFadden, Stock, and Gowen report.[39] Though continued progress is needed, most U.S. hospitals have begun to implement some of the evidence-based practices that research has demonstrated are efficacious in reducing hospital errors.

Challenges in Pediatric Evidence-Based Practice

Nurses caring for hospitalized children face similar challenges as nurses in all hospital settings. There is a substantial gap between evidence and practice, as many nurses do not understand or value research and have had little training that helps them find evidence on which to base their practice.[36, 40] Most nurses practice based on what they learned in nursing school and from their subsequent experiences with patient care.[41] When practice questions arise, nurses are most likely to ask peers for information and advice.[37]

Common challenges to nurses learning about and putting into practice guidelines based on the systematic identification and synthesis of the best available scientific evidence persist in all settings. For example, nurses' knowledge and competence with the recommended technique for endotracheal suctioning is inadequate, especially with regard to the instillation of normal saline.[42, 43] Bridging the gap between scientific evidence for practice and the application of the evidence in the clinical care of patients continues to challenge practicing nurses, nursing educators, nurse experts, and nursing administrators.

The following personal and organizational barriers to the use of research and the implementation of evidence-based practices among nurses have been identified:[37, 40, 41, 44–46]

- Perceived low usefulness of research in clinical decisionmaking
- Lack of time to access, read, and evaluate research
- Lack of access to the tools needed to search for evidence
- Inadequate skills to conduct information searches
- Real or perceived lack of assistance with information seeking
- Difficulty understanding research articles
- Belief that change will produce minimal benefits
- Perceived lack of authority
- Low management and staff support
- Lack of physician collaboration and buy-in
- Costs of resourcing the development of evidence-based practices

Unique challenges in nursing care for children. Some authors suggest that pediatric nursing, rooted deeply in tradition and ritual, is particularly resistant to evidence-based practice changes.[47, 48] Pain management in infants and children is an example of the influence of tradition, personal bias, the persistence of myths, and resistance to change.[48] However, it is important to note that SPN has recognized that evidence-based practice represents a shift in clinical decisionmaking and provides a more complete and comprehensive understanding of "best" clinical practice. Its position and recommendations are as follows:[49]

1. SPN endorses clinical practice based on "best evidence" from evidence-based practice sources and patient and family preferences.

2. SPN supports clinically based nurses who use an evidence-based practice approach to maximize clinical outcomes for pediatric patients and their families.
3. SPN supports advanced practice nurses in the roles of evidence-based practice mentors for clinically based nurses.
4. SPN supports nursing research that generates new knowledge of best practice based on measurable, improved patient outcomes.
5. The SPN Listserv provides an opportunity for best practice discussions among its members.
6. SPN supports nursing higher education that trains all levels of nurses in the application and dissemination of evidence-based practice.
7. SPN supports institutions' efforts to create a culture and resource infrastructure that incorporates evidence-based practice in all aspects of patient care delivery, including collaboration and sharing of ideas and information among other nursing institutions and agencies.

The *Journal of Pediatric Nursing* includes an evidence-based practice section in each issue, focusing on the search for and critique of the best evidence to answer challenging clinical questions so that the highest quality, up-to-date care can be provided children and their families. The American Academy of Pediatrics Steering Committee on Quality Improvement and Management develops and classifies clinical practice guidelines "intended to improve clinical care by reducing inappropriate variations, producing optimal outcomes for patients, minimizing harm, and promoting cost-effective practices"[50] (p. 874). The committee uses a three-step process in developing clinical practice guidelines:

1. Determination of the quality of the evidence in support of a proposed practice recommendation
2. Evaluation of the anticipated balance between benefits and harm when the recommendation is carried out
3. Designation of the recommendation's strength (*strong recommendation, recommendation, option*, or *no recommendation*).

Clearly, leadership exists for overcoming barriers to implementing evidence-based pediatric practice.

The challenges of family-centered care. Family-centered nursing of children places the concerns, needs, strengths, and capabilities of the family at the center of a hospitalized child's care. Rush and Harr[48] suggest family-centered care and evidence-based practices might be at odds at the bedside and recommend a "marriage" of the two to assure that the best care is achieved. More recent definitions of evidence-based practice include patient preference, but pediatric nurses will have an opportunity to lead efforts to include existing evidence-based strategies for family-centered care, as well as lead the further development of practice guidelines that include the perspective of the family in care. Several examples of evidence-based, family-centered care follow.

Nearly two decades ago, Martha Curley demonstrated that the nursing mutual-participation model of care diminished distress for parents of children in the pediatric intensive care unit.[51, 52] When nurses assisted parents of critically ill children to continue specific parenting activities with their children in the intensive care unit, parents reported less stress.

Bernadette Melnyk and colleagues[53–55] tested the effects of the Creating Opportunities for Parent Empowerment program with mothers of young children in the pediatric intensive care unit. Study participants were provided written and audiotaped information describing young

children's typical responses to critical illness and intensive care and parental-role information, which suggested strategies the parents could use to facilitate their children's adjustment. These parents, compared to the control group, reported less negative mood and parental stress, provided more support to their children during intrusive procedures, participated more in their children's care, and reported fewer posttraumatic stress symptoms after discharge.

A strategy to prepare parents for their child's transfer from the pediatric intensive care unit was tested for its impact on parental anxiety.[56] Study parents received written information explaining the transfer procedure and the level of care on the general pediatric unit, reinforcing the positive aspects of their child's transfer. The information was provided 24 to 48 hours prior to the transfer. Findings indicated that experimental group parents had lower levels of anxiety following transfer.

In 2004, Melnyk, Small, and Carno[57] critically appraised these five studies of parent-focused interventions aimed at improving coping and mental health outcomes for children and their parents. Despite what is known about the potential adverse effects of critical illness and intensive care for children and their families, interventions with proven effectiveness are not in place in pediatric critical care units across the United States. Clinical practice guidelines that incorporate evidence-based interventions are needed if they are to become the standard of care.

IPPC[27] is a consortium of seven academic children's hospitals, Education Development Center, NACHRI, the New York Academy of Medicine, SPN, and the Association of Medical School Pediatric Department Chairs. The group has both education and quality improvement objectives that address the growing empirical evidence that U.S. health care systems fail to meet the needs of children with life-threatening conditions and their families.

A commitment to culturally respectful, family-centered care of children with life-threatening conditions is evidenced as support of the family unit and involvement of the child and family in communication. Decisionmaking and care planning are two of six quality domains in the program. Evidence-based practice guides discovering what matters to families and incorporating the perspectives of children and families in care planning and implementation.[58]

The American Heart Association issued guidelines in 2000 that recommended, for the first time, that family members be given the option to be with their loved ones during resuscitation efforts, whenever possible.[59] Pediatric Advanced Life Support guidelines also endorse family presence during resuscitation of children.[60] However, clinicians in many settings have resisted following the guidelines, citing the belief that the family will suffer undue trauma and may not understand what is happening to their loved one, and concern that family presence may lead to litigation.[61] A literature review for evidence-based practice guideline development at the Children's Hospital, Denver, found that families want to have a choice about being present during resuscitation efforts, refuting previous beliefs that family presence is detrimental to family members or institutions. The review led to development of an evidence-based practice policy that may guide others to provide compassionate, family-centered care that respects family choice and supports their presence during resuscitation efforts.[62]

Evidence-Based Clinical Practice Guidelines: Exemplars

The development of guidelines for practice is vital to the implementation of evidence-based practices and the quality outcomes anticipated as a consequence of reducing unnecessary variation, enhancing benefit, minimizing harm, and promoting cost effectiveness. The gap between establishing evidence for practice and implementing evidence-based practice, however,

is significant. In fact, the IOM identifies it as a "quality chasm."[63] In July 2003, the National Quality Forum released 30 safe practices for better health care, calling it a road map for safety. The practices identified are supported by "evidence so clear that if they were universally implemented, they would significantly improve the situation with regards to medical errors and patient safety"[64] (p. 12). More than two-thirds of the 30 safe practices are related to Joint Commission national patient safety goals or other Joint Commission initiatives, and they are applicable to the care of hospitalized children. In addition, pediatric quality indicators proposed by AHRQ and those proposed by the IOM inform and direct efforts to improve the safety and quality of care for hospitalized children. The section that follows presents progress toward evidence-based clinical practice guidelines for pediatric care addressing national patient safety and quality objectives.

Pressure Ulcer Prevention

Pressure ulcers do occur in acutely ill children. However, there are differences among pediatric patients, such as between premature neonates and older infants or children; between all pediatric patients and those in at-risk groups, such as those with spina bifida and those who are critically ill; and in the distribution of pressure ulcers between infants, children, and adults.

Risk factors for pressure ulcer development are not different among pediatric patients or between children and adults. The factors include (1) decreased mobility, activity, and sensory perception; (2) increased moisture, friction, and shear forces; and (3) intrinsic factors that influence tissue tolerance associated with age, nutrition, and tissue perfusion.

The incidence of pressure ulcers among hospitalized children is consistent across studies. There is a 17 percent incidence in children in the intensive care unit following cardiac surgery,[65] 19 percent among infants in a neonatal intensive care unit,[66] 26 percent among children in a multidisciplinary pediatric intensive care unit,[67] 27 percent in a prospective, multicenter study of pediatric intensive care unit patients,[68, 69] and 23 percent in a recently reported study that included pediatric intensive care and general pediatric care patients.[70]

Prevention of skin breakdown begins with accurate prediction of pressure ulcer risk. The Braden Skin Risk Scale score, the gold standard for predicting pressure ulcer risk in adult patients, has been adapted for use with pediatric patients to reflect the unique needs of children.[71] A multicenter study of the Braden Q Scale demonstrated that its performance is similar in a pediatric intensive care population and in adult patients. The modified Braden Q, which is shorter, is comparable.[68] The Starkid Skin Scale used the Braden Q as the basis for developing a shorter, simpler tool to measure risk of skin breakdown. While it has high interrater reliability and high specificity, the initial study of its use found its sensitivity low.[70] It is, however, the only tool evaluated in general pediatric patient care.

Risk factors for the development of pressure ulcers include white race; younger age; diarrhea; use of medical devices, especially mechanical ventilation; and higher severity of illness, hallmarked by hypotension and prescription of vasoactive medication infusions. Lower Braden Q or Starkid Scale scores were predictive of risk for skin breakdown.

The location of pressure ulcers in pediatric patients is different than it is in adults. The most common location in pediatric intensive care patients was the head (occiput and ears). Acutely ill pediatric patients in the intensive care unit also developed lower-body pressure ulcers, with their heels most frequently affected.[68] In general care pediatrics, skin breakdown on the buttocks or perineum is most commonly related to diaper dermatitis.[70]

Most children in all studies had Stage I pressure ulcers and developed them early in hospitalization—likely when they were most ill. Prevention and treatment strategies have not been studied in children, but those recommended in the AHRQ evidence-based review of practices known to prevent pressure-related injury are logically applicable in pediatric patients. Evidence supports the use of pressure-reducing devices to distribute weight over a larger surface area, head-of-bed elevation to the lowest degree consistent with the patient's condition to minimize sheer-related injuries, elevation of the heels off the bed, and a turning schedule to provide pressure relief.[72] In addition, injuries from medical devices such as oximeter probes, endotracheal and tracheostomy tubes, BiPAP masks, catheters, and splints—which were not included in pressure ulcer data in the studies—warrant efforts at prevention from vigilant pediatric care providers. "Excellent skin care is a hallmark of quality nursing care."[70]

Catheter-Related Bloodstream Infection Prevention

Catheter-related bloodstream infection (CRBSI) is associated with increased morbidity, mortality, and health care costs.[73] While securing and maintaining reliable venous access is essential in acute care of hospitalized infants and children, use of central venous catheters carries a number of risks. Included are local infection, CRBSI, septic thrombophlebitis, endocarditis, metastatic infections (brain abscess, lung abscess, osteomyelitis), and mechanical complications during insertion.[74] Children are at greater risk than some adults for CRBSI. In pooled pediatric intensive care unit data reported by the Centers for Disease Control and Prevention (CDC) National Nosocomial Infection Surveillance System in 2003, the rate of CRBSI was 7.3 per 1,000 catheter days.[75] Bloodstream infection is the most common nosocomial infection in pediatric critical care units, followed by ventilator-associated pneumonia.[75, 76] Length of stay increases dramatically in the face of bloodstream infection, as do associated hospital costs.[77]

Strategies to reduce risk of CRBSI. Measures to minimize the risk for infection related to intravenous therapy have important implications for nursing care of acutely ill pediatric patients. Evaluation of the risk-reduction measures has, most often, been undertaken in studies with adult patients. Most, however, apply to the care of hospitalized infants and children.[74, 78] Important differences are noted. Factors over which nurses have direct influence are discussed.

Site selection. The presence of phlebitis and the density of skin flora at the catheter insertion site are risk factors for infection. For adults, lower-extremity insertion sites, including those in the femoral vein, are associated with a higher risk of deep vein thrombosis[79] and have been demonstrated to have relatively high bacterial colonization rates.[80] In children, femoral catheters have a low incidence of mechanical complication and may have an infection rate equivalent to catheters in alternative locations.[81–83]

Hand hygiene and aseptic technique. Hand hygiene with an antibacterial soap and water or with waterless alcohol-based gels or foams contributes significantly to reducing risk of CRBSI.[74, 84] Hand hygiene is recommended before and after palpating potential catheter insertion sites, and before and after inserting, replacing, accessing, repairing, or dressing an intravascular catheter.[74] During central venous cannulation, the CDC recommends maximal barrier protection (cap, mask, sterile gown, gloves, and drape). Skin asepsis with 2 percent aqueous chlorhexidine is recommended. Providone iodine, which has been the most widely used antiseptic for cleansing intravascular insertion sites, is acceptable if it is allowed to remain on the skin for at least 2 minutes, or until dry, prior to catheter insertion.[75]

Catheter site dressing changes. Recommendations for catheter site dressing changes are extrapolated to pediatrics from adult studies.[78] Central catheter dressings should be either sterile gauze or sterile, transparent, semipermeable dressing that covers the insertion site. The choice of dressing is a matter of preference, as no differences for CRBSI have been found between the two.[85] Gauze may be preferred in patients who are diaphoretic or who have oozing or bleeding at the insertion site. Dressings should be changed using aseptic technique at least weekly or if the dressing becomes damp, loosened, or visibly soiled.[75]

The longstanding practice of intermittent application of topical antibiotic ointment to the catheter insertion site is no longer endorsed by the CDC.[75] Application of antibiotic ointment increases the rate of catheter colonization with Candida species, promotes emergence of resistant bacteria, may compromise the integrity of the catheter, and has not consistently been shown to decrease the rate of CRBSI.

Replacement of intravenous administration sets. The optimal interval for routine replacement of administration sets has been well studied. Data reveal that replacing administration sets no more frequently than every 72 hours is safe and cost effective.[86, 87] Data from a more recent study demonstrated that phlebitis rates were no different when administration sets were left in place for 96 hours compared with 72 hours.[88] Data from an additional recent study with adults support delaying replacement of administration sets up to 7 days if the patient is not receiving total parenteral nutrition, blood transfusion, or interleukin-2 via the intravenous tubing.[89]

Implementing the recommendations. Multifaceted interventions are necessary to assure that evidence-based infection control guidelines to prevent CRBSI are followed. In a recent study in an adult surgical intensive care unit, CRBSI was nearly eliminated when five interventions were put in place to improve adherence with infection control guidelines during central venous catheter insertion.[90] The interventions were as follows:

1. An educational intervention to increase provider awareness of evidence-based infection control practices
2. Creation of a central catheter insertion cart to assure that needed equipment and supplies to provide asepsis during central venous catheter insertion or exchange were accessible in one location
3. Asking providers daily in interdisciplinary rounds about removal of central catheters to reduce risk from prolonged, but unnecessary exposure
4. Implementation of a checklist of items that assure compliance with evidence-based infection control guidelines, completed by the bedside nurse during central venous catheter insertion or exchange
5. Nurse empowerment to stop procedures if guidelines are not followed

The study authors report sustained improvement years following the initial implementation of the five interventions. Between January 2003 and April 2004, there were two CRBSIs in this surgical intensive care unit or 0.54/1,000 catheter days. No infections had occurred in more than 9 months. By their estimate, 43 CRBSIs and eight deaths may be prevented per year, saving nearly $2 million in additional costs annually.

The authors report the following important lessons learned from this initiative: (1) relatively simple and inexpensive interventions produced significant improvement; (2) processes that reduce steps in workflow are more likely to succeed than those that require more steps; (3) creating redundancy through the use of a checklist, as in aviation, is an effective technique to improve patient care safety; and (4) a culture of safety requires teamwork and collaboration.

Improving Communication and Collaboration

Health care errors and poor quality of care are consequences of a variety of workplace systems and processes. Care of hospitalized patients across the lifespan is provided in complex environments where limited time, parallel tasking, interdependence, and the need for decisionmaking despite uncertainty create unique demands. The importance of effective communication with patients and their families as well as between interdisciplinary teams is recognized as key to reducing errors and improving quality in a number of industries. Analysis of 2,455 sentinel events reported to the Joint Commission revealed that the primary root cause in more than 70 percent was communication failure. The seriousness of these failures is evident: approximately 75 percent of these patients died.[91]

Relational coordination. The concept of relational coordination was developed and validated in the commercial aviation business.[92] When team members and team relationships are well coordinated, there is frequent, timely, accurate communication, as well as problem-solving, shared goals, shared knowledge, and mutual respect. The impact of team relationships on outcomes for patients has been demonstrated in a number of studies.

The impact of relational coordination in health care was tested in a study of orthopedic surgery patients undergoing total joint replacement at nine hospitals in three U.S. cities.[93] Quality of care, postoperative pain and functioning, and length of stay were the outcome measures for this study. Patients evaluated the quality of care by completing a questionnaire that measured the patients' reported confidence and trust in their physicians, nurses, physical therapists, or case managers; knowledge of the identity of the physician, nurse, physical therapist, or case manager in charge of their care; belief that providers were aware of their medical history; belief that providers were aware of their condition and needs; belief that their providers supplied consistent information; belief that their providers worked well together; belief that they were treated with respect and dignity; satisfaction with their overall care; and finally, intent to recommend the hospital to others. Providers, including physicians, nurses, physical therapists, social workers, and case managers, assessed four communication dimensions (frequent, timely, accurate, and problem-solving communication) and relationship dimensions (shared goals, shared knowledge, and mutual respect) between each respondent and each of the five core disciplines involved in the care of joint replacement patients.

The study found that relational coordination varied significantly between the hospital sites. Quality of care was significantly improved by relational coordination and each of its dimensions. Postoperative pain was significantly reduced by relational coordination, whereas postoperative functioning was significantly improved by several dimensions of relational coordination, including the frequency of communication, the strength of shared goals, and the degree of mutual respect among care providers. Length of stay was significantly shortened by relational coordination and each of its dimensions.

Improving communication and teamwork. The Kaiser Permanente health care system has adopted standardized tools and behaviors from commercial aviation and has demonstrated their effectiveness in enhancing teamwork and reducing risk of patient harm.[94] Crew resource management training was provided to team members from a variety of clinical domains, including the operating room, the intensive care unit, obstetrics and perinatal care, and a cardiac treadmill unit. The teams each worked on a clinical project in which crew resource management techniques could be applied to improve the quality and safety of patient care, supported with site visits and educational sessions. The tools and behaviors to improve communication effectiveness

in this study were briefings using the SBAR (situation, background, assessment, recommendation) format, appropriate assertion, clear language, situational awareness, and debriefing. This work is explicated in the section on communication of this book.

Briefings. Brief, concise communication of critically important information transmitted in a predictable format has been adopted in the perinatal unit by nurses, midwives, and physicians to improve the team response to fetal distress. A common language is used to optimize problem recognition. Simple and effective rules are activated when a problem is recognized: the identifying person has 1 minute to look at it independently, 2 minutes to look at it with a colleague, and by minute 3 should be physically correcting the problem.

Perioperative briefings by surgical teams have virtually eliminated wrong-site surgeries and improved nursing turnover in the operating room by 16 percent. Employee satisfaction has risen; perception of safety in the operating room is judged "outstanding"; and significant improvements in teamwork, communication, responsibility for patient safety, and handling errors have been measured.[94]

Appropriate assertion and critical language. Creating environments where people will express their concerns and speak up is a key factor in safety. The hierarchy of caregivers in hospitals and differences in communication styles between nurses, physicians, and others often interfere with adequate communication. The common practice of indirect communication between nurses and physicians is risky. In assertive communication there is a series of steps to clearly communicate what is needed and reach a decision:

1. Get the person's attention.
2. Express concern.
3. State the problem.
4. Propose action.
5. Reach a decision.

Nurses have license to say "I need you to come now and see this patient." They need not provide an objective argument to convince a physician to see a patient. It is acceptable for nurses to say "Something is wrong, I'm not sure what it is, but I need you here now." Recently, emergency medical teams from Australia demonstrated that in-hospital cardiac arrests were reduced 65 percent by early intervention.[95] The number one criterion to call for help was a staff member who "was worried" about a patient.

Sharing goals. Patients in the intensive care unit at Johns Hopkins University Medical Center are cared for by intensivist-led teams, which include the intensive care unit attending physician, critical care fellows, anesthesia and surgery residents, nurse practitioners, nurses, respiratory therapists, and a pharmacist. During daily rounds, the intensive care unit team develops a plan of care for the day, spending 20 to 25 minutes at each patient's bedside. One attending physician questioned that rounds failed to clarify explicit patient care goals, prompting the team to measure their impact on team communication.[96]

When measured, less than 10 percent of residents and nurses understood the goals of care for the day. To improve communication among providers, the team developed and implemented a daily goals form, based on crew resource management principles, which outlines the tasks to be completed, the plan of care, and the plan for communication with the patient and family members. The following are discussed in rounds and noted:

1. What needs to be done for the patient to be discharged from the intensive care unit?
2. What is this patient's greatest safety risk? How can we reduce that risk?
3. Pain and sedation management

4. Cardiac/volume status
5. Pulmonary/ventilator management
6. Mobilization
7. Infection, cultures, drug levels
8. GI/nutrition status
9. Medication changes (Can any be discontinued?)
10. Tests and procedures
11. Scheduled labs, morning labs, chest x-ray
12. Consultations
13. Communication with primary service
14. Family communication
15. Can lines/catheters/tubes be removed?
16. Is this patient receiving DVT/peptic ulcer disease prophylaxis?

The daily goals form is completed for each patient during rounds, signed by the fellow or attending physician, and handed to each patient's nurse. The goals are reviewed at least three times each day by all providers, who initial the form to indicate their review. The form is updated if the goals of care change.

To evaluate the impact of the daily goals form on patient outcomes, intensive care unit length of stay was measured for 1 year following pilot testing, revision, and implementation. After implementing the goals form, the percentage of residents and nurses who understood their patient's daily goals increased to more than 95 percent. Intensive care unit length of stay decreased significantly from a mean of 2.2 days to 1.1 days. With a decrease in length of stay, the intensive care unit was able to admit 670 additional patients in the study year. In addition, the use of the goals form may have prevented complications such as CRBSI (by prompting removal of central venous catheters when no longer needed for therapy) and ventilator-associated pneumonia (by assuring head-of-bed elevation, peptic ulcer disease prophylaxis, and assuring patients were assessed for readiness for extubation).

The team learned that using an interdisciplinary communication tool is more important than the specific statements on the form. As its use has spread to other intensive care units in the Johns Hopkins system and to other hospitals, the structure and content of the form have changed. Other hospitals are invited to modify the form to meet their needs and are cautioned to expect frequent revisions in the beginning.

Interdisciplinary collaboration. Nurse-physician relationships have been characterized negatively for more than a century. The "doctor-nurse game," first described in 1967, is a stereotypical pattern of interaction in which nurses learn to show initiative and offer advice, while appearing to passively defer to physicians' authority.[97] The game has been replayed and revisited in the decades since, though a recent literature review suggests that this pattern of interaction is decreasing in frequency in contemporary health care settings.[98] The importance of managing the doctor-nurse game is illustrated in an analysis of nurse-physician collaboration in pain management practices and underscores the need to draw on nursing practice and knowledge to effectively challenge issues of power and status.[99]

Patient outcomes are linked to healthy professional relationships. A descriptive study with nurses at 14 hospitals that had achieved Magnet status (see section on the Magnet Recognition Program below) suggests that collaborative relationships between nurses and physicians contributes to lower mortality at magnet hospitals, compared with mortality at hospitals without the designation.[100] Nurses participating in the study described relationships with physicians along

a scale of collegial, collaborative, student-teacher, neutral, or negative. Collegial and collaborative relationships were differentiated based on the power base characterizing interactions. In collegial relationships, the power base is equal, although it may be different. Nurses respect physicians for their education, while physicians respect nurses for their knowledge and extended contact with patients. In collaborative relationships power is mutual, but not equal. In both, mutual dependence and willing cooperation are characteristic.

Subsequently, direct care nurses, nurse managers, and physicians at 44 clinical units in 5 hospitals where extensive collegial and collaborative relationships were identified have participated in interviews to identify structures that enable their positive relationships.[101, 102] Goals of the multisite initiative are to identify evidence-based management practices and suggestions for attaining high-level, productive, and beneficial nurse-physician relationships.

Improving team structure and heightening communication have been tested in a 5-year study with nurses and physicians caring for general surgery patients at a tertiary care hospital.[103] Well-defined patient care teams (physicians, case managers, and charge nurses) with clear role responsibilities were developed, and a formal, regular schedule of daily team meetings was initiated. Following the intervention, mean length of stay for surgical patients was decreased and patient volume increased, while a high level of patient satisfaction was maintained.

Differences in education and socialization may make collaboration difficult. Interdisciplinary learning opportunities have been effective in developing collaborative skills among those new to their professions.[104, 105] The registered nurse-resident physician preceptor program at the University of Kentucky pairs new residents with a registered nurse for an 8-hour orientation shift.[106] Physicians directly encounter the nurse's unique functions, perspectives, knowledge, and contributions.

A recent systematic review of evidence for the effectiveness of interdisciplinary education as a strategy to build collaborative relationships found no definitive outcomes, as studies had wide inclusion criteria, methodology, and outcomes.[107] The absence of evidence does not mean that interdisciplinary education is ineffective; it may simply mean that it has not yet been rigorously evaluated.

The same review examined evidence of the effectiveness of interdisciplinary collaboration interventions. Although the review found a heterogeneous sample of intervention studies, which prevented meta-analysis, clinical improvements in patient care were related to interventions that target improving interdisciplinary collaboration.[107] The authors have a funded randomized controlled trial to evaluate the impact of both an interdisciplinary education intervention and an interdisciplinary collaboration intervention with 20 general medicine units in four Toronto hospitals. Evaluation lasting 12 months of some 30,000 patient admissions is anticipated. Information about patient outcomes; patient and family satisfaction; readmission rates; evidence-based discharge prescriptions; length of stay; staff turnover; and interdisciplinary satisfaction and trust among nurses, physicians, and allied professionals will be collected. It is anticipated that the study will add rigor to the body of evidence for interdisciplinary collaboration.

Culture change is at the heart of improving communication, teamwork, and collaboration. Care complexity in today's hospital systems demands care coordination that is unparalleled. Individual provider excellence alone is insufficient; the team and its coordinated efforts must be excellent. Improving communication is evidence-based care that benefits patient safety and care quality.

Infant Position in Neonates Receiving Mechanical Ventilation

Mechanical ventilation is often required when treating critically ill newborns, especially those who are preterm. A systematic review of randomized controlled trials that compared the impact of several body positions during mechanical ventilation of sick newborns was conducted by the Cochrane Collaboration and reported in 2003.[108] Ten trials involving 164 infants were included in the review. The trials compared several positions: prone versus supine, prone versus lateral right, lateral right versus supine, lateral left versus supine, lateral right versus lateral left, and good lung dependent versus good lung uppermost. In all the trials, stable infants were selected for the intervention.

Only the prone position was more efficacious than supine positioning. Placing infants prone for short periods of time improved oxygenation. However, evidence that prone positioning produces sustained improvements in oxygenation was not reported.

None of the trials reported complications of repositioning infants who were receiving mechanical ventilation. However, accidents such as inadvertent extubation or umbilical catheter dislodgement are easily imagined. Infants who require prolonged mechanical ventilation may be at risk for the development of pressure ulcers if maintained in one position and would benefit from repositioning.

The review suggests that large controlled clinical trials are needed to determine the various benefits or problems from different positions. Studies that look at medium and long-term outcomes—duration of mechanical ventilation, skin integrity, hospital length of stay, and mortality—are necessary. In addition, reexamination of positioning interventions with infants who are less stable may help to clarify whether there are subgroups of infants with different disease severity who may benefit. Finally, questions about the effects of lateral positioning, especially in infants with asymmetrical pulmonary pathology, still need answers.

Smoking Cessation

Smoking and other tobacco-product use by adolescents is a major public health problem recognized by the World Health Organization (WHO). Data from 1999–2005 found that nearly 20 percent of adolescents report current tobacco use.[109] Tobacco cessation programs must address this significant public health problem. In addition, both adolescents and younger children may be exposed to second-hand smoke. Nurses who care for pediatric patients have an opportunity to address the health risks of smoking with both pediatric patients and their families. The Joint Commission recommends that smoking cessation advice be given to pediatric patients who are hospitalized with community-acquired pneumonia or asthma and their families. Indeed, Turner-Henson and colleagues[110] have urged nurses to consider assessment of smoking status as part of taking vital signs for all pediatric admissions and in outpatient settings.

A recent meta-analysis of the effects of nursing-delivered smoking cessation interventions with adults found nursing efforts to modestly increase the odds of quitting.[111] There was evidence that interventions were most effective for patients hospitalized with cardiovascular disease, and interventions with nonhospitalized adults were also beneficial. Studies of smoking cessation efforts with adolescents and during pregnancy were not included in the meta-analysis. However, it is not unreasonable to generalize from the findings that smoking cessation interventions with hospitalized patients were most effective. Patients in the hospital may be more

amenable to the intervention. Certainly, the opportunity to offer cessation advice and resources to pediatric or family tobacco users should not be missed.

A study of adolescent smokers' attitudes toward quitting and their beliefs about their parents' opinion about smoking included more than 4,500 U.S. high school students who had smoked within the previous 30 days.[111] All adolescent smokers were asked, "Have you ever seriously thought about quitting smoking?" Those who had seriously considered quitting were questioned about past attempts and how recent their last attempt was. Those who had not seriously thought about quitting were asked if they thought they would ever want to quit. Regardless of whether their parents smoked, adolescents who placed value on their parents' opinions were more likely to think seriously about quitting and to have tried to quit in the past 6 months. Recalling a parent's expressed desire that their child not smoke was associated with significant increases in the likelihood of seriously thinking about quitting, even among those adolescents whose parents smoked. Agreeing with the statement, "When I'm older, my parents won't mind that I smoke," was significantly associated with decreased odds of seriously thinking about quitting and recently attempting to quit. This study demonstrates that parents, both those who smoke and those who do not, may have a significant role in influencing young smokers' desire to quit smoking. Nurses need to exploit this information with families of adolescent patients.

A recent randomized clinical trial compared an Internet-based smoking cessation intervention (Stomp Out Smokes—SOS) developed at the University of Wisconsin with brief individual counseling sessions for adolescent smokers.[113] The smoking abstinence rate for teens who received individual counseling was twice that of those who accessed the Internet-based intervention at 30 days, 24 weeks, and 36 weeks. In fact, the SOS intervention participants accessed the site an average of only 7 days and 11 total logins. Likely, they did not have an adequate "dose" of treatment. More structured, personal, and proactive patient education delivered in person or by telephone or e-mail is recommended for intervention with adolescent smokers.

This section has presented a sample of the evidence-based practices that have implications for national safety and quality aims and the care of infants and children in hospitals. Nurses who care for pediatric patients must be actively involved in the development, testing, implementation, and evaluation of evidence-guided best practices.

Other Issues for Pediatric Care

Although this chapter has focused on pediatric inpatient care, most care for children takes place in outpatient settings. There are critical issues for children requiring outpatient care that impact their health and well-being and, therefore, the illnesses seen in hospitalized children and their potential to experience an adverse event. We must address these issues with the same vigor as the movement toward inpatient evidence-based practices. Otherwise, the overall health of children will deteriorate with lifelong consequences that will impact their quality of life and the cost of health care, as well as limit their opportunities to contribute to society in positive ways.

Poverty and Disparity

Poverty and disparities in health care, two overarching issues for children in this country, impact their care within the community and the inpatient setting. In most cases they are inextricably intertwined. In 2003, an estimated 35.9 million Americans (12.9 percent) lived in

poverty, 4.3 million newly poor since 2000. Approximately 733,000 American children lived in poverty.[114] This is a fluid statistic as third-party payers for children's health care are often public programs, which fill the gaps created by reductions in employer-based health plans. These State and Federal programs are subject to review and reduction at any time, when other financial issues or crises take priority.

Childhood Obesity

Childhood obesity is at epidemic proportions. One in every six children in the United States is obese or overweight.[115] Obesity is not only an adverse social stigma and a threat to quality of life; significant health issues are associated with it. Obese individuals are at greater risk for diabetes, cardiovascular diseases, and poor mental health than persons who are not obese. Children are not an exception. These chronic conditions increase the cost of care over a lifetime and can lead to serious disability.[114]

Poverty, disparities in health care, and childhood obesity present unique challenges for the health care system at large. Long-range planning must address these issues and tangential issues for our children to live healthy, productive lives.

Unique Issues in Adolescent Health

Adolescents (children ages 13–20 years) have unique health care needs, distinct from those of younger children and nonelderly adults. Their physiologic and social characteristics differ from those of younger children and adults. Adolescents require reproductive health care; care for sexually transmitted diseases; mental health care for depression, substance abuse, and other disorders; trauma care; and care for chronic diseases—asthma being the most common.[116]

Recent data reveal unique patient safety problems when adolescents are hospitalized. The incidence of adverse events in the Colorado and Utah Medical Practice Study found 2.74 percent more adverse events among adolescents than younger children.[117] In this study, more than three-quarters of adverse events for hospitalized adolescents occurred with diagnostic, medication, and pregnancy and delivery-related services.

There are racial disparities in the incidence of asthma, a leading cause of chronic illness in children and adolescents. African Americans have a higher prevalence of asthma and are four times more likely to be hospitalized and five times more likely to die of asthma than non-African Americans.[118, 119] Despite much attention on improving asthma care and asthma disparities, a 2003 IOM report still identified the quality of asthma treatment as one of 20 priority areas for national action.[120] Priorities in research to reduce asthma disparities were published by the National Heart, Lung, and Blood Institute in 2002.[121]

The Role of Nurse Scientists

Pediatric nurse scientists have actively engaged in scientific inquiry from the bench to the bedside for many decades. There have been rich contributions associated with nurse-patient interactions that focus on the patient in a holistic manner. Recommendations from Sue Thomas Hegyvary, editor of the *Journal for Nursing Scholarship,* might frame the future of pediatric nursing research. She proposed research that will

1. Attend to morbidity, mortality, and contributing factors at the micro and macro levels of society.
2. Support programs of study that are longitudinal, sequential, and comparative and that continue to examine phenomena from small to larger contexts.
3. Move from reviews of the literature, concept analyses, and proposals for investigation toward new knowledge in the field.
4. Focus on the interventions and outcomes of a study, rather than debate superior or inferior methodologies.
5. Synthesize the aforementioned recommendations to generate research beyond the theoretical and small-scale application.
6. Draw evidence-based conclusions based on scientific findings. In other words, only conclusions based on empirical findings should be promulgated as nursing science.[122]

Benchmarking, Funding, and Federal Data

Participation in national benchmarking and quality work can pose a significant expense for involved institutions. It is difficult, therefore, for some organizations to participate in this valuable work. Institutions should not face economic barriers to participation. Perhaps organizations that demonstrate need could be federally funded to join these efforts.

Funding for scientific work in pediatrics must be increased. However, appropriation discussions for Federal funding are highly competitive. Children are disadvantaged as they are not voting members of society. Although there are strong advocates for funding children's research, their voices can be muted by other specialty groups with voting power. It is critical that nurses, health care providers, and other pediatric stakeholders continue their efforts to speak for children in the halls of Congress.

A well-funded national strategy for organizing, analyzing, and reporting patient safety and quality data would accelerate progress in pediatric safety and quality improvement. The KID HCUP, the Kids Inpatient Database developed as part of the Healthcare Cost and Utilization Project, forms a sound basis for this work; however, not all States report these data, as participation is voluntary. No mandate for participation appears likely. Currently, 36 States report discharge data to AHRQ for inclusion in the KID HCUP database. Even when States do report, missing data can be a significant problem. For instance, reporting race is still optional. Lack of consistency in reporting makes it difficult to control for confounding variables when analyzing the data to answer research questions.

Despite its imperfections, the KID HCUP database is a rich source for health services researchers and practitioners to mine. It would be an even stronger tool if all States reported data and if uniformity and consistency were assured.

National Institute of Nursing Research. The National Institute of Nursing Research (www.ninr.nih.gov), established in 1993, began as the National Center for Nursing Research in 1985. It has been a leader in funding for nursing research in key areas (see Table 3). Part of the National Institute of Nursing Research mission is to identify and fund research in areas of science unique to nursing and vulnerable patients, including children. A full complement of funding is available, from intramural awards that support onsite education and training to develop young investigators, to extramural funding for investigator-initiated research and for centers that conduct and disseminate research for special populations.

Table 3. National Institute of Nursing Research—Extramural Areas of Science

Chronic illness & long-term care	Health promotion & risk reduction in adults	Cardiopulmonary health & critical care
Neurofunction & sensory conditions	Immune responses & oncology	Reproductive health & child health promotion
End-of-life & environmental contexts		

Other funding sources. The American Nurses Foundation (www.nursingworld.org/anf) and Sigma Theta Tau (www.nursingsociety.org) are two additional organizations that support nursing research. In addition, many specialty organizations have grant funds available on a competitive basis. A search on each organization's Web site can yield information about the availability of grants and their application process. All typically support both quantitative and qualitative research that can help launch an investigator's pilot work, in advance of funding for more comprehensive studies.

Positive Momentum for Nursing Practice: The Magnet Recognition Program

In the past decade, the Magnet Recognition Program, the seal of approval for professional nursing practice environments, has gained considerable momentum across the country. One of the hallmarks of this prestigious certification is that direct care nurses have clinical experts who help create an environment of scientific inquiry. Practice based on evidence is critical to both a culture that contributes to nursing satisfaction and to quality care for patients. Magnet momentum (www.nursingworld.org/ancc/magnet) continues to grow each year and can only advance the use of evidence-based nursing practices. Children and their families will reap the benefits of professional nursing practice driven by science, not tradition—valuable and worthy goals for us all.

Conclusions

Pediatric care is complex due to developmental and dependency issues associated with children. How these factors impact the specific processes of care is an area of science in which little is known. We are only beginning to understand the relationship between nurse staffing and adverse events in hospitalized children; effects that may be compounded by inadequate numbers of pediatric nurses. Throughout health care providing safe and high quality patient care continues to provide significant challenges. Efforts to improve the safety and quality of care are resource intensive and take continued commitment not only by those who deliver care, but by agencies and foundations that fund this work. Advocates for children's health care must be at the table when key policy and regulatory issues are discussed. Only then will the voice of our most vulnerable groups of health care consumers be heard.

Chapter 16. Prevention—Safety and Quality

Carol Loveland-Cherry

Background

To date, the preponderance of research on patient safety and the transformation of the work environment has focused on inpatient, acute care settings. Institute of Medicine (IOM) reports[1, 2] clearly recommend that work be done on "studies and development of methods to better describe, both qualitatively and quantitatively, the work nurses perform in different care settings"[2] (p. 325). Specifically, the recommendation is that research on patient safety needs to be addressed across care settings. Preventive services, primary care, and ambulatory care settings are areas in which there is a more limited body of work related to patient safety. Yet, these nonacute care settings constitute growing loci of health care services. This chapter will review the extant research on patient safety in preventive services, primary care, and ambulatory care settings. Preventive services, broadly defined, include screening, counseling, and chemoprophylaxis. This chapter will not focus on prevention of adverse events in ambulatory care or inpatient settings.

The Surgeon General's report[3] and subsequent plans for ensuring the health of the nation[4, 5] emphasize the role of prevention in addressing the leading causes of morbidity and mortality. Clinicians play important roles in both primary and secondary prevention.[6] Primary prevention is directed at measures to avoid or prevent the onset of disease or adverse condition. Secondary prevention focuses on the identification and treatment of asymptomatic individuals who have identified risk factors to prevent the development of active disease and/or reduce morbidity and mortality. Preventive services encompass health care provided in primary care settings, such as office-based practices and clinics, and in community-based settings. Preventive services are less regulated and controlled than health care services provided in institutions such as hospitals, long-term care facilities, and nursing homes. Not only have preventive services increased and become a central component of primary health care, these services also have become a focus of scrutiny in terms of quality and safety[6] (p. 13). Screening, counseling, preventive medications, skill building, and behavioral change strategies comprise the major foci of preventive services.

Two national task forces have been charged with the evaluation of preventive services. The Agency for Healthcare Research and Quality (AHRQ) convened the United States Preventive Services Task Force (USPSTF), an independent body of experts, to evaluate and make recommendations for clinical preventive services. The Centers for Disease Control and Prevention (CDC) established the Community Task Force to evaluate public health prevention programs.[7] Both task forces focus on establishing the efficacy of prevention strategies and also consider the relative harms and benefits of preventive services. The recommendations of these two task forces are available in print and online (http://www.ahrq.gov/clinic/prevenix.htm; http://www.thecommunityguide.org/) and will not be reviewed in this chapter.

Several IOM reports have emphasized the need to address not only the efficacy and effectiveness of health care strategies, but also patient safety.[8] The report *To Err is Human: Building a Safer Health System*[8] defines important terms. Safety is defined as "freedom from accidental injury" (p. 4) and error as "failure of a planned action to be completed as intended or the use of a wrong plan to achieve an aim" (p. 28). Error can occur in either the planning or

execution of health care services. In preventive services, the challenges are defining and tracking safety issues or adverse events. Thus, identification of literature related to patient safety and quality of care in preventive services is difficult. Further, with few exceptions, the studies are of medical errors. The studies of medical errors and adverse events cover doctors and other primary health care providers, such as nurse practitioners.

The research evidence for patient safety in preventive services falls into five distinct groups: identification and classification of errors in primary care, harms of screening, harms of information technology, errors arising from language in preventive services, and potential interventions to prevent errors and adverse events. The evidence in each of the first four groups will be summarized and assessed in this chapter; the potential interventions will be included within each of the relevant categories.

Research Evidence

Errors in Preventive Services/Primary Care

In the United States, the literature on patient safety has focused primarily on the inpatient, acute care setting. In contrast, a growing literature in the United Kingdom focuses on identifying, tracking, and assessing errors in primary care. Seven manuscripts describe some aspect of errors in preventive services, primary care, or ambulatory services. The first priority for promoting patient safety in primary care was to identify the most common errors that occur in primary care.[9]

Researchers have used several different methodologies to identify errors in primary care. The approaches include observational prospective studies,[10, 11] review of malpractice claims,[12] reports from physicians,[13, 14] and interviews with adult patients.[15] One systematic review has summarized literature in this area published between 1965 and 2001.[16] The different methodologies, including study length and modes of data collection, make it difficult to compare rates of errors or adverse events. The number of events reported were

- 117 errors for 15 physicians in 83 visits across 7 offices over 3 half-day sessions[11]
- 221 incidents from interviews with 38 patients asking them to recall events that occurred at any time in the past[15]
- 344 incidents from 42 physicians over 20 weeks[13]
- 940 incidents over 2 weeks across 10 practices[14]
- 805 incidents occurring between October 1993 and June 1995 from 324 physicians[10]
- 5,921 incidents from claims data for over a 15-year period[12]
- 1,223 incidents from 4 articles published 1995-2002[16]

Regardless of the methodology, similar categories of errors and events were identified and patterns emerged that provided the basis for development of classification systems. Dovey and colleagues[13] developed a taxonomy based on the identified types of errors and sources of errors. The most general groupings of errors resulted in two major categories: process errors, and knowledge and skills errors. Each of the two categories had three additional levels of specificity. For example, a process error in investigating a patient's condition, specifically in the process of laboratory investigations, might involve a wrong test being ordered or a test not ordered when appropriate. Bhasale and colleagues[10] classified incidents as pharmacological (e.g., inappropriate drug), nonpharmacological (e.g., treatment omitted/delayed), diagnostic (e.g., missed), or equipment (e.g., malfunction/ineffective). Preventable harms identified by patients were

classified as psychological (e.g., personal worth), physical (e.g., pain) or economic/other (e.g., avoidable personal medical expense).[15] Elder and colleagues[11] described office administration errors (i.e., charting, general office administration), physician-related errors, patient communication errors, and preventable adverse events. Rubin and colleagues[14] noted six categories of errors: prescriptions, communication, equipment, appointments, clinical, and others. Elder and Dovey[16] identified three categories: diagnosis—related to symptoms or prevention with either missed or delayed diagnosis; treatment—either drug or nondrug as incorrect/inappropriate, delayed or omitted; and preventive services—inappropriate, delayed, omitted, or procedural complication. In addition to classifying types of errors, Elder and Dovey identified related factors, such as clinician factors (clinical judgment and procedural skills error), communication factors (clinician–patient, clinician–clinician/health care system personnel), administration factors (clinician, pharmacy, ancillary providers, office setting), and blunt-end factors (personal and family issues of clinicians and staff, insurance company regulations, government regulations, funding and employers, physical size and location of practice, general health care system).[16] Kuzel and colleagues[15] offered a similar list of access breakdown, communication breakdown, relationship breakdown, technical error, and inefficiency of care.

Bhasale and colleagues[10] also identified differences in individuals involved in preventable incidents. The incidents involved slightly more females (58 percent) than males and more older individuals 25 years and older (around 85 percent) than younger ones. Overall, infants and females older than 75 years were overrepresented in the incidents. The same study described factors that mitigated the outcomes of adverse events: early intervention by reporting physician, patients, patient's relative, another provider; plain good fortune; patient's good physical or psychological condition; prior experience or training; reliability of professional backup; skilled assistant; high awareness via quality assurance activities; and reliability of equipment.

The data from this group of studies, regardless of the methodology, provide both identification of errors or adverse events in preventive services or primary or ambulatory care and direction for interventions. Dovey and colleagues'[13] major classifications of process and knowledge and skills errors provide major conceptual groupings within which to examine the specific error identified in the schema. Combined with Bhasale and colleagues'[10] identification of mitigating factors, this group of studies provides direction for both identifying errors and adverse events and for proposing interventions to address them. The findings specific to preventive services imply that errors or adverse events result from screening, counseling, or chemoprophylaxis being inappropriate, delayed, or omitted, or involve procedural complications. These errors or adverse events may arise from either process errors or knowledge and skill errors. Process errors are defined as resulting from some aspect of care delivery systems.[13] Examples of process errors include care that was provided but not documented in the patient's chart (e.g., a mammogram performed but not recorded) or a medication not being dispensed as ordered. Knowledge and skill errors are related to providers' clinical skills and knowledge (e.g., a wrong or missed diagnosis or a wrong treatment based on lack of clinician knowledge).

The next section examines two groups of studies that represent specific instances of areas with potential harms: medication errors and screening activities.

Adverse Drug Events in Preventive Services/ Primary Care/Ambulatory Care

Twelve studies[17–28] examined adverse drug events in primary or ambulatory care. None of these studies were specific to chemoprophylaxis. Rather, the foci were similar to those in acute care or inpatient care, but occurred in ambulatory or primary care settings. Thus, this group of studies was not included in this review as adverse drug events are covered in other chapters in this book.

Potential Harms Related to Screening in Preventive Services

Screening is a major intervention in preventive services. Although a number of benefits have been associated with screening activities in preventive services, risks have also been identified. Potential risks of screening include misunderstanding test results, misdiagnosis, mislabeling, stigmatization, and decreased psychological well-being.[28] Three major reviews[30–32] and 10 studies[33–42] examined the benefits, risks, and harms associated with screening activities. The most common screening tests reported were for breast, cervical, prostate, and colorectal cancers.

Screening mammography is recommended for women ages 40 years and older, but there is limited evidence for the upper age for screening. There are potential harms associated with mammography. The incidence of ductal carcinoma in situ (DCIS) increases in elderly women. The risk of death from DCIS progressing to invasive breast cancer is very low; therefore, the risks of surgery to treat DCIS outweigh the benefits. Three studies found that approximately 8 percent of women ages 70 years and older had an abnormal result from mammography, and 85 percent to 92 percent of those with an abnormal result did not have cancer.[31, 33, 35] A slightly lower percentage of clinical breast examinations (3.9 percent) resulted in abnormal results, but a higher percentage of these women (97 percent) did not have cancer on followup.[33] Thus, potential harms of screening mammography or clinical breast examination include unnecessary biopsy and the stress and worry related to the possibility have having cancer.[20]

Similarly, overdiagnosis and overtreatment in 40 percent of women[34] are potential harms of cervical cancer screening. Results of a cohort study of Pap smear results in postmenopausal women 44–79 years of age[37, 31] demonstrated a high incidence of false positive results (all but 1 of 110 abnormal Pap smears). Other harms of Pap smear screening include identification and treatment of inconsequential disease, high anxiety, low self-esteem, and disrupted partner relationships.[31]

In addition to the potential harms of psychological distress and false-positive results, perforation, bleeding, stroke, myocardial infarctions, Fournier gangrene and thrombophlebitis, and treatment of inconsequential disease are harms associated with colonoscopy in 3 of 1,000 screenings.[31] Woolf [36] identified potential harms of PSA testing for men without disease and for those with prostate cancer. False-positive results cause unnecessary followup procedures and anxiety. Treatment of inconsequential disease results in unnecessary procedures and potential complications.

These potential harms of cancer screening are especially important in decisionmaking for elderly individuals, as there are fewer studies and evidence for this segment of the population. Based on analysis of all-cause and cancer-specific mortality from the National Center for Health Statistics and Surveillance Epidemiology and End Results Survey (SEER), Rich and Black[38] concluded that potential harms may outweigh the small benefit of screening for breast cancer,

colon cancer, and cervical cancer in elderly individuals. Volk and colleagues[39] evaluated a patient-educational approach to shared decisionmaking for prostate cancer screening that included both potential benefits and harms of screening. The results of the randomized clinical trial indicated positive outcomes in terms of increased knowledge and more informed decisions regarding prostate cancer screening. Walter and Covinsky[40] advocated including potential harms in their framework for individual decisionmaking in cancer screening in elderly individuals.

In summary, harms of various cancer screening procedures have been identified. However, it is important to evaluate the potential harms for each procedure relative to the benefits for specific age groups and other individual considerations. Thus, the USPSTF recommends routine screening mammography for women ages 40 years and older; routine screening for cervical cancer in women who have been sexually active and have a cervix, but against routine screening for women older than 65; and routine colorectal cancer screening for men and women 50 years and older. However, the USPSTF is currently updating recommendations for screening for colorectal, cervical, and breast cancer. The USPSTF currently recommends against routine screening for pancreatic cancer or ovarian cancer. The task force concluded that there was insufficient evidence to recommend for or against routine screening for prostate cancer, skin cancer, oral cancer, or lung cancer.

Errors and Adverse Events Related to Language in Preventive Services

A small but interesting group of studies[41, 42] and one review[43] examined the role of language either as a barrier to receiving care or as a factor in adverse events. This area of study is particularly relevant given the growth of ethnic populations in the United States. Nearly 20 percent of U.S. citizens over the age of 5 years speak a language other than English at home.[41] However, it is estimated that "more than 50 percent of adults over the age of 18 who speak a language other than English at home speak English 'very well'"[41] (p. 254). Lack of proficiency in English may result in communication problems with health care providers and decreased utilization of care, and it may reflect cultural values and beliefs.[42] Results of two studies supported the potential for harm resulting from women not receiving preventive services[42] and infants of parents whose primary language is not English not receiving recommended preventive care.[41] Using data from a cross-sectional survey of 22,448 women completing the 1990 Ontario Health Survey, logistic regression calculated odds ratios for receiving breast examinations, mammograms, and Pap tests for women who reported a language other than English as spoken at home versus those who reported English as the primary language, adjusting for socioeconomic factors, contact with the health care system, and cultural measures.[42] Results indicated that women who reported a language other than English spoken at home were less likely to receive important preventive services than those who spoke English at home. These findings persisted after adjusting for the confounding variables. French-speaking women were less likely to receive breast examinations or mammograms, and women speaking other languages were less likely to receive Pap tests.

In a retrospective cohort study of 38,793 year-old infants enrolled in Medicaid, relative risk of receiving appropriate and timely preventive care was estimated using multivariate regression.[41] Primary language of parents, race and ethnicity, rural residence, and managed-care plan were independent variables. Results indicated that "fewer than one in six infants enrolled in Medicaid in their first year of life received recommended preventive care as defined by the

[American Academy of Pediatrics]"[41] (p. 257). Further, infants whose parents reported that English was not their primary language were half as likely to receive recommended preventive care. When confounding factors were considered, results indicated that Asian-American infants were less likely to experience disparities in preventive care associated with primary language than White, Hispanic, and African-American infants.

While the evidence is limited, the results of these two studies support the potential for adverse events resulting from language barriers. An obvious strategy would be to reduce the language barriers. A systematic review of the impact of medical interpreter services on the quality of health care[43] indicated that health care was compromised for patients not proficient in English; they were less likely to receive preventive screening, more likely to have a greater number of tests done at higher costs; and were less satisfied with care. Additionally, the quality of care is further compromised when untrained or ad hoc interpreters, especially children, are used. However, availability of trained interpreters was positively associated with obtaining preventive screening, such as mammograms. In light of the changing demographics and diversity of the U.S. population, this small but growing body of literature on language as a barrier or factor in adverse events in preventive services provides another challenge for the health care systems.

Errors and Adverse Events Related to Information Technology in Preventive Services

A final group of studies explored the impact of the growing use of information technology (IT) in health care. IT in health care has been examined from several perspectives. There is a literature on the use of e-mail and the Internet by consumers, another on the adoption of IT by health care systems, and a third on the unintended consequences of the use of IT in health care.

Although reports of the extent of use of the Internet and e-mail for health care vary from 35 percent to 80 percent of adults in the United States,[44] the actual and potential impact of IT in health care is significant. A survey of a nationally representative sample of 8,935 (69.4 percent of a random sample of 12,878) adults age 21 years and over, individuals age 50 and older, and veterans identified four frequent uses of the Internet and e-mail.[44] The most common use of the Internet (reported by 40 percent of respondents) was for information or advice about health or health care. This was followed by use of e-mail or the Internet to communicate with family or friends about health, use of e-mail or the Internet to communicate with a health care professional, and use of these technologies to communicate with other people with similar health conditions. However, use of the Internet for health care was a relatively infrequent activity (every 2 to 3 months or less frequently). Individuals younger than 75 years old and women were more likely to use the Internet and e-mail for health. Results also indicated that e-mail and the Internet were used most often to gain health-related information and had little effect on the number of contacts with health care providers or to obtain a prescription drug.

IT has been more developed and adopted for financial management than for quality and safety purposes.[45] Results from a study of IT use in a variety of health care settings in the Boston and Denver areas indicate that physician practices (the most common site of preventive services), which are generally run as "small independent practices"[46] (p. 6), use IT primarily to manage billing and schedule patients. Poon and colleagues[46] propose that the limited use of electronic health records in these practices is related to the perception of limited proven benefits relative to the required financial and time commitments needed.

Based on results from separate qualitative studies, Ash, Berg, and Coiera[47] presented evidence that implementation of electronic patient care information systems (PCISs) in many instances appears to promote rather than limit errors. They argued that factors, including the complexity of PCISs and the physical space and other system characteristics, contributed to the occurrence of "unintended consequences"[47] (p. 104). The authors identified errors in two general areas: process of entering and retrieving information, and communication and coordination processes. They attributed errors in entry and retrieval of information to the high level of interruption and "cognitive overload" related to practice environments. Further, the authors proposed that errors in communication and coordination were related to the assumptions of a linear workflow and communication as information transfer. They advocated for educating health care providers to have a critical approach to PCISs, that developers and vendors of PCISs be clearer about the limitations of the systems, and that clinicians be supported in continuing interactions that are part of monitoring the safety of clinical systems.

Research that evaluates the ability of IT systems to promote patient safety and reduce errors is limited but growing,[45] especially in preventive services. Five studies[48–52] examined the use of an electronic health record system to generate physician, telephone, and letter reminders for patients to obtain preventive services. Results indicated that all three types of reminders were effective. There is evidence supporting the reduction of medication errors and adverse events through the use of computerized physician order entry and online decision support.[53] Bakken and colleagues[54] advocated the use of informatics to address errors associated with impaired access to information through the use of personal digital assistants, to address communication failures associated with adverse events, to promote the use of standardized practice patterns, and to provide automated surveillance to detect and prevent real-time errors. The proposed approaches have direct application in preventive care settings.

Evidence-Based Practice Implications

The evidence on errors and adverse events in preventive care provides preliminary direction for practice. Few if any studies proposed or evaluated approaches to avoid or reduce errors and adverse events in prevention. However, a growing number of studies have evaluated strategies to reduce errors and adverse events in acute, inpatient, ambulatory, primary, and home care, and they provide potential direction for prevention as the field matures. Leape's[55] directives—identify what works, ensure that the patient receives it, and deliver it flawlessly—are relevant for ensuring safety in prevention. At this point, perhaps the most viable approach to assure patient safety in prevention practice is use of the guidelines of the USPSTF, AHRQ, the Community Task Force, and CDC.

Research Implications

The greatest challenge in patient safety and quality in preventive care is the lack of a strong body of evidence on which to base our understanding of errors and adverse events in prevention and, more broadly, in ambulatory and primary care settings. Research in preventive care is limited relative to that in acute care, inpatient settings, and home care. The focus has been on research evaluating the efficacy of preventive services, which includes an evaluation of the potential and actual harms of the services in order to determine the net benefit. While there is a growing body of evidence for safety and quality in health care in primary and ambulatory

settings, there is very limited literature on harms or adverse events in preventive care and how to avoid them. Additionally, much of the research is observational and descriptive, with few interventions being tested. The research on identifying and describing errors in primary and ambulatory care has relevance for preventive care. However, there is a need for research directed at explicating errors and adverse events in preventive care.

Once the types of errors and adverse events have been identified and described, then research describing the factors associated with these events is needed. Further, there is limited evidence on basic questions, such as when to begin or discontinue screening, chemoprophylaxis, or counseling and implications for adverse events or potential harms. Only then can nurses and other health care professionals develop and test strategies to reduce risk related to preventive services. For example, the evaluation of the use of IT to decrease risks and adverse events is a major focus in acute care, ambulatory care, and primary care settings. Would the use of IT approaches be appropriate in preventive services? How can the human factor principles of standardization, simplification, and use of protocols and checklists[55] be facilitated by the use of IT in prevention? Finally, the difficulties inherent in research on preventive services present significant challenges, including timing of services and consideration of contextual factors (age, culture, race/ethnicity, gender, setting, etc.).

Thus far, the evidence presented attempts to answer the following: (1) How do errors and adverse events in prevention differ from those for other types of health care services? (2) How do contextual factors contribute to potential errors and adverse events in prevention? and (3) What are potential areas of research for nursing that would contribute to addressing patient safety in prevention? The following areas are the critical research gaps:

- Descriptive data on errors and adverse events in preventive services
- Data on factors related to errors and adverse events in preventive services
- Evaluation of interventions to reduce errors and adverse events in preventive services.

Conclusion

The limited body of evidence on errors and adverse events in preventive services, especially from a nursing perspective, supports the need for additional research to move ahead in the area of patient safety. It is likely that some of the evidence from studies in ambulatory and primary care will provide direction for research and subsequent evidence-based practice in preventive care. However, there may be unique errors and adverse events associated with preventive services. It is clear that there is potential for errors and adverse events in preventive services, but additional evidence is needed to explicate what they are. The evidence that is available is largely from either descriptive studies or from randomized controlled trials (RCTs) examining the efficacy of preventive services, specifically in cancer screening. There is less systematic evaluation of counseling interventions for prevention. The nature of preventive services and their outcomes and where they are delivered increase the complexity of both establishing an evidence base and implications for practice. The continued evaluation of using information technology to address risks and adverse events is a promising area for study and practice.

The focus in safety and quality research in health care has been on preventable events rather than on preventive services. Screening, counseling, and chemoprophylaxis are the key elements of preventive services. The evidence base on errors and adverse events in preventive services is limited and needs to be developed to provide direction for practice.

Search Strategy

A search of the CINAHL®, Ovid MEDLINE®, Cochrane Database of Systematic Reviews electronic databases, and the AHRQ Web site from 1990 to 2006 was conducted using the following search terms: patient safety, safety, quality, preventive services. The search was further limited to research studies and reviews. A total of 115 references were identified and the abstracts reviewed. The criteria for inclusion in the review for this chapter were (1) systematic review of published research; (2) nonsystematic review of published research; and (3) published research that used randomized control, comparison, and pretest–post-test no control designs. Based on the review of the abstracts using these criteria, 6 reviews, 10 commentary or background articles, and 32 studies were selected for inclusion in the review.

Evidence Table. Prevention—safety and quality

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting and Study Population	Study Intervention	Key Finding(s)
Ash 2004[46]	Patient care information system-related (PCISs) errors	Literature review, nonsystematic, and series of qualitative studies	Qualitative studies (5) impact of PCISs in health care and unintended outcomes (2).	Health care delivery settings and interviews with professionals in the United States, Netherlands, and Australia	None	Types of errors: Process of entering and retrieving information – juxtaposition error, orders entered for or on behalf of the wrong person, cognitive overload, communication and coordination process – inflexibility, urgency, work-arounds, transfers, loss of communication, loss of feedback, decisions support overload, catching errors, multidisciplinary qualitative research.
Baker 2003[44]	Use of Internet and e-mail for health care information	Cross-sectional study	National survey of Internet use for health care and prevalence of e-mail use for health care (5). Use of Internet and e-mail for health care and effects on knowledge of health care and use of health care system (3).	4,764 individuals ages 21 years and older who were self-reported Internet users drawn from a research panel of more than 60,000 U.S. households	Internet and e-mail use	~40 percent of respondents with Internet access used Internet to look for advice or information about health or health care; 6 percent used e-mail to contact a health care professional; ~1/3 using Internet for health reported it affected a health or health care decision; little effect on health care utilization – 94 percent reported no effect on number of visits and 93 percent no effect on number of telephone contacts; 5 percent reported use of Internet to obtain prescriptions or pharmaceutical products.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting and Study Population	Study Intervention	Key Finding(s)
Bakken 2004[54]	Use of informatics to promote patient safety and enable evidence-based practice	Literature review, nonsystematic	Literature review, nonsystematic (6). Patient safety and evidence-based practice (3).	Review of literature on informatics infrastructure for patient safety and evidence-based practice	None	Examples of how components of informatics infrastructure can be integrated to achieve evidence-based practice and patient safety objectives in four areas: improving information access, automated surveillance for real-time error detection and prevention, facilitating communication among members of the health care team, and standardization of practice patterns.
Barratt 2002[56]	Harms of screening mammography	Systematic literature review	Decision-analytic, cost-effectiveness models; quality of life and life expectancy	Australian women 70 years and older	None	Five models met inclusion criteria; two included quality of life. Life-expectancy benefit of screening mammography diminishes with increasing age: 70–79 years, 40–72 percent without quality of life adjustment, 18–62 percent with it. 9,600 of 10,000 will be told they do not have breast cancer, ~400 will have further tests; ~70–112 will undergo breast biopsy and 19–80 cancers detected; ~ 15–20 percent will be DCIS; quality-adjusted life-year = $8,119–$27,751. Relatively cost-effective. Not studied: anxiety, mortality from mastectomy, post-op morbidity.
Barton 2005[57]	Risk factors for breast cancer	Literature review, nonsystematic/ narrative	Accepted screening methods and new technologies	Women in the United States	None	False-positive approach 50 percent after 10 screens; discovery of DCIS with transformation 14–60 percent; MRI more sensitive but led to >three times the number of biopsies with no cancer; high costs.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting and Study Population	Study Intervention	Key Finding(s)
Bhasale 1998[10]	Incident monitoring of potential harm in general practice	Noncomparative study	Observational study (5). Reports of number and type of incidents, contributing factors, mitigating factors, additional resource use (Level 1).	324 general practitioners (GPs) from nonrandom sample of Australian GPs 10/93–6/95	None	805 incidents reported: 76 percent preventable, 27 percent potential for severe harm, no long-term harm for 66 percent, related to pharmacological management, nonpharmacological management, diagnosis, or equipment; most common contributory factors poor communication between patients and health care professionals, actions of others, and errors in judgment.
Brawley 2005[30]	Biases, harms, accuracy of cancer screening	Literature review, nonsystematic/ narrative	Nonsystematic literature review (6). Harms of screening (2).	Review of screening modalities for specific cancers, including potential harms and accuracy of screening	None	Biases – selection, lead-time, length; harms – complications of treating true-positives and false-positives, labeling, mental anguish; accuracy – sensitivity, specificity positive predictive value, negative predictive value; breast cancer false-positives – repeat mammogram, ultrasound, biopsy; ovarian – additional, invasive evaluation; prostate – missed cases, clinically insignificant cases.
Brown 2006[20]	Pharmacist-physician relationship in detecting ambulatory medication errors	Noncomparative study	Observational study without controls (5). Data pharmacist's role, responsibilities, and expectations to inform physicians about medication errors (3).	Focus groups with 30 pharmacists and 31 patients in community pharmacies in Mississippi	None	Ambulatory pharmacist is common link between physician and patient, multiple physicians; pharmacist is patient educator, pharmacist is interceptor in detecting medication errors; hesitancy to contact physicians, physician accessibility barriers.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting and Study Population	Study Intervention	Key Finding(s)
Cohen 2006[41]	Disparities in pediatric preventive care associated with primary language of parent	Retrospective cohort study	Review of Medicaid data (5). Appropriate and timely receipt of six preventive care visits in first year of life (2).	Review of records for 38,793 Medicaid - enrolled 1-year-old infants in Washington State	Primary language of parent	Infants of parents whose primary language was not English were half as likely to receive recommended preventive care; disparity evident for white, Hispanic, and African-American but not Asian-American infants.
De Smet 2004[28]	Repeat prescribing	Systematic literature review	Repeat prescribing in ambulatory care patients: definition and scale of repeat prescribing; problems with repeat prescribing and areas for improvement; characteristics and results of intervention studies; conclusions and recommendations for future research (3).	Ambulatory care patients	Review of medications by pharmacist; feedback to patient and physician; home inventory of medications; monthly dispensing with protocol led to check on drug-related problems; chart review; written feedback by physician	Repeat prescriptions range from 29 percent to 75 percent; much by GPs without direct doctor-patient contact; overall interventions helped resolve pharmaceutical care issues – compliance; effects on health-related quality-of-life, death rate, health care consumption or total health care cost not observed; real clinical improvements – adverse effects score, lipid values, reduced inappropriate prescribing in elderly outpatients receiving polypharmacy; some showed positive effect on number of medications, medication units, and medication cost.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting and Study Population	Study Intervention	Key Finding(s)
Dovey 2002[13]	Medical errors in family practice	Noncomparative study	Observational study without controls (5); "error is defined as the failure of a planned action to be completed as intended or the use of a wrong plan to achieve an aim"; "safety is defined as freedom from accidental injury"; "anything that happened in your own practice that should not have happened, that was not anticipated, and that makes you say 'that should not happen in my practice and I don't want it to happen again'" (1).	42 family physicians from the National Network for Family Practice and Primary Care Research	Preliminary taxonomy of medical errors in family practice	330 error reports resulting in four-layered taxonomy: Process errors and knowledge and skills errors; knowledge and skills – receptionist failing to make urgent appointment, physicians decided to discharge patients before able to function well at home; process – treatment delivery problems, miscommunication; consequences – none, care delayed/extended, financial and time costs to patients, physicians, system, patient upset or lost trust in physician, became ill, did not regain health, admitted to hospital, or died.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting and Study Population	Study Intervention	Key Finding(s)
Elder 2002[16]	Errors and preventable adverse event from medical care in outpatient primary care settings	Systematic literature review	Systematic review of original research (7 studies); process errors and preventable adverse events (1).	Seven studies from family practice, ambulatory care, primary health care	Classification of preventable adverse events (PAE) and process errors in primary care	Limited number of small studies; classification of three main categories of PAEs – diagnosis (misdiagnosis related to symptoms or prevention) treatment (drug or nondrug), and preventive services (inappropriate, delayed, omitted, procedural complications); attributable to four groups of process errors: clinician factors (clinical judgment, procedural skills error), communication factors (clinician-patient, clinician-clinician, or health care system personnel), administration factors (clinician, pharmacy, ancillary providers, office setting), blunt-end factors (personal and family issues of clinicians and staff, insurance company regulations, government regulations, funding and employers, physical size and location of practice, general health care system).
Elder 2004[11]	Errors and preventable adverse events by family physicians in outpatient visits	Noncomparative study	Observational study without controls (5). Errors and preventable adverse events, patient harm (1).	15 family physicians in 7 practices in Cincinnati area	None	117 errors or preventable adverse events; most common were administration errors (charting, general office administration); physician-related errors; patient communication errors. Harms: actual minor physical discomfort, mild adverse drug reaction, moderate physical injury from a procedure, progression of disease; most common emotional distress and wasted time for the patient; potential harms development of preventable disease, pain or physical distress, progression of disease, drug-drug interactions, infection, and poor outcomes from procedure.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting and Study Population	Study Intervention	Key Finding(s)
Field 2004[24]	Strategies for identifying adverse drug events (ADEs)	Prospective cohort study	Observational study without controls (5); drug/drug-related incidents (1).	31,757 Medicare enrollees in large multispecialty group practice in New England over 12 months	None	1,523 ADEs, 28 percent considered preventable; positive predictive values for sources – 54 percent, highest provider reports but accounted for only 11 percent of ADEs and 6 percent of preventable ADEs, hospital discharge summaries very low PPV, computer-generated signals accounted for 31 percent of ADEs and 37 percent of preventable ADEs, electronic notes accounted for 35 percent of ADEs and 29 percent of preventable ADEs; little overlap in ADES identified across all sources; electronic strategies identify more ADEs than other sources; use multiple sources.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting and Study Population	Study Intervention	Key Finding(s)
Flores 2005[43]	Effect of medical interpreter services on health care quality	Systematic review	Systematic review of 36 studies (RCT, descriptive, qualitative, survey) on LEP (limited in English proficiency) (1). Quality of health care and errors related to use of interpreters; communication issues; patient satisfaction with care; and processes, outcomes, complications, and use of health services (2).	Urban emergency department, hospitals, physician offices	None	Lack of interpreters results in poor self-reported understanding of diagnosis and treatment plan. Ad hoc interpreters misinterpret or omit up to half of all physicians' questions, are more likely to commit errors with potential clinical consequences, have a higher risk of not mentioning medication side effects, and ignore embarrassing issues when children are ad hoc interpreters. Lack of interpreters affects communication and quality of psychiatric encounters, including positive effects of bilingual providers and an adverse impact of ad hoc and no interpreters. Bilingual providers and telephone interpreters yield highest levels for satisfaction. Interpreters resulted in increase of preventive screening and reduced disparities in LEP and EP patients: with interpreters, greater increase in office visits, number of prescriptions written and filled, but none in number of phone contacts, urgent care phone calls, or urgent care visits. Controversy on duration of visits. LEP with no or ad hoc interpreter have more medical tests, higher test costs, more frequent intravenous hydration, and higher risk of hospitalization.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting and Study Population	Study Intervention	Key Finding(s)
Gandhi 2003[19]	Adverse drug events in primary care	Prospective cohort study	Observational study without controls (5). Adverse drug events (1).	Survey of 661patients who received at least one prescription during a 4-week period (55 percent response rate) and chart review at four adult primary care practices in Boston (two hospital based and two community based)	None	25 percent (n = 162) had a total of 181 adverse drug events;13 percent (24) serious, 28 percent (51) ameliorable, 11 percent (20) preventable. Of 51 ameliorable 63 percent attributed to physician's failure to respond to medication-related symptoms, and 37 percent to patient's failure to inform physician of symptoms; most frequent medication classes – selective serontonin-reuptake inhibitors (10 percent), beta-blockers (9 percent), angiotensin-convertying-enzyme inhibitors (8 percent), nonsteroidal anti-inflammatory agents (8 percent). Multivariate analysis – only number of medications taken significantly associated with adverse events.
Gandhi 2005[26]	Outpatient prescribing errors	Prospective cohort study	Observational study without controls (5). Adverse drug events (1).	Outpatients over age 18 who received a prescription from 24 participating physicians in 4 adult primary care practices in Boston using prescription review, patient survey, and chart review	None	Screened 1,879 prescriptions from 1,202 patients and 661 surveys (55 percent response rate); 143 prescriptions contained a prescribing error, 3 errors led to preventable ADEs, and 62 had potential for patient injury. 1 (2 percent) was potentially life threatening and 15 (24 percent) were serious. Rates of medication errors and potential ADEs not significantly different at basic computerized prescribing sites vs. handwritten sites; advanced checks could have prevented 95 percent of potential ADEs; prescribing errors in 7.6 percent of outpatient prescriptions.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting and Study Population	Study Intervention	Key Finding(s)
Glassman 2006[27]	Effects of automated drug alerts on clinicians' knowledge and perceptions	Pretest and post-test study	Observational study with controls (4). Increased recognition of selected interacting dug pairs and perceptions of computerized order entry (3).	97 clinicians (82 physicians and 15 nurse practitioners/physician asst) in ambulatory settings in Southern California Veterans Affairs Healthcare System	Interval (~2 years) exposure to automated drug alerts via computerized patient record system (CPRS)	Clinicians recognize seven interacting and/or contraindicated drug-drug pairs at both time periods; recognition of three contraindicated drug-drug pairs moderately improved; more clinicians preferred order entry at followup vs. baseline (63 percent vs. 45 percent); most common barrier to use of order entry system was "poor signal to noise" ratio or too may nonrelevant alerts.
Gurwitz 2003[17]	Adverse drug events among older person in ambulatory setting	Retrospective cohort study	Observational study without controls (5). Adverse drug events (1).	Medicare enrollees cared for by multispecialty group practice during a 12-month period	None	1,523 adverse drug events – 27.6 percent (421) considered avoidable; 578 (38 percent) categorized as serious, life threatening, or fatal; overall rate of 50.1 adverse drug events/1,000 person-years; rate of 13.8 preventable adverse drug events/1,000person-years. Errors occurred most often at stages of prescribing (58.4 percent) and monitoring (60.8 percent); 21.1 percent of errors involved patient adherence. Most common medication categories were cardiovascular (24.5 percent), diuretics (22.1 percent), nonopioid analgesics (15.4 percent), hypoglycemics (10.9 percent), anticoagulants (10.2 percent).

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting and Study Population	Study Intervention	Key Finding(s)
Hibbard 2005[58]	Medical errors	Cross-sectional	Assess the effectiveness of 12 recommendation actions form AHRQ's 20 tips; respond to scenarios of 29 different possible medical errors; response to terms patient safety and medical errors; how effected are recommended actions; how likely are consumers to engage in actions.	195 consumers of medical care recruited from University of Oregon classified staff, mean age 42, 71 percent female, 81.5 percent Caucasian, 12 percent high school graduates, 55.4 percent college graduates, 14 percent listed health as fair or poor, 44 percent reported they or family member had experienced a medical error.	None	Patient safety (27 percent not a serious problem) perceived as less of a problem than medical errors (23 percent not a serious problem); more likely to engage in older established recommended actions (4.6) than newer recommended ones (2.9) or those actions requiring questioning (2.6). Self-efficacy and effectiveness of action related to likelihood to engage in recommended actions.
Hicks 2006[25]	Medication errors in children	Retrospective cohort study	Observational study without controls (5). Harmful medication errors in children (1).	Data from voluntary medication error reporting system (MEDMARX®) over 5 years for individuals <17 years old	None	816 harmful outcomes involving 242 medications; 11 medications accounted for 34.5 percent of errors; wrong dosing and omission errors common; associated with opioid analgesics (11 percent), antimicrobials (7.5 percent), antidiabetic agents (4.5 percent), fluids and electrolytes (4.4 percent).

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting and Study Population	Study Intervention	Key Finding(s)
Kerlikowske 1999[35]	Cost effectiveness and impact on life expectancy of mammography screening in women 70–79 years	Noncomparative study	Decision analysis and cost-effectiveness analysis using a Markov model (4). Deaths due to breast cancer averted, life expectancy, cost effectiveness (2).	General population of women 65 and older	Outcomes of screening mammography based on three screening strategies	Continuing screening to age 79 with bone mineral density in top 3 quartiles prevent 9.4 deaths and add ~2.1 days to life expectancy with incremental cost of $66,773 /year of life saved; continuing screening in all women to age 79 prevents 1.4 additional breast cancer deaths and adds 7.2 hours to life expectancy with incremental cost of $117,689/year of life saved. Goal is to prevent deaths from breast cancer at reasonable cost and minimize harms of screening healthy women. Incidence of DCIS increases with age with 25 percent of cancer being DCIS in elderly women; increases rate of surgical treatment of insignificant lesions; 8 percent of women ages 70 and older will have abnormal result; 85 percent–92 percent with abnormal result do not have cancer; worry and anxiety.
Koshy 2005[53]	Medical errors and patient safety	Literature review, nonsystematic/ narrative	Review of literature (5). Computer solutions to medical errors and patient safety (2).	Biometrics data base; biometrics – fingerprints, CPOE (computerized physician order entry), DSSs (decision support systems)	None	Proposed Patient Care Information System – integrated, seamless, with access to real-time patient information (biometrics, CPOE. electronic medical records, etc.). Recommendations: existing error-prevention strategies are not adequate to reduce errors and assure safe health-care deliver; proposes layout of linked data systems from hospital medical information system to regional database to central database

McDowell 1989[48]	Computerized reminders of blood pressure screening in primary care	Randomized clinical trial	Randomized clinical trial (2). Blood pressure screening rates (3).	8,298 patients ages 18 and older who had not had a blood pressure measurement during the previous year, from large family practice in Canada	Computer-generated reminder to physician to check blood pressure during visit vs. telephone reminder by nurse vs. reminder by letter vs. normal care control	Screening rates – 30.7 percent for physician reminder, 35.7 percent for letter reminder, 24.1 percent for nurse reminder, 21.1 percent for no reminder; reminders automatically generated from a computerized medical record.
Metlay 2005[23]	Medication-taking practices on high-risk medications in home-based older adults	Noncomparative study	Observational study without controls (Level 4).	Telephone survey of 4,955 community-dwelling older adults in Pennsylvania in PACE (a State insurance program) program	None	32 percent had not received any specific instructions about medications; 35 percent received instructions from primary care provider and 46 percent from pharmacist; 54 percent used pillbox to organize meds; those prescribed warfarin more likely to report receiving instructions than those with digoxin or phenytoin.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting and Study Population	Study Intervention	Key Finding(s)
Phillips 2004[12]	Malpractice claims in primary care	Retrospective cohort	Observational study without controls (4). Review of malpractice claims data 1985–2000 from Physician Insurers Association of America (4).	49,345 primary care claims; 26,126 peer reviewed, 5,921 assessed as negligent	None	No single condition accounted for >5 percent, internists and family practice/general practitioners more common than general pediatricians. Diagnostic error, failure to supervise or monitor case, improper performance, medication errors, failure/delay in referral, not performed, performed when not indicated, no medical misadventure, delay in performance, failure/delay in admission to hospital, failure to recognize a complication of treatment. Causes – problems with records, content issue; premature discharge from institution, x-ray error, vicarious liability, communication between providers, others; similar to the United Kingdom.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting and Study Population	Study Intervention	Key Finding(s)
Poon 2006[46]	Health care information technology (HIT) adoption	Multisite qualitative study	Multisite qualitative study; survey of electronic results review, CPOE, EHR (electronic health record), claims and eligibility checking, patient-doctor electronic communication, provider to provider electronic communication. Modified Delphi approach to obtain national estimates (5), adoption of HIT in two markets: Boston and Denver (4).	Key informants from stakeholder groups in each city	None	52 of 119 potential informants (44 percent) agreed to interview; functionalities to support financial reimbursement were better developed than those to support safety and quality clinical care; national estimate similar to those from Boston and Denver; major barriers; HIT adoption is limited.
Quaid 1993[29]	Psychological and ethical considerations in screening for disease	Literature review, nonsystematic	Nonsystematic review (6). Potential harms of screening (2).	Nonsystematic literature review of potential risks of screening for disease	None	Risks include misunderstanding of test results, misdiagnosis, labeling, stigmatization, and decreased psychological well-being; results may be misused by industry or insurance companies; screening should not be implemented until certain safeguards in place; clinicians and public should be educated about potential risks and benefits; use accurate, reliable, valid, and sensitive screening tests; obtain informed consent; followup surveillance; procedures to protect right to privacy should be implemented.

Rich 2000[38]	Screening for breast, cervical, and colon cancer	Cross-sectional study	Model days of life lost by stopping screening at various ages using SEER data (5). Days of life lost by stopping screening at various ages (1).	Randomized trial data, model using life tables to calculate life expectancy at various ages for stopping screen and for continuing until death for breast, cervical, and colon cancer	Stopping screening at various ages	Start age of 50 years, maximum potential life expectancy benefit of 43 days for breast cancer, 28 days for colon cancer. Start at age 20, maximum potential benefit of 47 days; 80 percent of benefit is achieved before age 75 for breast cancer, 80 years for colon cancer, and 65 years for cervical cancer. Small benefit may be outweighed by harms of anxiety, additional testing, and unnecessary treatment.
Rosser 1991[52]	Reminders for preventive procedures	Prospective randomized controlled study	Prospective randomized controlled study (2). Completion of preventive procedures (2).	8,502 patients 15 years or older not in a hospital or institution; 5,883 randomly assigned by family to a control, physician reminder, or telephone or letter reminder group; 2,619 not assigned to group but monitored	During 1 year patients in active reminder groups received a telephone or letter reminder of any overdue preventive procedures,and those in passive groups received a physician reminder vs. no reminder	All three reminder systems improved delivery of preventive services completion rates – 42 percent for letter reminder, 33.7 percent for physician reminder, 14.1 percent in control group; reminders were computer generated.
Rosser 1992[50]	Reminders of tetanus booster vaccination	Prospective randomized controlled study	Prospective randomized controlled study (2). Proportion of patients receiving tetanus toxoid during study year or had claim of vaccination in previous 10 years (2).	8,069 patients 20 years or older not in a hospital or institution – 5,589 randomly assigned to control, physician reminder, telephone reminder, or letter reminder group; 2,480 patients not randomized but monitored	No reminder vs. physician reminder at office visit vs. telephone reminder vs. letter reminder	Rates of recorded tetanus vaccination – 3.2 percent for control no reminder, 19.6 percent for physician reminder, 20.8 percent for telephone reminder, 27.4 percent for letter reminder; all three reminder systems were computer generated and increased the rate of tetanus vaccination, but all fell sort of achieving complete population coverage.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting and Study Population	Study Intervention	Key Finding(s)
Rubin 2003[14]	Errors in general practice	Noncomparative study	Observational study without controls (5). Staff reported errors – classification and frequency (1).	5 physicians, 1 nurse, 1 pharmacist, and 11 administrative staff from 19 practices in UK general practice, North East of England	Error classification	940 errors in prescriptions, communication, equipment, appointment, clinical, other; 75.6/1,000 appointments; most were administrative relating to prescriptions or communication; 13 percent related to computers.
Shekelle 2006[47]	Costs and benefits of health information technology (HIT)	Systematic review of studies related to HIT systems in all care settings	Systematic review of studies (meta-analysis, systematic review, original research) (1). Costs and benefits of HIT for pediatric care; ability of one aspect of HIT – the electronic health record (EHR); costs and cost effectiveness of implementing EHR; effect of HIT on making care more patient centered (2).	256 articles of 855 screened from electronic search of articles published 1995 to January 2004	None	156 studies about decision support, 84 assessed EHR, and 30 on computerized physician order entry (CPOE); 124 in outpatient or ambulatory setting, 82 in the hospital or inpatient setting; 97 used a randomized design; 11 controlled clinical trials, 33 pre/post-test design, 20 time series, 17 case studies with concurrent control; 211 hypothesis-testing studies, 81 had at least some cost data. Clinical decision support systems (CDSS) reduce medication dosing error; CPOE plus CDSS reduce incidence of harmful medication errors in inpatient pediatric and neonatal intensive care settings; evidence for HIT cost savings in pediatrics is limited but promising; current use of EHR systems is limited. Added guidelines show decrease in orders for overused tests and increase in orders for underused tests; costly – 3–13 years to break even. Limited evidence on patient-centered care. Barriers to HIT implementation – situational, cognitive and/or physical, liability, and knowledge and attitude. Potential to dramatically alter health care, but limited experimental evidence.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting and Study Population	Study Intervention	Key Finding(s)
Sawaya 2000[37]	Positive predictive value of cervical smears in previously screened women	Randomized controlled study	Prospective cohort study and randomized double-blind, placebo-controlled trial (2). Positive predictive value of cervical smears and the effect of oral estrogen plus progestin on incident cervical cytologic abnormalities (1).	2,561 women with a uterus and normal cytologic characteristics at baseline in 20 U.S. outpatient and community clinical centers	Annual smear; oral conjugated equine estrogens, 0.625 mg/d, plus medroxyprogesterone acetate, 2.5 mg/d, or identical placebo	Incidence of new cytologic abnormalities 2 years after a normal smear was 110/person-years. In 103 women with known histologic diagnoses, 1 had mild to moderate dysplasia; positive predictive value of any smear abnormality 1 year after normal smear was 0 percent, 2 years was 0.9 percent. Conclusion – cervical smear should not be warranted within 2 years of normal cytologic results in postmenopausal women.
Tabar 2004[33]	Efficacy of breast cancer screening by age	Randomized controlled trial	Clinical trial of breast cancer screening (2). Mortality (1).	133,065 Swedish women ages 40–74 with 13-year followup of 2,467 cancers	Breast cancer screening	30 percent reduction in mortality associated with screening in women 40–74 after 13 years, 34 percent in women 50–74, and 13 percent for women 40–49; reduced effect on mortality in women 40–49 due to prognostic factors of tumor size, lymph node status, and histologic type.
Triller 2005[21]	Prevalence of risk factors for adverse drug events (ADEs)	Retrospective cohort study	Observational study without controls (5). Risk factors for ADEs (2).	Data on 10 risk characteristics of patients at point of discharge discharged in 2000 to home health care, self-care, long-term care	None	Data on 4,250 discharges; risk characteristics varied across three groups: home health care – highest prevalence of heart failure, cardiovascular medication use, and poly pharmacy; long-term care – highest prevalence of hypoalbuminemia, cognitive impairment, and psychiatric drug use.

Walter 2001[40]	Framework for individualized decisionmaking for cancer screening	Cross-sectional study	Description of development of framework (6). Potential benefits and harms of screening (1).	Elderly individuals (50–90 years old); use of life expectancy tables and published data	Development of framework for individualized decisionmaking	Potential benefits presented as number needed to screen to prevent one cancer-specific death; variability in potential benefit for patients of similar ages with varying life expectancies; with <5 years unlikely to derive a survival benefit. Potential harms – greatest occur by detecting cancers that would never be clinically significant; burdens due to screening; individualized decisionmaking with consideration of patient's values and preferences.
Woloshin 1997[42]	Main spoken language as barrier to preventive services	Cross-sectional survey	Self-report of breast examination, mammogram, and Pap test (20).	22,448 women completing 1990 Ontario Health Survey, population-based random sample of households	Language spoken	French-speaking women or those who spoke a language other than English were less likely to receive important preventive services.

Chapter 17. Improving the Quality of Care Through Pain Assessment and Management

Nancy Wells, Chris Pasero, Margo McCaffery

Background

At some point in life, virtually everyone experiences some type of pain. Pain is often classified as acute or chronic. Acute pain, such as postoperative pain, subsides as healing takes place. Chronic pain is persistent and is subdivided into cancer-related pain and nonmalignant pain, such as arthritis, low-back pain, and peripheral neuropathy. These authors will draw from the body of knowledge related to chronic pain; however, this chapter will focus on the evidence supporting management of acute pain experienced by hospitalized adults.

Scope of the Problem

Almost 35 million patients were discharged from U.S. hospitals in 2004; of these patients, 46 percent had a surgical procedure and 16 percent had one or more diagnostic procedures.[1] Pain is common, and expected, after surgery. Recent data suggest 80 percent of patients experience pain postoperatively[2] with between 11 and 20 percent experiencing severe pain.[2, 3] Despite the availability of analgesics—particularly opioids—and national guidelines to manage pain, the incidence of postoperative pain has remained stable over the past decade.[4] Thus, acute pain associated with surgical and diagnostic procedures is a common occurrence in U.S. hospitals and remains inadequately managed for many patients.

Importance of Controlling Pain

Inadequately managed pain can lead to adverse physical and psychological patient outcomes for individual patients and their families. Continuous, unrelieved pain activates the pituitary-adrenal axis, which can suppress the immune system and result in postsurgical infection and poor wound healing. Sympathetic activation can have negative effects on the cardiovascular, gastrointestinal, and renal systems, predisposing patients to adverse events such as cardiac ischemia and ileus. Of particular importance to nursing care, unrelieved pain reduces patient mobility, resulting in complications such as deep vein thrombosis, pulmonary embolus, and pneumonia. Postsurgical complications related to inadequate pain management negatively affect the patient's welfare and the hospital performance because of extended lengths of stay and readmissions, both of which increase the cost of care.

Continuous, unrelieved pain also affects the psychological state of the patient and family members. Common psychological responses to pain include anxiety and depression. The inability to escape from pain may create a sense of helplessness and even hopelessness, which may predispose the patient to a more chronic depression. Patients who have experienced inadequate pain management may be reluctant to seek medical care for other health problems. (For more detail, go to the section, "Harmful Effects of Unrelieved Pain," below.)

Poorly managing pain may put clinicians at risk for legal action. Current standards for pain management, such as the national standards outlined by the Joint Commission (formerly known as the Joint Commission on Accreditation of Healthcare Organizations, JCAHO),[5] require that pain is promptly addressed and managed. Having standards of care in place increases the risk of legal action against clinicians and institutions for poor pain management,[6] and there are instances of law suits filed for poor pain management by physicians.[7] Nurses, as part of the collaborative team responsible for managing pain during hospitalization, also may be liable for legal action.

Hospitals stand to lose reputation as well as profit if pain is poorly managed. Patient satisfaction with care is strongly tied to their experiences with pain during hospitalization. Evidence indicates that higher levels of pain and depression are linked to poor satisfaction with care in ambulatory settings.[8] With the advent of transparent health care, report cards for hospitals are becoming more prevalent, and performance on pain management is likely to be one of the indicators reported.

Undertreatment of Pain

The undertreatment of pain was first documented in a landmark study by Marks and Sachar in 1973.[9] These researchers found that 73 percent of hospitalized medical patients had moderate to severe pain. The undertreatment of pain continues. Thirty years later in 2003, Apfelbaum and others[2] found that 80 percent of surgical patients experienced acute pain after surgery, and 86 percent of those had moderate to extreme pain. Of 1,308 outpatients with metastatic cancer from 54 cancer treatment centers, 67 percent reported pain.[10] Of those who had pain, 62 percent had pain severe enough to impair their ability to function, and 42 percent were not given adequate analgesic therapy. It is estimated that 45 percent to 80 percent of elderly patients in nursing homes have substantial pain that is undertreated.[11] These studies and others suggested that when patients had moderate to severe pain, they had only about a 50 percent chance of obtaining adequate pain relief.[12]

Harmful Effects of Unrelieved Pain

Patients suffer from pain in many ways. Pain robs patients of their lives. Patients may become depressed or anxious and want to end their lives. Patients are sometimes unable to do many of the things they did without pain, and this state of living in pain affects their relationships with others and sometimes their ability to maintain employment.

What is often overlooked is that pain has physically harmful effects. It is often actually physiologically unsafe to have pain.[13] The effects of pain on the endocrine and metabolic system, cardiovascular system, gastrointestinal system, and immune system—and the potential for future pain—are but a few of examples of how unsafe unrelieved pain may be.[13]

Pain causes stress. The endocrine system reacts by releasing an excessive amount of hormones, ultimately resulting in carbohydrate, protein, and fat catabolism (destruction); poor glucose use; and other harmful effects. This reaction combined with inflammatory processes can produce weight loss, tachycardia, increased respiratory rate, fever, shock, and death.[14] Unrelieved pain prolongs the stress response, adversely affecting the patient's recovery.[13]

The cardiovascular system responds to stress of pain by activating the sympathetic nervous system, which produces a variety of unwanted effects. In the postoperative period, these include hypercoagulation and increased heart rate, blood pressure, cardiac work load, and oxygen

demand. Aggressive pain control is required to reduce these effects and prevent thromboembolic complications. Cardiac morbidity is the primary cause of death after anesthesia and surgery.[13, 15]

Since the stress response causes an increase in sympathetic nervous system activity, intestinal secretions and smooth muscle sphincter tone increase, and gastric emptying and intestinal motility decrease. This response can cause temporary impairment of gastrointestinal function and increase the risk of ileus.[13, 15]

Unrelieved pain may be especially harmful for patients with metastatic cancers. Stress and pain can suppress immune functions, including the natural killer (NK) cells that play a role in preventing tumor growth and controlling metastasis.[13, 16] Further, management of perioperative pain is probably a critical factor in preventing surgery-induced decrease in resistance against metastasis.[17]

Unrelieved acute pain can result in chronic pain at a later date. Thus, pain now can cause pain later. If acute shingles pain is not treated aggressively, it is believed to increase the risk of postherpetic neuralgia.[18, 19] A survey of patients having undergone surgery found a high prevalence of chronic postsurgical pain in patients whose acute postsurgical pain was inadequately managed.[20]

Assessment of Pain

Assessment of pain is a critical step to providing good pain management. In a sample of physicians and nurses, Anderson and colleagues[21] found lack of pain assessment was one of the most problematic barriers to achieving good pain control. There are many recommendations and guidelines for what constitutes an adequate pain assessment; however, many recommendations seem impractical in acute care practice. Nurses working with hospitalized patients with acute pain must select the appropriate elements of assessment for the current clinical situation. The most critical aspect of pain assessment is that it is done on a regular basis (e.g., once a shift, every 2 hours) using a standard format.[5] The assessment parameters should be explicitly directed by hospital or unit policies and procedures.[5, 22, 23] To meet the patients' needs, pain should be reassessed after each intervention to evaluate the effect and determine whether modification is needed. The time frame for reassessment also should be directed by hospital or unit policies and procedures.[5]

An early *Clinical Practice Guideline on Acute Pain Management* released by the Agency for Health Care Policy and Research addressed assessment and management of acute pain.[22] This guideline outlines a comprehensive pain evaluation that would be most useful when obtained prior to the surgical procedure. In the pain history, the nurse identifies the patient's attitudes, beliefs, level of knowledge, and previous experiences with pain. Expectations of patient and family members for pain control postsurgically will uncover unrealistic expectations that can be addressed before surgery. This comprehensive pain history lays the foundation for the plan for pain management following surgery, which is completed collaboratively by the clinicians (physician and nurse), the patient, and his or her family.

Pain History

The pain history should include the following:

- Significant previous and/or ongoing instances of pain and its effect on the patient

- Previously used methods for pain control that the patient has found either helpful or unhelpful
- The patient's attitude toward and use of opioids, anxiolytics, or other medications, including any history of substance abuse
- The patient's typical coping response for stress or pain, including the presence or absence of psychiatric disorders such as depression, anxiety, or psychosis
- Family expectations and beliefs concerning pain, stress, and postoperative course
- Ways the patient describes or shows pain
- The patient's knowledge of, expectations about, and preferences for pain management methods and for receiving information about pain management[22] (p. 7–8)

Pain Assessment Tools

During the postsurgical period, pain assessment must be brief and simple to complete.[22] Because choice of intervention, including type of analgesic and dosing, is made based upon intensity, every pain assessment should include this type of measure. Numerous pain intensity measures have been developed and validated. Several tools provide a numeric rating of pain intensity (e.g., visual analogue scale, numeric rating scale (NRS)). Simpler tools such as the verbal rating scale, which classifies pain as mild, moderate or severe, also are commonly used. For patients with limited cognitive ability, scales with drawings or pictures are available (e.g., the Wong-Baker FACES scale). Patients with advanced dementia require behavioral observation to determine the presence of pain; tools such as the PAIN-AD are available for this patient population. (For more detail, go to section “Tools to Assess Pain Intensity in Cognitively Intact and Impaired Adults,” below.)

The Joint Commission developed pain standards for assessment and treatment based upon the recommendations in the *Acute Pain Clinical Practice Guideline.* The Joint Commission requires that hospitals select and use the same pain assessment tools across all departments. This standard suggests providing options among scales such as the NRS, the Wong-Baker FACES scale, and a verbal descriptor scale.

Selecting the pain assessment tool should be a collaborative decision between patient and health care provider. When this is done during the preoperative period, it ensures the patient is familiar with the scale. If the nurse selects the tool, he or she should consider the age of the patient; his or her physical, emotional, and cognitive status; and preference.[22] We tend to think of these intensity scales as verbal, but patients who are alert but unable to talk (e.g., intubated, aphasic) may be able to point to a number or a face to report their pain. The pain tool selected should be used on a regular basis to assess pain and the effect of interventions. It should not, however, be used as the sole measure of pain perception.[24]

Location and quality of pain are additional assessment elements useful in selecting interventions to manage pain. Since patients may experience pain in areas other than the surgical site, location of pain using a body drawing or verbal report provides useful information. The pain experienced may be chronic (e.g., headache, low-back pain) or it may be related to the positioning and padding used during the procedure. The quality of pain varies depending upon the underlying etiology. Instruments such as the McGill Pain Questionnaire[25, 26] contain a variety of verbal descriptors that help to distinguish between musculoskeletal and nerve-related pain. Typically, patients describe deep tissue pain as dull, aching, and cramping, while nerve-related pain tends to be more sporadic, shooting, or burning.[27, 28]

Pain interferes with many daily activities, and one of the goals of acute pain management is to reduce the affect of pain on patient function and quality of life.[24] The ability to resume activity, maintain a positive affect or mood, and sleep are relevant functions for patients following surgery. The Brief Pain Inventory[10, 29] includes four items that may be useful in assessing this aspect of the pain experience. Using an NRS format, assessment of interference with ability to walk, general activity, mood, and sleep during the recovery period will assist in selecting interventions to enhance function and quality of life.

The final elements of pain perceptions involve determining current aggravating and alleviating factors.[22, 24] Aggravating factors may be as simple as patient position, a full bladder, or temperature of the room. Alleviating factors include the interventions used (e.g., analgesics) and cognitive strategies used to control pain. Examples of such strategies are distraction, positive self-talk, and pleasant imagery. The pain history will provide insight into the coping strategies previously used by the patient and their effectiveness with previous painful episodes.

In addition to self-reported pain perceptions, a comprehensive assessment of pain following surgery includes both physiological responses and behavioral responses to pain[22] (p. 11). Physiological responses of sympathetic activation (tachycardia, increased respiratory rate, and hypertension) may indicate pain is present. Behaviors that may indicate pain include splinting, grimacing, moaning or grunting, distorted posture, and reluctance to move. While these nonverbal methods of assessment provide useful information, self-report of pain is the most accurate. A lack of physiological responses or an absence of behaviors indicating pain may not mean the patient is not experiencing pain. (Go to section “Tools to Assess Pain Intensity in the Cognitively Impaired,” below, for more detail.)

Adequate pain management requires an interdisciplinary approach.[22, 24] Documentation of pain assessment and the effect of interventions are essential to allow communication among clinicians about the current status of the patient’s pain and responses to the plan of care. The Joint Commission requires documentation of pain to facilitate reassessment and followup. The American Pain Society suggests that pain be the fifth vital sign as a means of prompting nurses to reassess and document pain whenever vital signs are obtained.[30] Documentation also is important as a means of monitoring the quality of pain management within the institution.

Monitoring the Quality of Pain Management

Establishing and maintaining an institutional pain performance improvement plan is a Joint Commission requirement.[5] Institutions should develop interdisciplinary approaches to acute pain management with clear lines of responsibility for achieving good acute pain control.[5, 22, 24] This interdisciplinary approach includes an individualized plan of care for pain control, developed in collaboration with the patient and family. Systems should be in place to monitor pain management that alerts the clinician when pain is poorly managed. For example, in an institution with a computerized documentation system, an alert may pop up when a patient’s pain exceeds a threshold. The threshold may be set individually by patient and clinician or institutionally. A reasonable threshold might be moderate to severe pain, which means a pain score of greater than 4 on a 0–10 scale.[31] The plan of care provides the basis for monitoring the quality of acute pain management provided.

American Pain Society Current Guidelines

One of the first quality improvement programs was developed by the American Pain Society.[23] The quality improvement guideline was refined and expanded in 2005[24] (p. 1576) based upon a systematic review of pain quality improvement studies conducted over the past 10 years.[32] The emphasis has shifted from processes to outcomes.

- Recognize and treat pain promptly.
- Involve patients and families in pain management plan.
- Improve treatment patterns.
- Reassess and adjust pain management plan as needed.
- Monitor processes and outcomes of pain management.

The goal of pain management after surgery is to prevent and control pain. Postsurgical pain, like cancer pain, is expected to be present continuously with spikes of increased pain with movement, deep breathing and coughing, and ambulation during the fist 24–48 hours after surgery. Around-the-clock dosing is recommended during this early postsurgical period to prevent severe pain and control continuous pain.

Quality Indicators[24] (p. 1578)

Quality indicators for pain management focus on appropriate use of analgesics and outcomes.

- Intensity of pain is documented using a numeric (0–10) or descriptive (mild, moderate, severe) rating scale.
- Pain intensity is documented at frequent intervals.
- Pain is treated by route other than intramuscular.
- Pain is treated with regularly administered analgesics, and, when possible, multimodal approach is used. (Multimodal approach includes a combination of pain control strategies, such as opioids, nonsteroidal anti-inflammatory drugs, nonpharmacological interventions.)
- Pain is prevented and controlled to a degree that facilitates function and quality of life.
- Patients are adequately informed and knowledgeable about pain management.

To efficiently monitor quality indicators, patient records should contain documentation of

- Pain intensity (0–10 or mild, moderate, severe)
- Analgesics prescribed and administered, including drug, route, and dosing
- Impact of pain on function and quality of life (e.g., ability to walk, general activity, mood, sleep)
- Pain education for patient and family member(s)

Patient Satisfaction

Although satisfaction with pain management currently is used as a measure of institutional quality, satisfaction with pain management is no longer recommended as a quality indicator for pain control.[24, 32] This is because patient satisfaction findings are difficult to interpret. In their review of 20 quality improvement studies conducted between 1992 and 2001, Gordon and colleagues[32] noted 15 studies reported high satisfaction with pain management despite many

patients experiencing moderate to severe pain during hospitalization. Thus, patient satisfaction data should be cautiously interpreted and, if used, used in conjunction with other quality indicators. Because of the current focus on report cards for health care organizations, patient satisfaction data are routinely collected and easily obtained for review.

Many institutions use commercial patient satisfaction surveys to monitor satisfaction with care. Most of these surveys have at least one item on satisfaction with pain management. Institutions also may use generic health status or quality of life surveys, such as the Medical Outcomes Study Short From-36, to monitor patient outcomes; most of these surveys include one or more questions on pain experienced. Regular review of these patient satisfaction data can be used as a quick measure of quality of pain care. If satisfaction scores on pain management dip, a more thorough investigation of pain management processes is warranted.

Use of an interdisciplinary team to monitor current pain practice, identify areas for improvement, and oversee quality improvement plans is consistently recommended in the guidelines.[5, 22, 24] To effectively monitor pain practice within a hospital, electronic systems are needed to capture and collate data on the indicators in a readily available form. One method of changing clinician behavior is through the use of feedback on performance; thus the reports generated for interdisciplinary committee review also may be used to assist clinicians to review and adjust their performance.

Current Guidelines

Many State and professional organizations have developed clinical practice guidelines to direct health care providers in adequate management of acute pain. The 1992 *Acute Pain Clinical Practice Guideline*[22] lays the foundation for the more current guidelines. Listed below is a sample of current guidelines available from the National Guideline Clearing House.

- Pain management guideline; developed by the Health Care Association of New Jersey; released July 2006. This guideline includes definitions of pain (acute and chronic); clear direction for assessment and treatment with pharmacological and nonpharmacological interventions (including physical and occupational therapy); policies for pain education for staff, patients, and families; and direction for quality monitoring. The guideline is applicable to pain management in acute care and long-term care nursing facilities. Web site: http://www.guidelines.gov/summary/summary.aspx?doc_id=5526&nbr=003757&string=pain+and+assessment+and+nursing
- "Pain Management"; written for the 2nd edition of *Geriatric Nursing Protocols for Best Practice*; published in 2003. This guideline addresses pain in the elderly, assessment strategies, and nursing interventions to control pain. Pharmacological and nonpharmacological interventions are included in the guideline. Web site: http://www.guidelines.gov/summary/summary.aspx?doc_id=3514&nbr=002740&string=pain+and+assessment+and+nursing
- *ASPAN Pain and Comfort Clinical Guideline*; developed by American Society of Perianesthesia Nurses; released August 2003. This guideline provides direction for assessment, interventions, and expected outcomes for the preoperative and postoperative phases of treatment. Use of pharmacological and nonpharmacological interventions is endorsed. Web site: http://www.guidelines.gov/summary/summary.aspx?doc_id=5526&nbr=003757&string=pain+and+assessment+and+nursing

- *Clinical Practice Guideline for the Management of Postoperative Pain*; developed by the Veterans Health Administration; released May 2002. This guideline is organized into two main algorithms, one for the preoperative phase and the other for the postoperative phase. The pain management plan is set within the context of comprehensive pre- and postsurgical care and includes discharge planning. A patient-focused objective is provided for each step of the pain management plan. Emphasis is placed upon reassessment and modification of the treatment plan. Clear descriptions of common opioid side effects and interventions to reduce them are included in the guideline. Web site: http://www.guidelines.gov/summary/summary.aspx?doc_id=3284&nbr=002510&string=pain+and+assessment+and+nursing
- The American Society of Pain Management Nursing has published two position statements on pain management issues that pose difficulty ethically and in practice. Practice recommendations based upon research and clinical expertise are included in both position statements.
  - Herr et al. Pain assessment in the nonverbal patient: Position statement with clinical practice recommendations. *Pain Management Nursing* 2006;7(2):44-52.
  - American Society for Pain Management Nursing. ASPMN position statement: pain management in patients with addictive disease. *Journal of Vascular Nursing* 2004;17(3):99-101.
- With the implementation of the Joint Commission standards for pain management, the requirements for "as needed" (PRN) orders were altered. The American Society of Pain Management Nursing and the American Pain Society developed a consensus statement on the use of PRN range orders to guide nursing practice.
  - Gordon et al. Use of "as needed" range orders for opioid analgesics in the management of acute pain. *Home Healthcare Nurse*, 2005;23(6):388-96.

Research Evidence

Analgesics, particularly opioids, are the primary treatment for acute pain. It is estimated that up to 90 percent of cancer pain can be adequately managed with analgesics using the World Health Organization (WHO) analgesic ladder.[33, 34] Although no evidence exists to estimate the likelihood of adequately managing acute pain, it is reasonable to infer that the vast majority of postsurgical pain can be well managed with the appropriate use of analgesics. While there are many factors that contribute to poor pain management—lack of assessment and inadequate or inapposite use of analgesics are primary, and modifiable, factors.[35] Thus, it is the responsibility of clinicians to be knowledgeable about the analgesics used to treat pain, including onset, peak action, and duration of the drug(s) administered; common side effects, and methods of managing those side effects.[36] Easy access to an equianalgesic table assists in providing good pain control when switching from one opioid to another and from one route to another. This approach is particularly important when preparing the postsurgical patient for discharge with an oral analgesic.

The objective for postsurgical and procedural pain is to prevent and control pain.[22, 24] This does not mean that patients will be pain free, a misconception that some patients and families have when entering the hospital. This misconception is best addressed during the preoperative pain assessment by collaboratively setting goals for pain control and function. A multimodal approach (balanced analgesia), which includes opioids, nonopioids such as nonsteroidal anti-

inflammatory drugs (NSAIDs), and adjuvant medications such as anticonvulsants, is recommended. (For more detail go to the "Balanced Analgesia" section in this chapter.) Following the WHO's analgesic ladder for control of cancer pain, the Clinical Practice Guideline Committee recommended the use of NSAIDs for mild to moderate pain with the addition of opioids for moderate to severe pain.[22]

Principle of Analgesic Management of Pain

Based upon evidence and clinical practice, there are several principles of analgesic management to meet the objective of preventing moderate to severe pain:

- When continuous pain is anticipated, a fixed-dose schedule (around the clock) should be used.
- A PRN order of a rapid onset analgesic may be necessary to control activity-related (breakthrough) pain.
- To ensure opioids are safely administered, begin with a low dose and titrate to comfort.
- Modification in analgesic administration is based upon assessment of the effect of the previous dose, including change in pain intensity, relief, and side effects experienced.
- Patients respond differently to various opioid and nonopioid analgesics; therefore if one drug is not providing adequate pain relief, another in the same class may result in better pain control.
- Assessment of effect should be based upon the onset of action of the drug administered; for example, IV opioids are reassessed in 15–30 minutes, whereas oral opioids and nonopioids are reassessed 45–60 minutes after administration.

Opioid Analgesics

A series of three systematic reviews have been published in the past 5 years examining the efficacy, safety, and side effect profile of opioids used to manage postsurgical pain.[2, 37, 38] The first review[3] concluded that patient-controlled analgesia (PCA) and epidural routes of administration were superior to intramuscular (IM) injections when pain intensity and relief were considered. The safety of opioids used to control postsurgical pain was examined for hypotension and respiratory depression; observed rates were less than 5 percent for hypotension and less than 1 percent for respiratory depression.[37] The most common opioid side effects included 25 percent nausea, 20 percent vomiting, 23.9 percent mild sedation, 2.6 percent excessive sedation, 14.7 percent pruritis, and 23 percent urinary retention. The use of intravenous PCA was associated with the highest levels of nausea and sedation, whereas epidural analgesia was associated with the highest rate of urinary retention.[38] This series of systematic reviews suggests the IM route of administration produces the poorest outcomes. Approximately one in every four patients will experience common opioid side effects; however, the rate of excessive sedation, respiratory depression, and hypotension related to opioids are low in the postsurgical population.

Patient and Family Education

Beginning with the *Acute Pain Clinical Practice Guideline*,[22] patient and family education has been a central recommendation for acute pain management. This education is best

implemented during the presurgical clinic visit or during admission pain assessment. The essential elements of pain education include telling the patient the following:

- Preventing and controlling pain is important to your care.
- There are many interventions available to manage pain; analgesics (opioid and nonopioid) are the most effective in managing acute pain.
- Some people are afraid of using opioids because of the side effects and risk of addiction. Side effects can be managed effectively with medication. The risk of addiction when using opioids to control acute pain is extremely low.
- Your responsibility in achieving good pain control is to tell us when you are experiencing pain or when the nature or level of pain changes.
- Complete pain relief usually is not achievable; however, we will work with you to keep pain at a level that allows you to engage in activities necessary to recover and return home.

This last comment flows directly into a discussion about goals for pain management during the hospitalization. This goal is set in light of the functional requirements (e.g., when ambulation will begin, need for deep breathing) to promote recovery. Thus, the patient, family member(s), and nurse collaboratively set a tolerable or satisfactory level of pain and function during the hospitalization, which is documented either in the patient's room or record so that all clinicians are working toward the same goals for pain control. Shared goal setting is one dimension of relational coordination associated with adequate postsurgical pain management.[39] Information obtained from the pain history (e.g., previous experience with pain and what helped or did not help, typical coping strategies used) will assist in developing a plan of care that incorporates the patient's preferences into the plan.

Patient-Nurse Interactions

One of the earliest evidence-based protocols was developed as part of the Conduct and Utilization of Research in Nursing (CURN) project. *Pain: Deliberative Nursing Interventions*[40] describes an approach to a patient's complaint of pain that includes skilled communication to determine the patient's needs. While administering analgesics may be the most appropriate way to meet the patient's needs, the nurse may uncover other factors contributing to discomfort, such as uncomfortable position, thirst, or the need to urinate.[40] Addressing these needs will improve patient comfort and communicate the nurse's desire to promote comfort. McCaffery[35] suggested that the time spent with the patient to communicate concern and caring may go a long way in providing patient comfort. The content of this 5-minute conversation may include the following:

- Listening to patient concerns
- Communicating the desire to help the patient become more comfortable
- Determining strategies that might achieve more comfort[35] (p. 78)

Communication with patients is one of the core dimensions of relational coordination, an approach examined in the orthopedic surgical population.[39] In a cross-sectional study of nine hospitals, Gittell and colleagues[39] found that the better the relational coordination, the better the postsurgical pain relief. Of note, four dimensions (frequent communication, shared goals, shared knowledge, and mutual respect among clinicians) were associated with this improvement in pain control. Thus, this study suggested that communication, goal setting, and patient education contributed to better pain outcome.

Nondrug Techniques To Manage Pain

People naturally use many nondrug strategies, such as distraction, imagery, and massage, to alleviate pain. During episodes of acute pain, patients may rely on these previously used and "proven" methods. For example, Kwekkeboom[41] found women recovering from breast and gynecological surgery used a variety of nondrug techniques in addition to analgesics to relieve pain at home. Although the techniques varied, methods to increase relaxation were common (e.g., breathing, meditation, imagery, and music). Hospitalized patients also may use techniques that have worked for them in the past; in a study of nondrug techniques to manage postsurgical pain, Pellino and colleagues[42] reported that between 19 and 28 percent of patients in the usual care control group used nondrug techniques during the first 3 days after surgery. Thus, patients in pain may spontaneously (i.e., without instruction or help) use a wide variety of nondrug methods to control their pain. Before suggesting or instructing patients in the use of nondrug techniques, nurses need to be aware of the methods used effectively and preferred by the patient. For example, in a trial of five cognitive-behavioral techniques to manage cancer pain in ambulatory patients, Anderson and colleagues[43] noted that a number of patients had difficulty using their assigned technique because it did not match their usual coping style. In addition to applying the wrong technique, instructing patients in the use of a specific technique, such as imagery, may undermine their confidence in the techniques they typically use to control pain.

Nurses have used nondrug techniques for years to help patients manage pain. These techniques have been labeled differently over the years. Noninvasive, nonpharmacological, nondrug, and complementary therapies have been used interchangeably to reflect nonmedical therapies. McCaffery[35] noted that there is no classification system for these nondrug techniques. For the purposes of this chapter, techniques will be grouped as cognitive and physical. Cognitive techniques focus primarily on mental functions that require some degree of attention. Distraction or focusing attention away from the pain may be one of the primary mechanisms resulting in pain relief. Relaxation and music are included in this cognitive category. Physical techniques focus on altering physiological processes that may reduce pain. Massage and the application of heat and cold are included in this category. One possible mechanism of action for massage and heat/cold therapy is the stimulation of the large diameter fibers, which are hypothesized to reduce central pain transmission. Reducing muscle tension, which may contribute to pain transmission, is another possible mechanism of action.

Relaxation. There are many methods available to achieve a relaxation response. Some require initial training and practice to be used effectively; progressive muscle relaxation, systematic relaxation, and autogenic training are skills that require some practice. Each session using progressive, systematic, or autogenic training may take 15–30 minutes. Typically in research, the instructions are delivered via audiotape, a method that may be used for hospitalized patients as well. Simpler forms of relaxation, which may be more suitable to institute during an acute pain episode, include jaw dropping and rhythmic breathing.

Reviews on the effectiveness of relaxation for pain relief have arrived at different and often opposite conclusions.[44–46] This is not surprising because of the wide variety of techniques that were used as well as the small number of studies published (11 to 12 in the most recent reviews). The recent randomized clinical trials also contribute to this inconsistency.[43, 47, 48] Therefore, the current evidence does not support a consistent, predictable effect of relaxation on pain.

Music. Sedating or soothing music is instrumental, rhythmic, and 60–80 beats per minute. In much of the research, musical pieces are selected from five types of music identified by Good

and colleagues:[49] synthesizer, harp, piano, orchestral, or slow jazz. The intervention is delivered via audiotape and headphones. The duration is typically 20–30 minutes and may involve a single or multiple exposures.

A recent meta-analysis of 51 studies examining the effect of music on pain concluded that although music produced a significant reduction in pain intensity (0.5 units), this result may not reflect a clinically important change.[50] Gordon and colleagues[24] suggest a 1.5 to 2.0 unit change in pain intensity on a 0–10 scale constitutes a clinically important difference. Despite the large number of studies included, approximately 50 percent were of low quality, leading to low confidence in the results of the analysis. Contrary to previous meta-analyses,[51] Cepeda and colleagues[50] did not find differences in pain reduction related to whether the music was patient- or clinician-selected. Recently published studies, all conducted on patients undergoing cardiovascular procedures, found significant short-term reductions in pain, distress, or anxiety after exposure to music.[52–54] In each of these studies, music was used during an episode of increased pain (e.g., getting up from a chair). While these studies hold promise, currently the evidence for the effectiveness of music in reducing acute pain is weak to moderate.

Massage. Massage is defined as the systematic manipulation of soft tissues by manual or mechanical means.[55] Nurses have used massage—a back rub—to improve circulation, promote comfort, and enhance sleep. More recently investigators have examined hand and foot massage as an alternative to back or body massage. The duration of massage varies from 5 to 20 minutes. Wong and Keck[56] suggested that 20 minutes of massage was required to achieve the desired effect, but little evidence exists to substantiate this claim.

Reviews of the massage literature conclude it has a beneficial effect on anxiety and tension, depression, and stress hormones (cortisol and catecholamines).[57, 58] The evidence on the beneficial effects of massage on reducing pain is positive, but involves few studies, so that firm conclusions cannot be drawn. More recent studies produced inconsistent findings, particularly in terms of the effect of massage on pain control.[56, 59–62] As with the relaxation and music literature, studies of the effect of massage suffer from methodological problems[57] that produce unstable or biased results.

Heat/cold therapy. The application of heat and ice to reduce pain or promote comfort has been a common nursing intervention, which may require a physician's order to implement.

Despite the use of heat and cold by nurses, there are few studies investigating the impact on pain or function. A meta-analysis of heat and cold for low-back pain concluded that continued use of heat (over a 5 day period) improved pain intensity and function.[63] Only two studies on the use of heat for postsurgical pain were found, and the findings from these were inconclusive.[64] The application of ice/cold for low-back pain has limited evidence to support it's use.[63] Cold therapy has been investigated in patients undergoing orthopedic surgeries (primarily total knee arthroplasty) and has been found to improve pain, range of motion, and function.[65] However, a study by Smith and others[66] found that pain was similar with the cryo pad (a new technology to deliver cold therapy) and the compression bandage applied by the surgeon at the end of surgery; in addition, the cold therapy increased the cost of care and took more nursing time. Thus, using cold therapy via the cyro pad provides no benefit over compression bandages after knee replacement and is less cost efficient.

Use of multiple nondrug therapies for pain management. Introduction to a variety of nondrug techniques may be used to better meet patients' needs. Two recent studies examined the effect of providing multiple nondrug techniques (e.g., a cafeteria style) on postsurgical pain. In both studies, the interventions were developed to allow the patient maximum control and require

minimum nursing time. Common techniques used in both studies included relaxation, music, and massage.[42, 67] While it is too early to determine if providing a pain "tool kit" will have benefit to postsurgical patients, Kshettry and colleagues[67] demonstrated the feasibility of implementing such a program in a busy intensive care unit (ICU).

Evidence-Based Practice Implications

Lack of adequate assessment and inappropriate treatment remain the major factors of undertreatment of pain. There is ample evidence that the appropriate use of analgesics—the right drug(s) at the right intervals—can provide good pain relief for the majority of patients. Thus, institutions should place their money and effort on improving these provider behaviors (assessment, prescription and administration of analgesics).[35] The use of nondrug therapies is recommended in most pain guidelines; however, the evidence for their consistent benefit in terms of pain intensity, relief, or improved function is weak at best. This result does not mean a nondrug technique, or several techniques provided cafeteria style, may not improve a patient outcome. The nurse who uses these techniques should be aware that the effect is not predictable.[35]

Ensuring Patient Safety

Following are some patient safety issues that relate to pain management:

- When administering sedatives, consider the patient's physical safety (e.g., using bed rails, fall precautions, assistance with ambulation).
- Eliminate errors related to PCA infusions (improper dose/quantity, wrong drug, drug omission) by using systems to double-check drug and dose (e.g., bar coding, nurse-nurse checking).[68]
- Eliminate errors and complications related to catheter administration (initial dose testing, monitoring catheter and response to medication).[69]
- Nondrug techniques have minimal adverse events reported and do not pose safety issues.
- Protect skin when applying heat or cold.

Tools To Assess Pain Intensity in Cognitively Intact Adults

The first step in relieving pain to prevent its harmful effects, and doing so safely, is to assure that patients are properly assessed for pain so that appropriate pain relief measures can be implemented. Otherwise, pain may be unnoticed by clinicians or may be undertreated.

Self-report is the most reliable way to assess pain intensity. When the patient is able to report pain, the patient's behavior or vital signs should never be used in lieu of self-report. For the cognitively intact adult, assessment of pain intensity in the clinical setting is most often done by using the zero to 10 numerical rating scale or the zero to 5 Wong-Baker FACES scale.[70] The NRS consists of a straight horizontal line numbered at equal intervals from zero to 10 with anchor words of "no pain" for zero, "moderate pain" for 5, and "worst pain" for 10. The FACES scale consists of six faces showing progressive pain intensities, beginning with a smiling face and ending with a crying face.

Once the patient knows how to use a pain intensity scale, the patient should be taught how to establish a comfort-function goal. This is the pain intensity at which the patient is easily able to

perform necessary activities, such as ambulating after surgery or being able to concentrate on job-related activities. Interventions are implemented to achieve and maintain this pain rating as much of the time as possible.[70]

Tools To Assess Pain Intensity in Cognitively Impaired Adults

When the patient is unable to self-report pain, other less reliable measures must be used to identify the existence of pain and estimate the probable intensity. These assessment measures form a hierarchy, arranged in order of probable importance:[70, 71]

- Conditions, such as surgery, or procedures, such as wound care, that are likely to cause pain.
- Patient behaviors that are likely to indicate pain. A behavioral assessment tool, discussed below, may be used. Whenever possible, a pain behavior scale should be chosen that has been researched for reliability and validity in the clinical setting.
- Knowledge of others who know the patient, such as the family or caregivers. They should be asked if they see behaviors that may indicate pain or if they know of preexisting conditions, such as arthritis, that cause pain.

If any of the above suggest pain is present, the clinician may assume pain is present and use the acronym APP to record assessment when a pain intensity rating cannot be obtained. Next, a conclusion is made about an appropriate intervention based on the probable intensity of pain. If appropriate, a trial dose of analgesic is given and the patient's behavior is observed before and after this intervention. If the behavior subsides, this may indicate that indeed the patient has pain and that the analgesic should be continued. If there is no change in behavior, a stronger dose of analgesic may be indicated.[71]

Behavioral assessment tools are helpful in identifying the existence of pain and evaluating interventions. These scales are of two types: (1) pain behavior scales, and (2) pain behavior checklists. Some of these scales are scored by identifying the number or intensity of behaviors. However, this score is not a pain intensity score. No research as yet confirms that a pain behavior score is a pain intensity score.[71] Therefore, it is unsafe to use pain behavior scores as pain intensity scores. A patient with only a few behaviors may have as much pain as a patient with many more behaviors.

An example of a pain behavior scale is the Behavioral Pain Scale (BPS), developed for use in the critically ill patient in the ICU.[72] It evaluates and scores three categories of behavior:

1. Facial expression, scores range from 1 for relaxed to 4 for grimacing
2. Upper-limb movement, scores range from 1 for no movement to 4 for permanently retracted
3. Ventilator compliance, scores range from 1 for tolerating ventilator to 4 for unable to control ventilation

Once again, a score above 3 may indicate pain is present and the score can be used to evaluate intervention, but cannot be interpreted to mean pain intensity. For a pain behavior scale to be useful, the patient must be able to respond in all categories of behavior. For example, the BPS would be useless in a patient who is receiving a neuromuscular blocking agent.

Behavior checklists differ from pain behavior scales in that they do not evaluate the degree of an observed behavior and do not require a patient to demonstrate all of the behaviors specified, although the patient must be responsive enough to demonstrate some of the behaviors. These

checklists are useful in identifying the patient's "pain signature," that is, the pain behaviors unique to the individual.[73]

An example of a pain behavior checklist is the Pain Assessment Checklist for Seniors with Limited Ability to Communicate (PACSLAC).[74] The PACSLAC evaluates 60 behaviors such as facial expressions, activities, and mood. A check mark is made next to any behavior the patient exhibits. The total number of behaviors may be scored, but again, this cannot be equated with a pain intensity score. It is unknown if a high score represents more pain than a low score. In other words, a patient who scores 10 out of 60 behaviors does not necessarily have less pain than a patient who scores 20.[71] However, in an individual patient, a change in the total pain score may suggest more or less pain. A more comprehensive description of pain assessment tools for the cognitively impaired are located at the following Web site in the education section of Pain in the Elderly: http://www.cityofhope.org/PRC/.

Balanced Analgesia

Analgesics are usually divided into three categories: (1) nonopioids, which include acetaminophen and NSAIDs; (2) opioids, which include morphine-like drugs; and (3) adjuvant analgesics, which include local anesthetics and anticonvulsants. Using an analgesic from each one of the three groups, referred to as balanced or multimodal analgesia, may improve the safety of analgesic therapy. When more than one analgesic is used, the same level of pain relief may be achieved with a lower dose of each analgesic. For example, use of a local anesthetic along with an opioid usually allows reduction of the opioid dose needed for adequate pain control.

Safe Use of Opioids

Of all the analgesics used in pain control, the most safety issues arise with the use of those referred to as mu opioids, or morphine-like drugs such as morphine, hydromorphone (Dilaudid™), and fentanyl. Clinicians fear causing harm with these analgesics by administering too much and causing life-threatening respiratory depression. Sometimes this fear results in undertreatment of pain. Clinicians need to be educated about the effective methods of preventing respiratory depression and appropriate use of naloxone if respiratory depression does occur.

Opioid-induced respiratory depression is preceded by an increasing level of sedation. An alert patient will not suddenly succumb to respiratory depression. Consequently, respiratory depression can be prevented by observing sedation levels and decreasing the opioid before respiratory depression occurs. Box 1 presents a sedation scale that nurses can use at regular intervals to monitor patients receiving opioids. This scale should be used for all opioid naïve patients with moderate to severe pain when opioid dosing is initiated. These patients should be monitored at least every 2 hours during the first 24 hours of opioid therapy. Using this scale, the nurse knows when it is or is not safe to administer additional opioid and when the opioid dose should be decreased or stopped.

When selecting a sedation scale for prevention of opioid-induced respiratory depression, care must be taken to be sure that the selected scale matches the intended purpose. For example, the Ramsey is appropriate for monitoring the patient's tolerance for ventilation in the ICU, but is not intended for use in prevention of opioid-induced respiratory depression. It contains irrelevant items, such as agitation, which have nothing to do with opioid-induced respiratory depression.

Nurse monitoring of sedation levels and respiratory status is more appropriate for preventing opioid-induced respiratory depression than relying on pulse oximetry or apnea monitory. These

can give a false sense of security.[75–77] Further, decreased oxygen saturation is a later sign of impending respiratory depression. Capnography may more accurately detect respiratory depression and apnea;[78] however, further research is required to recommend widespread use of the method outside of the operating room or post-anesthesia care unit. The use of mechanical monitoring is recommended if a patient has a preexisting condition that requires it, such as sleep apnea or chronic obstructive pulmonary disease.[76]

Instructions for the safe use of naloxone to reverse clinically significant opioid-induced respiratory depression are included in Box 1. Naloxone must be titrated carefully. Giving too much naloxone or giving it too fast can precipitate severe pain and increase sympathetic activity leading to hypertension, tachycardia, ventricular dysrhythmias, pulmonary edema, and cardiac arrest.[79]

The IM route of administration is not recommended for pain management.[76] It is painful, and it has unreliable absorption with a 30–60 minute lag time to peak effect and a rapid drop in action. In addition to being ineffective, the IM route is dangerous because patients are often alone at the time of peak effect of the opioid administered, can become excessively sedated, vomit, and aspirate. A better alternative is the intravenous (IV) route of administration. Points to consider in the overall safe management of opioid naïve patients receiving IV or intraspinal analgesia are in Box 2.

Box 1: Pasero - McCaffery Opioid-induced Sedation Scale

S = Sleep, easy to arouse

Acceptable: No action necessary; supplemental opioid may be given if needed.

1 = Awake and alert

Acceptable: No action necessary; supplemental opioid may be given if needed.

2 = Slightly drowsy, easily aroused

Acceptable: No action necessary; supplemental opioid may be given if needed.

3 = Frequently drowsy, arousable, drifts off to sleep during conversation

Unacceptable: Decrease opioid dose by 25–50 percent . Administer acetaminophen or an NSAID, if not contraindicated, to control pain; monitor sedation and respiratory status closely until sedation level is less than 3.

4 = Somnolent, minimal or no response to physical stimulation

Unacceptable: Stop opioid. Notify anesthesia provider; very slowly administer dilute IV naloxone (0.4 mg naloxone in 10 mL saline; 0.5 mL over 2-minute period); administer acetaminophen or an NSAID, if not contraindicated, to control pain; monitor sedation and respiratory status closely until sedation level is less than 3.

Box 2: Safe Care of the Opioid Naïve Patient Receiving Opioids by IV or Intraspinal Routes

- Develop standardized, preprinted order sets that include
    - Opioid prescription
    - Administration of nonopioid analgesia, e.g., acetaminophen and an NSAID
    - Monitoring parameters
    - Activity, ambulation
    - IV access if indicated
    - Management of breakthrough pain
    - Treatment of adverse effects
    - When to notify anesthesia or primary care provider (e.g., unrelieved pain, excessive adverse effects)
- Monitor sedation and respiratory status every 1 to 2 hours for the first 24 hours after opioid therapy is initiated, then every 4 hours until IV or intraspinal opioid therapy is discontinued, then routine in stable patients (see Sedation Scale, Box 1).
- Monitor other vitals signs every 4 hours until IV or intraspinal opioid therapy is discontinued, then per routine in stable patients (evaluate need to monitor blood pressure more often in some patients).
- When possible, avoid sedating drugs for treatment of opioid-induced adverse effects, such as antihistamines for pruritus and antiemetics for nausea.
- Develop criteria for selecting appropriate patients to receive
    - Patient-controlled analgesia (PCA)
    - Family-controlled analgesia (parent or significant other)
    - Nurse-activated dosing (primary nurse)
- Teach patients, family members, and visitors about the proper use of PCA and the dangers of anyone other than the patient or an authorized person pressing the button.

Research Implications

The evidence base supporting the use of analgesics to manage acute pain is strong and clear—to date, analgesics, particularly opioids, are effective in controlling acute pain. Undertreatment of acute pain, however, remains prevalent despite the availability of analgesics and guidelines. Undertreatment is attributed to clinician behaviors—lack of adequate pain assessment and inadequate prescription and administration of analgesics—that are modifiable.

Thus, the research in this area needs to be directed toward effective strategies for changing clinician attitudes and behaviors that will result in better pain management for patients.

The evidence base for the use of nondrug therapies to manage acute pain requires further development; the current knowledge does not support achieving consistent outcomes from these therapies. Lack of standardization of nondrug therapies is one of the drawbacks of the current literature. Using standard relaxation or massage techniques with a determined duration (i.e., dose) and frequency (i.e., interval) would improve our ability to summarize the literature and determine the effectiveness of these therapies for pain control.

Conclusion

Education about safe pain management will help prevent undertreatment of pain and the resulting harmful effects. Safety includes the use of appropriate tools for assessing pain in cognitively intact adults and cognitively impaired adults. Otherwise pain may be unrecognized or underestimated. Use of analgesics, particularly opioids, is the foundation of treatment for most types of pain. Safe use of analgesics is promoted by utilizing a multimodal approach, that is, using more than one type of analgesic to treat the individual's pain. Opioid use is often avoided or inadequate for fear of causing life-threatening respiratory depression. Nurse monitoring of sedation levels when opioids are initiated is one way to assure safety. While nondrug techniques pose minimal safety issues, the current evidence does not support that these techniques produce consistent, predictable pain management outcomes.

Search Strategy

The terms "pain assessment" and "pain management" were used in the literature search. The research was limited to the English language, published in the last 10 years, meta-analyses, practice guidelines, literature reviews, clinical trials, and randomized clinical trials (RCTs). The literature for nondrug techniques was searched using the key terms "relaxation," "music," "massage," "heat and cold," and "pain." The nondrug literature was limited to the English language, meta-analysis, and literature reviews.

Cepeda 2007[50]	Music	Meta-analysis	Pain intensity Pain relief Opioid use	51 RCTs reviewed > 2,600 patients All types of pain	Music	Studies of postsurgical pain showed a 0.5 reduction in intensity with music (14 studies). Patient- versus provider-selected music showed no benefit in pain intensity. Patients exposed to music had 70 percent greater likelihood of reporting > 50 percent pain relief than those not exposed (4 studies). Patients exposed to music required 57 mg less of morphine in 1st 24 hours postsurgery than those not exposed (5 studies). No difference in medication side effects by use of music (4 studies). Clinical importance of benefit of music not clear.
Chandler 2002[64]	Heat/cold	Literature review		2 studies Acute pain		Limited evidence to support the use of heat for pain control in clinical settings.
Chang 2006[54]	Music	Randomized controlled trial	Pain intensity Heart rate (HR) Resp rate (RR) Blood pressure (B/P) Oxygen saturation (SpO2) Collected 15, 30, and 45 minutes after clamp applied	ICU in 2 acute care hospitals in Hong Kong N = 43 compression with C-clamp after percutaneous cardiac intervention	Patient selected music from 15 selections of soft, slow, nonlyric music Control: usual care	Significant difference in pain intensity after 45 minutes of compression. Patients exposed to music had significant reduction in pain. Patients in control group had significant increase in pain. HR, RR, and SpO2 significantly lower with music at 30 and 45 minutes compared to control. Systolic B/P, HR, and RR declined with music over time. Analysis controlled for multiple comparisons. Music has benefit during a painful procedure in ICU.

Voss 2004[52]	Music	Randomized controlled trial	Pain intensity Pain distress Anxiety	Hospital in United States N = 61 CV surgery patients	Patient selected music (6 types) Scheduled rest Control: usual care 30 minutes during chair rest	Significant reductions in pain intensity, distress, and anxiety pre-post chair rest for music and rest groups. Post hoc test indicated patients exposed to music reported significantly less pain intensity, distress, and anxiety than the rest or control patients. Music reduced outcomes from 57–72 percent after 30 minutes of chair rest compared to controls.
Wong 2004[56]	Massage	Pretest, post-test	Pain intensity Distress Heart rate (HR) Resp rate (RR) Blood pressure (B/P)	Teaching hospital in United States Postsurgical patients	20 minute foot and hand massage No control	Significant decrease in pain intensity and distress pre-post massage. Significant decrease in HR and RR; differences small and not clinically important. No difference in B/P pre- to postmassage.

Chapter 18. Medication Management of the Community-Dwelling Older Adult

Karen Dorman Marek, Lisa Antle

Background

For many older adults, the ability to remain independent in one's home depends on the ability to manage a complicated medication regimen. Nonadherence to medication regimens is a major cause of nursing home placement of frail older adults.[1] In the United States, an estimated 3 million older adults are admitted to nursing homes due to drug-related problems at an estimated annual cost of more than $14 billion.[2] Older adults are the largest users of prescription medication, yet with advancing age they are more vulnerable to adverse reactions to the medications they are taking. Approximately 30 percent of hospital admissions of older adults are drug related, with more than 11 percent attributed to medication nonadherence and 10–17 percent related to adverse drug reactions (ADRs).[3–5] Older adults discharged from the hospital on more than five drugs are more likely to visit the emergency department (ED) and be rehospitalized during the first 6 months after discharge.[6] Nursing interventions that assist older adults in managing their medications can help prevent unnecessary, costly nursing home admissions, hospitalizations, and ED visits, as well as improve their quality of life.

The purpose of this review was to identify evidence-based interventions related to medication management and the community-dwelling older adult. The focus of this review was interventions that fall within the scope of practice of the registered nurse. The guidelines do not address the specific intervention of medication prescribing. However, the interventions are applicable to professional nurse providers whether they are prescribing or not. This chapter discusses risk factors for problems in medication management followed by evidence-based interventions in areas of medication reconciliation, medication procurement, medication knowledge, physical ability, cognitive capacity, intentional nonadherence, and ongoing monitoring.

Risk Factors

There is a wide variety of factors that place the community-dwelling older adult at risk for problems in medication management. The young-old (ages 66–74) have been found to be more adherent to medication regimens than middle-aged older adults, but after age 75, older adults present decreased comprehension of medication instructions and adherence.[7–15] Living arrangements influence the older person's ability to manage medications, and older adults who live alone were found to be more prone to medication errors.[16–21] It is postulated that this is related to the fact that there is no one to monitor, assist, or remind the older person about taking their medications. Persons with chronic disease, especially depression, have a higher incidence of nonadherence to their medication regimen.[7, 10, 22–30] Many of the risk factors related to inadequate medication management are items that are more prevalent in older adults living in the community. Other factors that will be discussed in more detail later in the chapter are physical impairments such as poor vision, grip strength, and cognitive decline.

Older adults are more prone to adverse events due to the clinical complexity of their care rather than age-based discrimination.[31] A study of older adult outpatients who took five or more medications found that 35 percent experienced adverse drug events.[32] In addition, individuals with complex regimens had difficulty naming and explaining the purposes of medications and appeared to be at high risk for nonadherence.[33] The greater the medication complexity, the less likely the older adult is to adhere to the medication regimen.[34] The larger the number of medications, the more likely the older adult will be nonadherent.[3, 9, 13, 19, 28, 35–46] It is not only the number of medications but also the number of doses per day and actions related to taking medications that contribute to complexity of a medication regimen.[34] In a study of medication compliance, the compliance rate was 87 percent for daily dosing, 81 percent for twice a day, 77 percent for three times a day, and 39 percent for four times a day.[47] In addition, a change in prescribed drug regimen has been found to be a predictor of medication nonadherence in older adults.[9] Finally, the number of prescribing providers adds to the complexity of managing one's medications, and persons with more than one prescribing provider were found to be prone to medication errors.[16, 19]

Research Evidence

Medication Reconciliation

Medication reconciliation is the first step in assisting older adults in the medication management process. Multiple studies have demonstrated discrepancies from 30 percent to 66 percent in what medications were ordered by the prescribing provider and the actual medications the older adult was taking.[16, 48–52] Prescribing providers were often unaware of prescribed medications their patients were taking,[16, 53–55] and the larger the number of prescribing providers, the greater the chance of medication discrepancies.[3, 42, 56, 57] A study of elderly patients 2 days after hospital discharge found 64 percent were taking at least one medication that was not ordered, 73 percent failed to use at least one medication according to instructions, and 32 percent were not taking all drugs ordered at discharge.[58] Another challenge in reconciliation of medications is determining exactly what medications older adults are taking in their home. One study found 49 percent of community-based older adults kept stores of old medications from the year before, and 6 percent admitted they self-prescribed medications on at least one occasion.[59] Over the counter (OTC) medication use also needs to be assessed, because estimates of older adults' use of OTC drugs range from 32 percent to 86 percent.[60–62] A recent study of older adults with hypertension attending a blood pressure clinic found 86 percent reported two or more self-medication practices using OTC drugs that could result in an adverse drug interaction.[63]

Multiple studies have demonstrated that 10–74 percent of medications prescribed for older adults were inappropriate.[48, 57, 64–74] A study of "brown bag" medication reviews, in which patients bring all of their medications with them (often in a brown paper bag) to a medical or pharmacy consultation, revealed that 12 percent of the patients had medication problems that could potentially result in hospital admission.[75] A review of ED visits of patients 65 years and older found 10.6 percent of the visits were related to an adverse drug event, and 31 percent had at least one potential adverse drug interaction in their medication regimen.

Pharmacy reviews have demonstrated a reduction in polypharmacy in older adults and decreased adverse drug events in older patients.[76–82] Beer's set of criteria for potentially inappropriate medication use in older adults is one example of criteria developed for pharmacy

screening.[83, 84] There are a variety of drug interaction programs that quickly identify adverse drug interactions.

Also, patients who were given a medication card with a list of current medications were more compliant with their medication regimen.[85] Use of a medication list that is shared with the patient's primary care physician decreased patient rehospitalizations in one study.[86]

Medication Procurement

Not filling or refilling prescriptions is a common cause for medication nonadherence in older adults.[87–91] In a study of elderly patients at 15 days posthospitalization, 27 percent had not filled their new prescriptions.[92] Patients who participated in programs that provided pharmacy delivery and refill reminders had fewer adverse drug events and higher compliance than those who did not.[78]

If the cost of medication is viewed as high, older adults are more likely to not adhere to their medication regimen and be hospitalized.[3, 11, 56] Lack of funds, especially at the end of the month, is one reason older adults delay filling prescriptions.[93] In addition, chronically ill older adults are more likely to experience financial burdens associated with covering out-of-pocket costs for their prescription medications, cut back on medications due to cost, and use less medicines monthly.[89, 93–98] A study of use of medications after an increase in the copayment found a reduction in use of up to 45 percent in nonsteroidal anti-inflammatory drugs and 23 percent in antidiabetic drugs.[99]

Older adults who have insurance to cover medications have greater adherence.[12, 14, 19, 100] In one study, both adherence to medications and clinical outcomes improved while the number of hospitalizations declined when cardiovascular drugs were provided to indigent patients who could not afford to buy them.[101]

Medication Knowledge

Studies of older adults' knowledge of medications have found more than 50 percent knew the names and purpose of their medications; however, less than 25 percent knew the consequences of drug omission or toxic side effects.[9, 16, 54, 102] For example, one study of elderly patients with congestive heart failure found that 30 days after a new medication was prescribed, only 64 percent of the patients could identify when they were supposed to take their medicine.[103] Also, older adults were found to have insufficient knowledge of inhaler technique and understanding how medications can improve their asthma.[104] Noncompliant patients on anticoagulant therapy were more likely to report they did not know why their medication was prescribed.[105] In a study of OTC medication use, few older adults knew precautions related to the OTC drugs they were taking.[61] One study of older adult medication knowledge found that older adults understood prescribed medications better than OTC drugs, especially nutritional supplements.[106]

Patient education is a key intervention to assist older adults with medication management. Patient knowledge of drugs is positively associated with adherence.[16, 21, 91, 105, 107–112] However, older adults require specific educational methods. Learning is more effective in older adults if information is explicit, organized in lists, and in logical order. Instructions that are compatible with the older adults' schema for taking medications are better remembered,[113] and well-organized prescription labels are more useful for older adults.[114] Pictures are not helpful unless the picture is clearly related to the content.[115–118] A combination of both oral and written formats was identified by older adults as most helpful.[119] Medication schedules or charts in combination with teaching or counseling enhances patient medication adherence.[85, 86, 120–124] Four weeks after

starting a new medication for a chronic illness, patients identified a substantial need for further information.[125] Studies have demonstrated that patient education and counseling over several home visits or with followup phone calls produces increased medication adherence in recipients.[126–141]

Physical Ability

Poor vision and low manual dexterity are associated with poor medication self-management.[9,21,39,142–144] The inability to read medication labels has been associated with nonadherence to long-term medications in the elderly.[43,145] One study found 28 percent of community-based older adults did not keep their medication bottles properly closed so that they could open them, and 47 percent admitted that labels on their medications were unclear and they could not read them due to poor eyesight, inability to read English, or small writing on the label.[59] Studies have demonstrated that from 31 percent to 64 percent of older adults living at home have difficulty opening medication containers, with childproof containers presenting the most difficulty.[9,144,146] In studies of persons with chronic obstructive pulmonary disease (COPD), 38 percent used their inhaled medications with poor technique,[89] and poor hand strength was associated with nonadherence in inhaler use.[147] In another study of COPD patients, more than 50 percent had difficulties with their inhalers.[112]

Medication-container modification is one area of intervention for older adults who have difficulty opening or reading containers. Use of nonchildproof containers is one option for older adults. However, blister packs or other variations of unit dose packaging have resulted in increased compliance.[148–150] In a recent study of older adults, 64 percent were unable to open childproof containers, and 10 percent were unable to use blister packs.[9] Also, different tablet formations that increase the ease of breaking tablets have been found to increase patients' abilities to comply with their medication regimen.[151] Finally, talking medication containers and large-print labels are modifications that can be useful for persons with visual impairment.

Cognitive Capacity

Poor cognition is associated with both over adherence and under adherence of a prescribed medication regimen.[9,14,18,28,37,38,142–144,152–155] A study of community-dwelling women found that 22 percent were unable to accurately perform a routine medication regimen; however, only 2 percent self-identified that they had difficulty with their medications.[156] Forgetting is a major reason medication doses are missed.[9,78,88,89,157–162] The most prominent type of medication noncompliance is dose omission, but overconsumption is a common mistake, especially in persons on a once-daily dose schedule.[163]

There are a number of interventions to assist older adults with remembering to take their medications. One simple method is the use of memory cues that prompt patients to take their medications.[148] Development of memory cues must be tailored to the patient's lifestyle.[90,164] Placing medication in a special place and use of a daily event such as meal time improve medication adherence.[91,106,165,166] A study that examined the most common ways older adults remembered to take their medications found the following methods to be beneficial: (1) placing containers in a particular location, (2) taking medications in association with meals/bedtime, (3) using a timed pill box, (4) reminders from another person, and (5) using written directions or a check-off list.[159]

Compliance aids such as pill box organizers have been found to increase medication adherence.[16,78] Medication schedules and calendars are helpful, especially in combination with education and use of a pill box.[38,40,78,120,150,167,168] In addition, electronic monitoring that provides feedback to the user increases adherence.[141,169–171] Older patients using a voice-reminder-message medication dispenser were significantly more compliant than those using a pill box or self-administering medications.[172,173] Patients using topical pilocarpine were significantly more compliant using an electronic medication alarm device.[174] Programs that use daily telephone reminder calls also have demonstrated increased medication compliance.[155,175] Several studies have demonstrated that dose simplification from two times a day to one time a day produces higher compliance and improved patient outcomes.[122,176–182]

Intentional Nonadherence

One study of chronically ill persons who were starting a new medication found that almost a third did not take their medication as prescribed, and half of the time it was deliberate.[125] Older adults' perceptions of the seriousness of their illness and vulnerability to complications were significantly related to medication adherence.[13,46,90,91,97,166,183] In fact, low self-efficacy and beliefs that others are responsible for one's health care are predictors of medication nonadherence.[21,89,105,159,184–194]

A major reason that older adults skip doses or stop taking their medications is related to medication side effects.[9,11,16,26,38,46,89,91,93,110,125,159,161,162,191,195–198] In a comparison of compliant and noncompliant patients in fluvastatin treatment, the noncompliant patients were more likely to experience side effects of the medication.[199] Six months after discharge for acute coronary syndrome, 8 percent of those taking aspirin,12 percent of those taking beta-blockers, 20 percent of those taking ACE inhibitors, and 13 percent of those taking statins had discontinued taking their medications.[200]

Use of commitment-based interventions has been found to increase self-efficacy and medication compliance.[201] Education that addresses patient involvement with decisionmaking, such as focusing on appropriate versus inappropriate use of medication, can improve self-efficacy.[202] Patients with depression who participated in a program to enhance self-management and prevent relapse had significantly greater long-term adherence to their medication regimen.[203] Patients whose provider had an open, collaborative communication style also were more adherent to their medication regimen.[204]

Ongoing Monitoring

Older adults have narrow therapeutic windows and require close monitoring, especially when on multiple medications.[205] Ongoing monitoring of the older adult's medication management is critical. A study of home care patients found 16 percent had skipped a medication in the last 24 hours, 6 percent were taking the wrong dose, and 5 percent were experiencing adverse effects from their medication.[87] In one study, symptomatic hypotension was identified in 13 percent of community-based elderly.[67] In another study, older adults treated for urinary tract infections and sleeping disorders experienced a significantly higher risk of ADRs.[206] A review of ED visits of patients 65 years and older found 10.6 percent of the visits were related to an adverse drug event, and 31 percent had at least one potential adverse drug interaction in their medication regimen.[207] Pharmacist management of repeat prescriptions found 12.4 percent of patients had compliance

problems, side effects, ADRs, or drug interactions.[208] A total of 35 percent of elderly ambulatory patients reported at least one adverse event within the previous year.[209]

Monitoring medication adherence is an ongoing process. The longer people are on a medication, the more likely they are to have difficulty following the medication regimen.[179, 210] For example, in one study, only 31 percent of people with type 2 diabetes who were on oral hypoglycemics adhered to their medication regimen.[211] In another study, persons on oral hypoglycemic medications were nonadherent an average of 64.7 days in one year.[212] Since adherence to medication regimen for type 2 diabetes is strongly associated with metabolic control, interventions related to monitoring and improving adherence are critical.[213]

Patients taking Digoxin who are not adherent have an increased number and duration of hospitalizations and twice the mortality rate than those who are adherent.[214] Also, in a study of long-term compliance of antihypertensive drugs, patients on ACE-inhibitors, beta-blockers, calcium channel blockers, and diuretics were more likely to be noncompliant,[215] as were persons using bronchodilators and benzodiazepines.[60]

Practice-Implications: Medication Management Practice Guidelines

Medication Reconciliation

1. Review with patient all prescribed and nonprescribed medications the patient is taking. Include over-the-counter (OTC) medications, herbs, and vitamins.[216]
2. Screen for adverse drug interactions. If adverse drug interactions are identified, report to the prescribing provider any medications of concern.[76–82,84,216]
3. Identify the primary or secondary medical diagnosis related to each prescribed medication. If the medical diagnosis is unknown, request the diagnosis from the prescribing provider.[84,216]
4. For patients age 65 and older, apply Beer's criteria for inappropriate medication for the elderly. If any medications appear in Beer's criteria, report to the prescribing provider any medications of concern.[84]
5. Provide to the prescribing provider(s) a list of all medications (prescribed and OTC) the patient is taking and a list of corresponding medical diagnoses.[216]
6. Verify prescribed medications and related medical diagnoses with the prescribing provider(s).[84]
7. Provide the patient or caregiver a current list of all medications the patient is taking with dose and frequency; have the patient share this list with the prescribing provider or other health care providers as needed.[85,86,216]

Medication Procurement

1. Assess the patient's or caregiver's ability to procure medications.[87–92]
    a. Identify how and where the patient obtains and refills prescriptions.[87–92]
    b. Assess how the patient pays for medications.[3,11,56]
    c. Assess if medications doses are ever missed due to lack of funds.[93]
2. If the patient or caregiver has difficulty obtaining or refilling prescriptions, assist the patient with creating a system to procure medications via

   a. Pharmacy delivery.[78]
   b. Refill reminders or automatic refill service.[78]
   c. Scheduling family or friends to pick up medications.
3. If funds to purchase medication are a problem,[89,93–98]
   a. Refer the patient to a social worker to obtain Medicare Part D coverage, other insurance coverage, or participation in drug company programs.[12,14,19,99,100]
   b. Consult with the pharmacist regarding use of generic drugs.
   c. Consult the prescribing physician about availability of drug samples.[101]

Medication Knowledge

1. Assess the patient's or caregiver's knowledge of
   a. Dose and frequency of medications taken.[9,16,33,54,102,103]
   b. Special instructions related to medications, such as "take with food."[33]
      i. If the patient uses an inhaler, understanding of the correct inhaler technique.[104]
   c. Medication mode of action.[9,16,54,102]
   d. Side effects to monitor and report.[9,16,54,102]
2. With each change in medication regimen (including OTC drugs), review medication purpose, dosage, frequency, side effects to monitor and report, and other medication-specific instructions.[61]
3. Interventions related to medication knowledge include[16,21,91,105,107–112]
   a. Provide written instructions related to medications in large letters and bullet or list format.[115–119]
   b. Tailor instructions to how the patient takes his or her medicine.[113]
   c. Group information starting with generalized information, followed by how to take the medicine, and then the outcomes such as side effects to watch for and when to call the doctor.[114–118]
   d. Use medication schedules or charts to reinforce instructions.[85,86,120–124]
   e. If the patient did not know important medication information at a previous encounter, review dose, time, side effects to monitor and report, and special instructions at the next visit.[125–141]

Physical Ability

1. Assess for decreased manual dexterity or vision impairment and its affect on the patient's ability to identify the correct medication, open medication containers, and prepare medications (e.g., breaking tablets) for administration.[9,21,39,43,142–145]
   a. Observe the patient opening medication containers.[9,59,144,146]
   b. If the patient uses an inhaler, observe the use of the inhaler.[89,112,147]
   c. If the patient is required to break tablets, assess his or her ability to do so.[151]
   d. If the patient is unable to open or see the label and contents of each medication container, provide one of the following:
      i. Pill box or other easy-open container.[150,172,217] If the patient is unable to fill the pill box, identify someone who can assist him or her.
      ii. Medication calendar with pill box.[155,167,168,218]
      iii. Blister packs.[138,149] Consult the pharmacy about the availability of the drug in blister packs or nonchildproof containers.

iv. If tablet breaking is required and the patient has difficulty doing it, consult with the pharmacist about tablets that are easier to break or tablets that are the correct dosage without requiring breaking.[151]

Cognitive Capacity

1. Assess the patient's or caregiver's cognitive capacity to organize and remember to administer medication.[106, 156]
    a. Assess when doses are taken.
    b. Assess what cues the patient uses to remember to take medication.
    c. Assess what dose is most difficult to remember.[9,78,88,89,157–162]
    d. Assess how often a dose is missed or an extra dose is taken.[9,14,18,28,37,38,142–144,152–155]
2. Teach the patient or caregiver the use of memory cues based on one of the following methods:[148,159]
    a. Clock time. Ask if the patient or caregiver is usually aware of the time of day or keeps track of time through a watch or clock.
    b. Meal time.[90,91,106,164–166] Ask if the patient eats meals at a regular time.
    c. Daily ritual, such as using the bathroom in the morning, shaving, or hair combing.[90,91,106,164–166]
3. If the patient requires additional support,
    a. Provide memory-enhancing methods or devices such as
        i. Medication calendar or chart.[38,40,78,120,150,167,168]
        ii. Electronic reminder or alarm.[141,169–171,174]
        iii. Voice-message reminder.[172,173]
        iv. Telephone reminder.[155,175]
        v. Pill box.[16,78] (If the patient is unable to fill a pill box, identify someone who is willing to assist him or her.[158])
        vi. Electronic medication dispensing device.[173]
        vii. Combine methods and devices when possible.[38,40,78,120,150,167,168]
    b. Discuss dose simplification with the prescribing provider.[122,176–182]

Intentional Nonadherence

1. Assess if medication doses are missed intentionally.[125]
    a. Drugs at high risk for intentional noncompliance include the following:
        i. ACE-inhibitors[200,215]
        ii. Beta-blockers[200,215]
        iii. Calcium channel blockers[200,215]
        iv. Diuretics[215]
        v. Bronchodilators[60]
        vi. Benzodiazepines[60]
    b. If the patient intentionally misses doses, assess the reason(s).
        i. Belief medication is not helping.[13,46,90,91,97,166,183]
        ii. Fear of adverse side effects.[13,46,90,91,97,166,183]
        iii. Side effects.[9,11,16,26,38,46,89,91,93,110,125,159,161,162,191,195–198]

   c. The following medications are most risky for patients to miss:
      i. Coumadin[105]
      ii. Digoxin[214]
      iii. Beta-blockers[200]
      iv. Insulin
      v. Prandinm® (repaglinide)
      vi. Antibiotics
      vii. ACE-inhibitors[200]
2. If the patient misses medication doses for reasons related to health beliefs,
   a. Explore with the patient his or her health concerns for not taking medication.[202]
   b. Discuss the benefits of taking medication as prescribed.[202]
   c. Provide positive reinforcement for taking medication as prescribed.[201]
3. For patients on high-risk medications, reinforce the danger of missing medication doses.[105]
4. If the patient misses medication doses for reasons related to medication side effects,
   a. Explore with the patient a plan to manage the side effects.[203]
   b. Modify the regimen to reduce the side effects.

Ongoing Monitoring

1. For all patients on a prescribed medication regimen, monitor the patient with each encounter for the following:
   a. Medication adherence
      i. Monitor both under- and overadherence.[87,179] Overconsumption occurs frequently in a once-daily dose schedule.
      ii. For persons using inhalers, assess
         1. Inhaler emptying rate.[89,104,147]
         2. Reported forgetfulness.[104]
         3. Use of short-acting inhaler.[89,104]
   b. Medication side effects[67,205]
      i. If medication side effects present, notify the prescribing provider, as appropriate.
   c. Lab work, as appropriate, for prescribed medications[216]
      i. Cockcroft-Gault Formula or other creatinine clearance measure at least annually. If creatinine clearance <50 ml/min, notify the prescribing provider.
   d. Medication effectiveness[205]
      i. If signs and symptoms of the problem the medication is treating are present, notify the prescribing provider, as appropriate.

Research Implications

There is a large volume of research related to medication management and the elderly. Medication management is a complex process that must be interdisciplinary in its approach. Many of the evidence-based interventions discussed are not discipline specific. A team of providers is needed to provide safe and therapeutic medication management.

There is a large amount of research related to risk factors for medication nonadherence. However, there is less evidence related to appropriate interventions to enhance adherence and medication self-management. In addition, the most effective programs have multiple interventions, so identifying the specific evidence for each intervention component is difficult. For example, one study included a combination of interventions of medication review, modification of containers, medication education, and a drug reminder chart.[138] All are important components of a medication program for older adults, yet it is difficult to identify the evidence supporting each component. What is promising is the use of technology to assist in medication management.[173,219] This includes clinical screening software for adverse drug interaction and potentially inappropriate prescribed medications, electronic adherence monitoring, and electronic medication reminders. Much of this new technology is currently being tested.

Conclusion

Medication management is a complex process that consists of multiple activities. Factors associated with problems in the performance of these activities include living alone, impaired vision, impaired cognitive function, ages 75 and older, having three or more medications and/or scheduled doses in one day, and more than one prescribing provider. Medication reconciliation is a key first step in medication management. Multiple studies have demonstrated large discrepancies in what medications are ordered by the prescribing provider and the actual medications the older adult is taking. Evidence supports medication reconciliation interventions that include a screen for inappropriate medications and adverse drug interactions, in addition to verification of medications that are prescribed. Other areas of medication management include assessment and interventions related to medication procurement, medication knowledge, physical ability, cognitive capacity, and intentional nonadherence. Ongoing monitoring of these areas is crucial.

Nurses play a pivotal role in the medication management process of older adults. Considering the expense of prescription drugs in the current health care system, a small investment in providing comprehensive assessment and interventions to assist older adults in accurate and safe management of their medications will provide cost-effective care and increase the quality of life of older adults struggling to manage their often-complex medication regimens.

Search Strategy

To conduct this review, a search was done in August 2005 of PubMed®, the Cumulative Index to Nursing & Allied Health Literature, Cochrane Database of Systematic Reviews, HealthStar, ISI Web of Science, Social Service Abstracts, Database of Abstracts of Reviews of Effectiveness, and Internet searches for citations occurring from January 1990 to August 2005. Key search terms used alone and in combination included medication adherence, compliance, elderly; aged; outcomes; polypharmacy; medication management; chronic illness; chronic disease; and individual types of chronic illnesses. All searches were limited to patients ages 65 and older and Web sites in the English language. The ISI Web of Science was used to track citations to major works, and article references were reviewed for inclusion. Bibliographies of retrieved articles also were searched for relevant articles not identified in the reference database searches.

Evidence Table. Medication Management of the Community-Dwelling Older Adult (Includes studies design level 4 and above)

Source	Safety Issue Related to Clinical Practice	Design Type (level)	Study Design, Study Outcome Measure(s) (level)	Study Setting and Study Population	Study Intervention	Key Finding(s)
Allard 2001[220]	Inappropriate prescribed medication	Randomized Controlled Trial (RCT)	1. RCT (Level 2) 2. Error over time (Level 2)	1. Community-dwelling older adults, age > 70 years and taking > 3 drugs 2. Treatment (*n* = 136) • Subgroup received case conference w/ intervention (*n* = 80) 3. Control (*n* = 130)	Medication review by nurse, pharmacist, and physician with monthly nurse followup. Potentially inappropriate prescriptions (PIPs) reported to prescribing physician.	Mean PIPs decreased in treatment group, but not significant.
Andrejak 2000[176]	Medication adherence	RCT	1. RCT (Level 2) 2. Clinical outcome (Level 1)	1. Multicenter: 6 month study, persons 18 and older with essential HTN (diastolic BP,95-115) 2. Mean age 57 3. Two treatment groups: • Twice-daily dosing (*n* = 62) • Once-daily dosing (*n* = 84)	Dose simplification: once a day, group one; twice a day, group two.	Evidence suggests that daily dosing enhances daily compliance, missing fewer doses, and taking medications on time as scheduled by the patient's provider ($P < 0.01$).
Bond 2000[208]	Medication adherence	RCT	1. RCT (Level 2) 2. Adverse events (Level 1)	1. Outpatient general medical clinics (19) 2. Community pharmacies (*n* =62) 3. Two groups: • Treatment (*n* = 904) • Control (*n* = 1,397)	Pharmacists monitored for • compliance • adverse reactions • symptoms • medication problems	The intervention group had more compliance problems identified ($P = 0.001$), while the control group had more items prescribed ($P = 0.003$) and resultant higher prescription costs.

Source	Safety Issue Related to Clinical Practice	Design Type (level)	Study Design, Study Outcome Measure(s) (level)	Study Setting and Study Population	Study Intervention	Key Finding(s)
Bonner 2002[53]	Medication compliance	Non-compar-ative study	1. Observational study without controls (Level 5) 2. Surrogate outcome: observed errors (Level 2)	1. Rural general practice older adults (50) 2. Selection: • Random presentation at surgery • > 4 meds • Significant medical history	1. Clinical pharmacist medication screening 2. Physician verification and correction of errors transcribed to a portable medication summary card	40% of subjects noncompliant, 8% of clinical pharmacist's medication issues required a change in therapy, and 18% reported medical information to the clinical pharmacist that the physician was unaware. The use of a medication card summary implemented via clinical pharmacist and physician intervention was ineffective in improving older adult medication compliance.
Bouvy 2003[131]	Medication compliance	RCT	1. RCT (Level 2) 2. Error over time (Level 2)	Heart failure patients treated with loop diuretics in an outpatient heart failure clinic or admitted to participating hospitals • Treatment (*n* = 74) • Usual Care (*n* = 78)	Pharmacist led monthly medication education for 6 months	Medication education decreased the number of missed doses (relative risk 0.33 [CI 95% 0.24–0.38]) and consecutive missed doses (relative risk 0.32 [CI 95% 0.19–0.55]). No significant difference in rehospitalization rate, mortality, and quality of life (QOL).
Cargill 1992[126]	Medication compliance	RCT	1. RCT (Level 2) 2. Error over time (Level 2)	1. Age 60and older 2. Three groups (total *n* = 70) • Control • Education • Education & followup phone call	1. Home visits: medication education, followup phone call 2 weeks s/p medication education 2. Compliance measured via pill count	Followup phone calls & education improved compliance (*P* = 0.0097). Compliance decreased as prescribed medications increased (*P* = 0.0097). Compliance was higher with home visit nurse led medication education with supportive followup.

Source	Safety Issue Related to Clinical Practice	Design Type (level)	Study Design, Study Outcome Measure(s) (level)	Study Setting and Study Population	Study Intervention	Key Finding(s)
Coleman 2004[49]	Care transition	Prospective cohort study	1. Non-RCT (Level 3) 2. Adverse events (Level 1)	1. Age 65 and older posthospitalization 2. Two groups: • Treatment (*n* = 158) • Control (*n* = 1,235) from administrative data	1. Medication self-management 2. Patient-centered record 3. Primary care and specialist followup 4. Education of warning signs and symptoms of worsening condition.	Odds ratios comparing rehospitalization 30 days: 0.52 (95% CI = 0.25–0.96), 90 days: 0.43 (95% CI = 0.25–0.72), and 180 days: 0.57 (95% CI = 0.36–0.92). Median time to first rehospitalization decreased (*P* = 0.003). Care transition was effective in decreasing hospital admissions. Intervention patients reported high levels of confidence in care management.
Day 1998[221]	Medication knowledge and compliance	RCT	1. RCT (Level 2) 2. Pretest/post-test (Level 3)	1. Rehabilitation Hospital patients 2. Mean age = 64.8 3. Two groups: • Self-administered medication during hospitalization (*n* = 24) • Nurse-administered medication (*n*=15)	1. Self-administration of medications while hospitalized. 2. Education	No significant differences found between groups. Small sample size.
Detry 1995[181]	Medication compliance	Non-RCT	1. Non-RCT (Level 2) 2. Observed errors (Level 3)	1. Persons treated with slow release nifedipine or amlodipine 2. for at least 4 weeks prior to study inclusion. 3. Mean age = 60 4. Two groups: • crossover at 6 weeks • once a day (*n* = 160) • twice daily (*n* = 160)	Dose simplification: once daily amlodipine versus twice daily slow release nifedipine for 4 weeks	Compliance with once-a-day dosing was higher than twice-daily dosing (*P* < 0.001). No significant difference in BP was identified.

Source	Safety Issue Related to Clinical Practice	Design Type (level)	Study Design, Study Outcome Measure(s) (level)	Study Setting and Study Population	Study Intervention	Key Finding(s)
Dezii 2001[177]	Dosing medication compliance	Retrospective cohort study	1. Retrospective cohort comparison (Level 4) 2. Medication errors related over time (Level 2)	1. HTN patients new to therapy 2. Two groups: • Single pill group (n = 969) • Two pill combination group (n = 624)	Dose simplification	Dose simplification to single-pill dosing vs. two-pills dosing significantly increased the persistence with prescribed therapy ($P < 0.05$).
Eisen 1990[182]	Medication compliance	RCT	1. RCT (Level 2) 2. Observed errors over time (Level2)	1. VA medical center clinic HTN patients 2. Three groups: • Once-daily dose (n = 45) • Twice-daily (n = 40) • Three times daily (n = 20)	1. Dose simplification 2. Measurement by electronic blister pack that recorded medication removal.	Once-a-day dosing adherence rate was higher than 3-times-a-day dosing ($P < 0.05$). Compliance increased as number of daily doses decreased.
Esposito 1995[167]	Medication adherence	RCT	1. RCT (Level 2) 2. Errors over time (Level 2)	1. Age 65 and older at hospital discharge 2. Four groups: • Group I – standard education (n = 11) • Group II – standard education and 30 minute verbal instructions (n = 8) • Group III – standard education and medication schedule (n = 10) • Group IV – standard education, medication schedule, and 30 minute verbal instructions (n = 14)	Medication schedule with verbal reinforcement.	Higher compliance rates were found in subjects who used medication schedule. Pilot, small study.

Source	Safety Issue Related to Clinical Practice	Design Type (level)	Study Design, Study Outcome Measure(s) (level)	Study Setting and Study Population	Study Intervention	Key Finding(s)
Fillet 1999[76]	Polypharmacy	Noncom-parative study	1. Observational study without controls (Level 5) 2. Measurable outcomes with unestablished connection to outcome (Level 3)	1. Medicare managed care organization patients 65 and older on 5 or more medications, over 3 month period. 2. 5,737 identified as high risk and surveyed, with 2,615 responding (response rate = 46%). 3. 275 primary care physicians surveyed, with 56 (20%) responding.	1. Identification of patients at risk for polypharmacy. 2. Empowerment letters sent to patients with brown bag to encourage a primary care provider (PCP) appointment for medication review. 3. All PCPs provided with practice guidelines regarding polypharmacy and patient-specific medication management reports.	17% of patients informed their PCP about a new prescription or nonprescription medication they were taking. The review resulted in medication changes in 51% of the reviews. 29% reported a decrease in frequency of dosing, and 20% had a medication discontinued. 45% of the physicians reported at least one medication change.
Friedman 1996[132]	Medication Adherence	RCT	1. RCT (Level 2) 2. Clinical outcome (Level 1)	1. Persons age 60 and older under treatment for hypertension from community sites such as senior centers with BP>160/90 2. Two groups: • Treatment (n = 133) • Control (n = 134)	1. Automated telephone patient monitoring and counseling. 2. Weekly-treatment subjects reported self-measured BP, knowledge, and adherence to medications and side effects.	Medication adherence was higher (P = 0.03) and diastolic blood pressure lower (P = 0.02) in the treatment group.
Fulmer 1999[175]	Medication compliance	RCT	1. RCT 2. Observed errors (Level 2)	1. Community dwelling, age 65 and older with diagnosis of CHF 2. Three groups: • Control (n = 14) • Telephone (n = 13) • Videophone (n = 15)	1. Telephone group received daily telephone call reminders. 2. Videophone group received daily videophone call reminders.	Control group had lower compliance than the groups who received either videophone or telephone calls (P < 0.04).

Source	Safety Issue Related to Clinical Practice	Design Type (level)	Study Design, Study Outcome Measure(s) (level)	Study Setting and Study Population	Study Intervention	Key Finding(s)
Goodyer 1995[123]	Medication compliance	RCT	1. RCT (Level 2) 2. Errors over time (Level 2)	1. Outpatient clinic patients 70 years and older with chronic stable heart failure 2. Two groups: • Treatment (*n* = 50) • Control (*n* = 50)	Three month pharmacist-led medication counseling with three home visits	Compliance and medication knowledge were higher in treatment group ($P < 0.001$). Both exercise and distance to breathlessness improved in the treatment group and worsened for controls ($P < 0.01$). No significant changes were noted in Nottingham Health profile.
Hawe & Higgins 1990[222]	Medication compliance	Non-RCT	1. Nonrandomized control trial (Level 3) 2. Errors over time (Level 2)	1. Inpatient persons age 55 and older 2. Two groups assigned by month of admission: • Treatment (*n* = 149) • Control: received dummy intervention (*n* = 119)	1. Group-based inpatient educational session followed by individual pharmacist predischarge instruction and individual medication record card. 2. Measurement: • Compliance by subject report • Interviews 1 month and 3 months postdischarge	No significant difference in compliance at 1 and 3 months; however, the program was effective in a subgroup of persons taking four or more drugs, with the treatment group compliance rate at 55% versus the control at 32% at 3 months.
Hanlon 1996[77]	Inappropriate medications	RCT	1. RCT 2. Adverse events (Level 1)	1. Patients 65 and older of a general medical VA clinic 2. Two groups: • Treatment (*n* = 105) • Control (*n* = 103)	1. Pharmacist met with patients during scheduled clinic visits evaluating drug regimens. 2. Recommendations made to prescribing physician.	Inappropriate prescribing lower in treatment group ($P = 0.0006$), fewer ADRs in intervention group ($P = 0.19$).
Hayes 1998[117]	Medication knowledge	RCT	1. RCT (Level 2) 2. Knowledge post-test (Level 3)	1. Patients discharged from three rural emergency departments, age 60 and older. 2. Two groups: • Treatment (*n* = 30) • Control (*n* = 30)	Geragogy-based medication instruction sheets	Utilization of Geragogy-based medication instruction sheets increased patient knowledge of medications ($P = 0.16$).

Source	Safety Issue Related to Clinical Practice	Design Type (level)	Study Design, Study Outcome Measure(s) (level)	Study Setting and Study Population	Study Intervention	Key Finding(s)
Huang 2004[135]	Medication education	Non-RCT	1. Nonrandomized control trial (Level 3) 2. Clinical outcomes (Level 1)	1. Patients of district health center, 65 and older, diagnosed with diabetes mellitus, living alone, with resting BP less than 160/100 mmHg. 2. Matched on age, sex, education, and history of diabetes. 3. Three groups: • Group 1 – home-based nursing (*n* = 15) • Education program (*n* = 15) • Control (*n* = 14)	1. Group 1 – daily nurse visits to supervise diet, exercise, medication, and self-monitoring blood sugar. 2. Group 2 – weekly nurse visits to supervise diet, exercise, medication, and self-monitoring blood sugar. Nursing weekly home visits vs. daily home visits.	Both intervention groups had reductions in blood sugar and HGA1c ($P < 0.001$), cholesterol, & LDL ($P < 0.05$). Subjects with daily nurse visits had greater weight loss ($P < 0.05$).
Kimberlin 1993[82]	Medication compliance and knowledge	Non-RCT	1. Nonrandomized trial (Level 3) 2. Adverse events (Level 1)	1. Subject criteria • Age 60 or older • Capable of self-care • Taking four or more medications or medications from a list of targeted drugs with narrow therapeutic ranges or likely to cause problems in the elderly. 2. Two subject groups: • Treatment (*n* = 410) • Control (*n* = 352) 3. Pharmacist assignment to treatment (n = 55) or control (n = 33).	Intervention pharmacists participated in home study and 1-day workshop on drug therapy for elderly patients.	Subjects of intervention pharmacists more likely to report pharmacists provided information and assessed for problems than were control subjects. No significant differences were found in compliance or hospitalizations. However, the addition of each medication in the drug regimen elevated the odds of a subject reporting a problem with med therapy by 1.115.

Source	Safety Issue Related to Clinical Practice	Design Type (level)	Study Design, Study Outcome Measure(s) (level)	Study Setting and Study Population	Study Intervention	Key Finding(s)
Krska 2001[81]	Medication review	RCT	1. Group RCT (Level 2) 2. Errors over time (Level 2)	1. Community-dwelling older adults • Age 65 or older • Four or more medications • At least two chronic conditions 2. Two groups: • Treatment (*n* = 168) • Control (*n* = 164)	Pharmacist medication review with pharmaceutical care plan with medication regime changes in collaboration with general practitioner.	All subjects reviewed had at least two PCIs, and a greater number were resolved at followup in the intervention group. No significant difference was found in quality of life or cost between groups.
Leirer 1991[155]	Medication adherence	RCT	1. RCT (Level 2) 2. Errors over time (Level 2)	1. Community-dwelling older adult volunteers • Mean age 70.9 2. Excluded cognitively impaired, depressed, debilitating conditions, or taking two or more medications. 3. Two groups: • Treatment (*n* = 8) • Control (*n* = 8)	1. Both groups given medication schedule and portable bar code reader to record simulated medication taking for 1 week. 2. Treatment group received voice mail reminders.	Voice mail reminders enhanced medication adherence ($P = 0.03$), memory failure contributes to medication nonadherence ($P = 0.05$).
Lipton 1994[80]	Medication compliance and resource utilization	RCT	1. RCT (Level 2) 2. Errors over time (Level 2)	1. Geriatric hospitalized patients on three or more medications at discharge. 2. Two groups: • Treatment (*n* = 350) • Control (*n* = 356)	Pharmacist-led drug consultation service at hospital discharge, 1 week, 2–4 weeks, 2 months, and 3 months postdischarge via phone (85%) or home visit. Followup phone calls.	Pharmacist consultation decreased medication complexity ($P < 0.001$), number of medications ($P < 0.001$), and average daily doses ($P = 0.02$) at 3 months. Medication compliance, missed doses, and knowledge were impacted the greatest at 3 months ($P < 0.001$). No significant difference in health care use or charges were identified.

Lourens 1994[85]	Medication compliance	RCT	1. RCT (2) 2. Errors over time (Level 2)	1. Outpatient clinic (mean age 72) 2. Two groups: • Counseling only (*n* = 49) • Counseling and medication card (*n* = 48)	1. Pharmacist counseling both groups. 2. Written medication card in treatment group.	Subjects with written medication card had both higher knowledge increased compliance (*P* < 0.001).
Lowe 1995[223]	Medication compliance	Prospective cohort study	1. Nonrandomized control trial (Level 2) 2. Errors over time (Level 2)	1. Hospitalized older adults (mean age 79) 2. Two groups: • Treatment (*n* = 42) • Control (*n* = 37)	1. Inpatient self-medication management program 2. Education	Both compliance (*P* = 0.02) and medication knowledge (*P* < 0.001) were higher in the self-medication management group.
Lowe 2000[138]	Medication compliance	RCT	1. RCT (Level 2) 2. Errors over time (Level2)	1. Community-dwelling older adults, > 65, taking three or more medications 2. Two groups: • Intervention (*n* = 73) • Control (*n* = 79)	Pharmacist-led Intervention that included • Medication review and verification with PCP • Modification of medication containers • Medication education • Drug reminder chart	Medication review, verification, education, and modification of containers increased medication compliance (*P* < 0.0001) and medication knowledge (*P* < 0.0005).

Source	Safety Issue Related to Clinical Practice	Design Type (level)	Study Design, Study Outcome Measure(s) (level)	Study Setting and Study Population	Study Intervention	Key Finding(s)
Malone 2001[224]	Optimizing medication therapy	RCT	1. RCT (Level 2) 2. Clinical outcome (Level 1)	1. Older adult ambulatory veterans (mean age = 66.8) who were high risk for drug-related problems. 2. High risk defined as having three or more of the following criteria: • 5 or more medications • 12 or more daily doses • 3 or more chronic conditions • 4 or more changes to drug regimen over past year • Taking less than 80% of prescribed medications • On medications that require monitoring 3. Two groups: • Treatment (n = 523) • Control (n = 531)	1. Intervention subjects received a minimum of three ambulatory clinical pharmacist in-person visits or phone calls. 2. Intervention protocol included • Physical assessment: • Compliance monitoring • Lab monitoring • Drug screening • Identifying untreated diseases • Referrals to primary care and specialist physicians	Clinical pharmacist-led intervention had no effect on HRQOL. Change in health status declined less in treatment (P < 0.004), but was not clinically meaningful. Intervention dose-response relationship for general health perceptions (P < 0.004), vitality (P < 0.006), and change of health over the past year (P < 0.007) was found.
McKenney 1992[171]	Medication compliance	RCT	1. RCT (Level 2) 2. Clinical outcome (Level 1)	1. Ambulatory patients from retirement community or primary care center 2. Age 50 or older 3. Treated for HTN for 12 months 4.Four groups	1. Group A (n = 17): control 2. Group B (n = 18): timepiece cap as stimulant strategy 3. Group C (n = 18): timepiece cap + pocket-size BP recorder 4. Group D (n = 17): timepiece cap + pocket-size BP recorder + BP cuff for self-monitoring	Timepiece cap used alone improved compliance significantly (P < 0.01) and lowered mean SBP/DBP lower (P < 0.01). The addition of blood pressure reporting card and home blood pressure monitoring increased compliance and reduced BP (P < 0.01).

Source	Safety Issue Related to Clinical Practice	Design Type (level)	Study Design, Study Outcome Measure(s) (level)	Study Setting and Study Population	Study Intervention	Key Finding(s)
Meredith 2002[79]	Inappropriate prescribing	RCT	1. RCT (Level 2) 2. Clinical outcomes (Level 1)	1. Newly admitted Medicare home health care patients 2. Selection criteria • At least 4 weeks of skilled service • At least one medication problem • Age 65 and older 3. Two groups: • Treatment (*n* = 130) • Control (*n* = 129)	Medication improvement program • Screen for duplication, cardiovascular issues, use of psychotropics, and NSAIDs. • Medication use plan discussed directly with prescribing physician by home care nurse.	Intervention improved medication use in 12 patients per 100 (95% CI = 0.0–24.0, *P* = 0.051), by decreasing medication duplication in 47 patients per 100 (95% CI = 20–74, *P* = 0.003), and improvement of the use of cardiovascular drugs in 37 patients per 100 (95% CI = 9–66, *P* = 0.17). No significant changes in clinical outcomes of general health (SF-36, cognitive impairment (MMSE) and ADLs.
Murray 1993[150]	Medication compliance	RCT	1. RCT (Level 2) 2. Errors over time (Level 2)	1. Persons 60 and older living in urban public housing for older adults on at least three medications 2. Three groups: • Group 1 (*n* = 12): conventional packaging, varied dosing • Group 2 (*n* = 10): conventional packaging and BID dosing • Group 3 (*n* = 9): unit-of-use packaging and BID dosing	Unit-of-dose packaging: single cup holding all meds to be taken at dosing time and BID dosing	Compliance in older adults was higher with dose simplification and unit-of-dose packaging (*P* = 0.017).

Source	Safety Issue Related to Clinical Practice	Design Type (level)	Study Design, Study Outcome Measure(s) (level)	Study Setting and Study Population	Study Intervention	Key Finding(s)
Naunton 2003[78]	Medication compliance	RCT	1. RCT (Level 2) 2. Adverse events (Level 1)	1. Community-dwelling older adults age 60 and older on four or more medications 2. Two groups: • Intervention (*n* = 57) • Control (*n* = 64)	1. Pharmacist home visit 5 days after hospital discharge included medication review, compliance encouragement, education, intervention when appropriate, with communication to community providers. 2. Followup at 90 days.	Intervention group had a median of three drug-related problems at 5-day visit and had declined to one problem at 90 days, compared to two problems for the control group ($P < 0.0001$). Intervention group unplanned rehospitaliztions were lower ($P < 0.0001$) and compliance higher ($P < 0.0001$).
Park 1992[168]	Medication adherence	RCT	1. RCT (Level 2) 2. Errors over time (Level 2)	1. Community-dwelling older adults • Taking two or more medications • Age 60 or older 2. Four groups: • Control (*n* = 16) • Medication schedule chart (*n* = 15) • Medication organizer (*n* = 15) • Schedule and organizer (*n* = 15)	Use of medication schedule and organizer compliance devices	Omission errors were the lowest in the group that used both schedule and medication organizer. Adults ages 71 and older had a lower rate of adherence (85%) than adults ages 60–70 (94%).
Patton 1997[128]	Medication adherence	Pre- and post-test	1. Nonrandomized control study (Level 3) 2. Clinical outcomes (Level 1)	1. HMO clinic patients with SBP 145 or greater and DBP 85 or higher consistently for at least 6 months. 2. Total subjects = 107 3. Median age 69	1. Nurse interactive education with written information. 2. Followup phone calls at 1, 3, 6, and 12 months after initial education.	Medication education with telephone followup decreased SBP/DBP ($P < 0.01$). Older adults had a greater reduction in BP ($P = 0.01$).
Pereles 1996[225]	Medication compliance and knowledge	RCT	1. RCT (Level 2) 2. Errors over time (Level 2)	1. Geriatric rehabilitation inpatients 2. Two groups: • Treatment (*n* = 51) • Control (*n* = 56)	Inpatient program that included three stages of increasing responsibility to independently self-medicate.	Treatment group at 1 month had fewer self-medication errors than control ($P < 0.001$). No difference between groups in knowledge, morale.

Perri 1995[170]	Medication compliance	Non-RCT	1. Non-RCT (Level 3) 2. Errors over time (Level 2)	1. Community-dwelling pharmacy customers taking a chronic medication with a new refill or prescription 2. Two groups: • Intervention (*n* = 88) • Control (*n* = 98)	Stimulant "counter cap" prescription vile that indicates when cap was last opened.	Subjects using the counter cap had improved medication compliance (*P* = 0.0366).
Piette 2000[129]	Medication adherence	RCT	1. RCT (Level 2) 2. Clinical outcomes (level 1)	1. Adults receiving diabetes treatment at a county health clinic 2. Mean age 56 3. Two groups: • Intervention (*n* = 124) • Control (*n* = 124)	1. Biweekly automated assessment and self-care education telephone calls 2. Nurse educator followup	Intervention group monitored glucose, feet, and weight more frequently and had fewer problems with medication adherence (*P* < 0.03). HbA_{1c} lower in intervention group (*P* = 0.01).
Raynor 1993[120]	Medication compliance	RCT	1. RCT 2. Errors over time (level 2)	1. Inpatient adults taking 2–6 medications 2. Four groups: • Nurse standard counseling • Nurse counseling and reminder chart • Pharmacist counseling • Pharmacist counseling and reminder chart	1. Counseling 2. Reminder chart or medication schedule	Groups that received reminder chart had higher medication compliance and medication knowledge than those that received counseling only (*P* < 0.01).
Rich 1996[127]	Medication adherence	RCT	1. RCT 2. Errors over time (level 2)	1. CHF patients at hospital discharge, age 70 or older 2. Two groups: • Intervention (*n* = 80) • Control (*n* = 80)	Comprehensive patient education, dietary and social service consultations, med review, and intensive postdischarge followup.	Intervention group medication adherence at 30 days posthospitalization higher than control group (*P* = 0.003).

Source	Safety Issue Related to Clinical Practice	Design Type (level)	Study Design, Study Outcome Measure(s) (level)	Study Setting and Study Population	Study Intervention	Key Finding(s)
Robbins 2004[141]	Medication adherence	Non- RCT	1. Non-RCT (Level 3) 2. Errors over time (Level 2)	Females age 65 and older with osteoporosis taking low-dose estrogen (*n* = 109)	Educational program • Monthly phone calls for 12 months. • Quarterly clinic visits. • Pill box for 6 months. • Minority women (*n* = 44) used an electronic monitoring bottle for an additional 6 months.	Adherence improved with the electronic monitoring bottle at 12 months ($P < 0.05$) in the minority women.
Rudd 2004[140]	Medication compliance	RCT	1. RCT (Level 2) 2. Clinical outcomes (Level 1)	1. Adults treated for hypertension in an outpatient clinic 2. Mean age = 60 3. Two groups: • Treatment (*n* = 74) • Control (*n* = 74)	1. Nursing case management with patient instruction on use of blood pressure equipment and self-monitoring. 2. Followup nurse calls at 1 week, 2 and 4 months. 3. Hypertension management program with standardized algorithms to modulate drug therapy based on subject's reported home blood pressure.	Intervention group had lower BP and higher adherence ($P < 0.05$).
Smith 1997[136]	Medication compliance	RCT	1. RCT (Level 2) 2. Errors over time (Level 2)	1. Adults age 65 and older at discharge from the hospital 2. Two groups: • Treatment (*n* = 28) • Control (*n* = 25)	1. Pharmacist inpatient discharge education related to pharmaceutical plan of care 2. Telephone help line	Intervention group compliance higher 10 days postdischarge ($P < 0.01$).

Source	Safety Issue Related to Clinical Practice	Design Type (level)	Study Design, Study Outcome Measure(s) (level)	Study Setting and Study Population	Study Intervention	Key Finding(s)
Solomon 1998[226]	Medication compliance	RCT	1. RCT (Level 2) 2. Clinical outcomes (Level 1)	1. Outpatient clinic patients with hypertension or COPD 2. Mean age 66 3. Treatment HTN (*n* = 63), COPD (n = 43) 4. Control HTN (*n* = 70), COPD (*n* = 55)	Standardized pharmaceutical care, including assessment and regularly scheduled therapeutic and educational interventions.	HTN intervention group had greater SBP decrease, higher compliance, and fewer hospitalizations than HTN control ($P < 0.05$). COPD treatment group had lower use of other providers at 4 weeks (when compared to the COPD control group).
Stewart 2003[137]	Medication adherence	RCT	1. RCT (Level 2) 2. Clinical outcomes (Level 1)	1. Patients attending hypertension clinic, mean age = 57 2. Two groups: • Treatment (*n* =41) • Control (*n* =42)	1. Both groups participated in an educational program related to management of hypertension and cardiovascular risk modification. 2. Treatment group received six telephone calls to patient and six to family member over 34 weeks.	Group receiving telephone calls had greater weight loss ($P = 0.007$), knowledge related to hypertension ($P = 0.008$), adherence to medication regimen ($P = 0.05$).
Sturgess 2003[217]	Medication compliance	Group RCT	1. Group RCT (Level 2) 2. Errors over time (Level 2)	1. Community-dwelling older adults age 65 and older taking four or more medications and were regular visitors to participating pharmacies 2. Ten pharmacies randomized so that five were interventional and five were control. 3. Total of 191 subjects recruited: • Intervention (*n* =110) • Control (*n* = 81)	Intervention pharmacies received intensive training related to • Disease management education • Rationalized medications • Compliance strategies • Monitoring for 18 months	Compliance greater ($P < 0.05$) and fewer problems with medications ($P < 0.05$) in intervention group when compared to control. No difference between groups in health care costs, utilization, and quality of life was identified.

Source	Safety Issue Related to Clinical Practice	Design Type (level)	Study Design, Study Outcome Measure(s) (level)	Study Setting and Study Population	Study Intervention	Key Finding(s)
Taylor 2003[122]	Medication review	RCT	1. RCT (Level 2) 2. Clinical outcomes (Level 1)	1. Outpatient clinic patients with three or more of the following high-risk factors: • 5 or more medications • 12 or more doses per day • 4 or more medication changes in past year • 3 or more concurrent diseases • history of medication noncompliance 2. Two groups: • Treatment (*n* = 33) • Control (*n* = 36)	1. Pharmacist intervention that included • Medical record review • Medication history review • Pharmaceo-therapeutic evaluation • Patient education • Monitoring 2. Length of treatment 1 year	Ratings for inappropriate prescribing improved in the intervention group while decreasing in the control group. In the intervention group, knowledge scores were higher (*P* = 0.000), number of prescribed medications decreased (*P* = 0.002), patient satisfaction was higher (*P* = 0.000), number of hospitalizations (*P* = 0.003) and ED visits (*P* = 0.044) were both lower when compared to the control group.
Varma 1999[124]	Medication compliance	RCT	1. RCT (Level 2) 2. Clinical outcome (Level1)	1. Persons age 65 and older with CHF who were hospitalized or attended outpatient clinic 2. Two groups: • Intervention (*n* = 42) • Control (*n* = 41)	1. Pharmacist-led medication education 2. Medication review with dose simplification	Treatment group had higher knowledge of medications (*P* = 0.0026) and fewer hospital admissions (*P* = 0.006). No difference identified in quality of life between groups.
Ware 1991[148]	Medication compliance and medication packaging	RCT	1. RCT (Level 2) 2. Errors over time (Level 2)	1. Setting both inpatient at a geriatric assessment and rehabilitation unit and postdischarge 2. Two groups: • Treatment (*n* = 4) • Control (*n* = 39)	1. Webster-Pak medication packaging unit-dose system 2. Hospital practice prior to discharge in both groups	Compliance was higher in subjects who used unit-dose packaging system (*P* < 0.05).

Source	Safety Issue Related to Clinical Practice	Design Type (level)	Study Design, Study Outcome Measure(s) (level)	Study Setting and Study Population	Study Intervention	Key Finding(s)
Weinberger 2002[130]	Medication Compliance	Group RCT	1. Group RCT (Level 2) 2. Clinical outcomes (Level 1)	1. Pharmacy customers who had COPD or asthma as an active problem and received 70% or more of medications from a single drug store 2. Three groups: • Intervention (*n* = 447) • Control group with peak expiratory flow rates (PEFR) monitoring (*n* = 363) • Usual care control (*n* = 303)	Tailored education by pharmacist based on patient-specific data provided to the participating pharmacists.	Treatment group had higher PEFRs compared to control groups (*P* = 0.02), more satisfaction with their pharmacist (*P* = 0.001), and more satisfied with their health care at 6 months (*P* = 0.01) when compared to the control groups. The asthma patients in the pharmaceutical care group had more breathing-related ED and hospital visits than the usual care group (odds ratio, 2.16 [CI 95% 1.76–2.63; *P* < 0.001]); however, the mean age for this group was 45, younger than the COPD group whose mean age was 62.
Wilson 2001[151]	Medication compliance	RCT	1. RCT (Level 2) 2. Indirect connection to outcome (Level 3)	1. Community-dwelling outpatients over age 70 with type 2 diabetes 2. Two groups of 15 each	1. Use of Glynase Prestabs for easier tablet breaking. 2. Use of push-and-snap method to break tablets.	Higher percentage of successful tablet breaking and less pain for Glynase Prestabs than generic tablets.
Winland-Brown 2000[172]	Medication adherence	RCT	1. RCT (Level 2) 2. Errors over time (Level 2)	1. Residents of older adult independent living facility, continued monitoring 2. Three groups: • Pre-filled pill box (*n* = 16) • Voice activated (*n* = 24) • Control (*n* = 21)	Medication management methods • Pill box • Medication dispenser with voice-activated reminders	Numbers of missed doses were fewer in voice-activated group (*P* < 0.01) compared to control and compared to prefilled pill box (*P* < 0.01).

Two groups of 11 each with crossover after 3 months	Blister-packed medications for 3 months and standard pill bottles for 3 months	Compliance was higher when subjects took medication via blister packaging (P = 0.01).

Chapter 19. Care Models

Bonnie M. Jennings

Background

The organization of care delivery is determined by a variety of factors such as economic issues, leadership beliefs, and the ability to recruit and retain staff. Ideally, evidence of the effect of care models on quality and patient safety would also be a major factor in decisionmaking.

Historically, four traditional care models have dominated the organization of inpatient nursing care. Functional and team nursing are task-oriented and use a mix of nursing personnel; total patient care and primary nursing are patient-oriented and rely on registered nurses (RNs) to deliver care.[1, 2] In the late 1980s, a number of nontraditional nursing care delivery models emerged that use various mixes of licensed and unlicensed nursing personnel.[3–5]

Care models do not exclusively pertain to the organization of nursing care, however, or the inpatient setting. Models have been examined for medical housestaff,[6] pharmacy services,[7] and social workers.[8] They have been considered for ambulatory care,[9–12] home care,[13–15] and nursing homes.[16] Care models also exist for specific patient populations such as elderly patients,[17–20] people with mental health needs,[21] and individuals with chronic conditions[22] to include disease management models[23, 24] and the use of technology.[25]

Research Evidence

Despite the interest in a variety of care models, it is difficult to discern which models work best. Neither the traditional nor the nontraditional inpatient nursing care models have been evaluated rigorously for their effects on patient safety.[2, 4, 26] Emerging models from other care disciplines, other settings, and particular patient populations are also lacking rigorous empirical assessments of their relationship to patient safety.

A number of investigations examining care models addressed nurses' perceptions of the care model.[1, 27–38] Only two investigations combined the nurses' perceptions with patient safety measures.[39, 40]

Several studies did not meet the criteria for inclusion in this review, largely due to weak designs. Of these, some reported pilot data,[6, 7, 13, 24, 41, 42] some were quality-improvement projects,[14, 17, 43] and others used qualitative methods.[32, 36,44–48] Like the quantitative studies, the rigor of the qualitative investigations varied. However, these qualitative studies illuminate important aspects of care models not evident in quantitative investigations. For example, Ingersoll[32] and Redman and Jones[36] were among the first investigators to assess the effects of patient-centered care models on nurse managers. The data from both of these studies expose the pressure and role confusion experienced by nurse managers. Subsequently, a quantitative investigation found nurse managers experienced a high level of emotional exhaustion, a key component of burnout.[49]

Among the quantitative studies of care models included in the evidence table, only one used a design that combined systematic review and meta-analytic techniques.[23] No randomized controlled trials were identified. The remaining seven studies used Level 3 designs. In two of

these studies, large databases were used to examine different care models for home-based long-term care[15] and mental health services.[21]

All five studies of nursing care models meeting inclusion criteria focused on acute care work redesigns in which the mix of nursing personnel was altered in some way. For each of these five investigations, data were reported from only one hospital.[39, 40, 50–52] Of these studies, one evaluated changes in care delivery models at one university teaching hospital with two campuses in the same city.[39] The remaining studies were smaller in scale focusing data collection on one,[50, 51] two,[52] or three units[40] in the same facility. Most often, measurements were done at three points in time—pre-implementation, and at 6 and 12 months after the model was introduced.[39, 40, 52]

Evidence-Based Practice Implications

The eight studies in Table 1 illustrate two main clusters of research. The first pertains to studies of inpatient nursing care models. Statistically discernible differences were rarely evident, and when they were, there was no clear pattern to guide practice.[39, 40, 50–52] For example, there were statistically fewer falls reported in two studies after units implemented care models using fewer RNs, presumably because there were more staff to assist patients.[50, 51] Fewer medication errors were detected in only two reports.[39, 52] However, quite unexpectedly and counter intuitively, postoperative pain scores were statistically higher on a unit after the number of RNs increased.[50]

There were no consistent patterns visible in findings among the studies that followed changes in the care model over time—before implementation and at 6 and 12 months.[39, 40, 52] However, the studies with multiple measurements showed that initial indicators of success were rarely sustained over time. This is similar to results from the study by Greenberg and colleagues[21] in which most positive effects of change lasted only one year. Despite the growing number of work redesign studies, the findings are too disparate even among those with stronger designs to offer a clear direction about practice changes to improve patient safety.

The second cluster of care model studies consists of three investigations that were conducted by other disciplines.[15, 21, 23] These studies demonstrate that the interest in determining which care models operate best is not isolated to nursing. The improved ability to detect statistical differences in these models may derive from their large sample sizes, their statistical techniques, or their use of different outcomes. The systematic review and meta-analysis of disease management programs for individuals with depression offers the strongest evidence for guiding care delivery.[23] With only one study of consumer-directed home-based long-term care,[15] and one of service-line delivery of mental health services,[21] practice changes for these areas should be considered carefully.

Research Implications

We actually know very little about the relationship between care models and patient safety. Randomized controlled trials (RCTs) might contribute evidence that would help investigators, administrators, and policy makers sort through the confusion. RCTs would be particularly difficult to conduct, however, given the need to have longitudinal data. The rapidly changing health care environment is not conducive to such endeavors.

The most glaring need relates to clarifying the work that needs to be done for patients and then determining which clinicians are best suited to provide it. Looking only at the work of nurses, which has dominated studies of care models in acute care settings, fails to consider nonnursing staff who are critical to the patient care mission.

We also know very little about care models that promote patient safety in outpatient settings, home care, or long-term care. These are areas that remain to be explored.

Conclusion

Care delivery models range from traditional forms, such as team and primary nursing, to emerging models. Even models with the same name may be operationalized in very different ways. The rationale for selecting different care models ranges from economic considerations to the availability of staff. What is glaring in its absence, however, is the limited research related to care models. Even more sparse is research that examines the relationship between models of care and patient safety. Ideally, future studies will not only fill this void, but the models tested will be developed based on a comprehensive view of patient needs, taking the full complement of individuals required to render quality care into account.

Search Strategy

Both MEDLINE® and CINAHL® databases were searched from 1995 to 2005 to identify research-based articles published in the English language that were pertinent to this review. Search terms were identified with the guidance of a reference librarian. The term "care models" was not a search option in CINAHL®. Therefore the CINAHL® search terms included "care delivery modules," "nursing care delivery systems," and "care modules." The MEDLINE® search was based on two terms, "care models" and "organizational models." Together, these searches yielded 549 citations, 55 in CINAHL® and 494 in MEDLINE®.

The abstracts for each of the 549 citations were reviewed. From this assessment it was determined that 82 of the articles were sufficiently focused on nursing or patient care models and should be considered further. Most of the 467 papers that were omitted used the word "model" in their title, but the work was not related to care models per se. For example, articles about medical management models were not used in this review. Additionally, a number of papers addressed topics with no discernible connection to care models (e.g., life support decisions for extremely premature infants).

The 82 articles were located and carefully read. As a result, 31 additional papers were omitted from the actual analysis. Reasons for these omissions included the lack of sufficient detail about the study, duplicate publications, and studies of advanced practice nurses. This left 51 articles for consideration in this review.

Table 1. Evidence Table for Care Models

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Barkell 2002[50]	Inpatient nursing work redesign	Pretest (January–June 1999) and post-test (January–June 2000) (6)	Design: Level 3 Patient outcomes: pneumonia, urinary tract infection (UTI), postoperative pain perception (Level 2), patient satisfaction	A surgical unit in a 508-bed teaching hospital in the Midwest, all patients under DRGs 148 (major small and large bowel procedures with comorbidities or complications) & 149 (bowel resection without complications); 59 patients pre-, 37 patients post; 59% female pre- and post	Total patient care. In this intervention, the ratio of RNs to unlicensed assistive personnel increased as compared to the ratio in the previous model of team nursing. The total budgeted full-time employees decreased with the total patient care model.	Pain scores for postoperative days 1 and 2 were higher with total patient care (P = 0.017). Pneumonia and UTIs occurred too infrequently to analyze. There was no detectable statistical difference in patient satisfaction.
Benjamin 2000[15]	Home-based long-term care	Cross-sectional (4)	Design: Level 3 Patient outcomes: safety (physical and psychological risk, sense of security), unmet needs (activities of daily living) (Level 2), patient satisfaction	In-Home Supportive Services (IHSS) program in California; 1,095 IHSS Medicaid beneficiaries with disabilities in professional agency models (PAMs) and consumer-directed models (CDMs): about half the recipients were over age 65 (50% PAM, 54% CDM), most were female (77% PAM, 70% CDM); CDM recipients had more functional impairments	Professional agency model vs. consumer-directed model	Both models had positive outcomes. Absolute differences were small but statistically significant for safety, unmet needs, and service satisfaction, with the CDM scores more positive.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Greenberg 2003[21]	Changed organizational structure	Nonrandomized trial (3)	Design: Level 3 Patient outcomes: continuity of care, readmission (Level 2)	139 Veterans Administration Medical Centers; facility-level data for patients receiving mental health services over a 6-year period	Service-line organization (interdisciplinary) v. profession-based leadership	Statistically significant effects were demonstrated in care continuity and readmission rates within 180 days during the first year after implementing a mental health service line. A few continuity effects lasted 3 or more years, but most positive effects lasted only 1 year.
Grillo-Peck and Risner 1995[51]	Inpatient nursing work redesign	Pretest (January–June 1992) and post-test (January–June 1993) (6)	Design: Level 3 Patient outcomes: falls, medication errors, procedure errors, nosocomial infections (Level 2), length of stay	A neuroscience unit in an 800-bed not-for-profit hospital in Ohio, all patients under DRG 14 (cerebrovascular disease excluding transient ischemic attack): 71 patients pre-, 85 patients post; 56% female pre-, 55% post	Nursing partnership model (fewer RNs, more unlicensed assistive personnel)	The only statistically detectable differences related to fewer falls (X^2 = 4.77, $P \leq 0.05$).

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Heinemann 1996[52]	Inpatient nursing work redesign	Nonrandomized trial with the same variables measured at 3 points in time using different patients (6 months before the change, 6 and 12 months after the change) (3)	Design: Level 3 Patient outcomes: falls, medication errors, intravenous (IV) infections (Level 2), patient satisfaction	A 518-bed private, not-for-profit hospital in Florida, all patients on two randomly selected medical-surgical units; pilot unit had 36 beds for general surgery/ trauma patients (*M* patient days for a 6-month period = 5,477), control unit had 34-beds for orthopedic/trauma patients (*M* patient days for a 6-month period = 4,654).	Partners in patient care (PIPC)—experimental (pilot) unit; Total patient care—control unit.	Significant differences between the units were evident only when the ratio of events to patient days was examined: medication errors (*P* = 0.008) and falls (*P* = 0.037), but not for IV infections (*P* = 0.309). Patient satisfaction scores were higher on the pilot unit.
Neumeyer-Gromen 2004[23]	Models of care for patients with depression	Systematic review (11) and meta-analysis (1)	Design: Level 1 Patient outcomes: depression severity (Level 1), adherence to treatment regimen, (Level 2), patient satisfaction	Only randomized controlled trials published from 1992 to 2002; 10 studies met the inclusion criteria; patients had a mean age of 43 years, 71% were women, and about 70% were white, 75% were diagnosed with major depression	Disease management programs (DMP) to implement guideline-driven care	Relative risk (RR) for the effect of DMP on depression severity was 0.75 (95% confidence interval [CI] = 0.70–0.81, *P* < 0.00001). The study with an ongoing intervention over 2 years showed a significant advantage of DMP (RR = 0.44, 95% CI = 0.28–0.67). Adherence to medication for at least 90 days favored DMP (RR = 0.59, 95% CI = 0.46–0.75, *P* = 0.00001). The overall effect for patient satisfaction favored DMP (RR = 0.57, 95% CI=0.37–0.87, *P* = 0.009).

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Seago 1999[39]	Inpatient nursing work redesign	Cross-sectional, same variables measured at 3 points in time using different patients (6 months before the change, 6 and 12 months after the change) (4)	Design: Level 3 Patient outcomes: medication errors, falls, pressure ulcers, (Level 2), patient satisfaction	A large university teaching hospital with two campuses: patient days—30,462 at time 1, 29,584 at time 2, 29,210 at time 3	Change in care model from primary care to patient-focused care	A statistically significant decrease was found only for medication errors (0.97% before the change; 0.78% at 6 months, *P* = 0.016; 0.80% at 12 months, *P* = 0.027).
Tourangeau 1999[40]	Inpatient nursing work redesign	Nonrandomized trial with the same variables measured at 3 points in time using different patients (6–7 months before the change, 6 and 12 months after the change) (3)	Design: Level 3 Patient outcomes: IV therapy outcomes, falls, medication incidents, call bell usage	A 258-bed acute care community hospital in Toronto; all patients on three medical-surgical units; the experimental units had 57 beds (general medicine/surgery) and 70 beds (medicine/geriatric rehabilitation); the control unit had 38 beds (postcoronary)	Unlicensed assistive personnel (UAP)-RN partnership model on two experimental units; Total patient care with an all-RN staff on the control unit	Adverse IV outcomes decreased in all units; falls decreased initially on the experimental units and then increased; falls declined on the control unit at all measurement points; on all units, medication incidents increased from baseline to 6-months and then decreased below baseline; call bell usage declined dramatically at 6-months then increased to a rate similar to baseline.

Chapter 20. Leadership

Bonnie M. Jennings, Joanne Disch, Laura Senn

Background

Reports from the Institute of Medicine (IOM) have emphasized that leadership is essential to achieving goals related to quality care[1] and patient safety.[2] Leadership is expected from individuals at all levels of an organization, from the executive suite to those working directly with patients. Leadership is also expected regardless of where care is delivered—inpatient units, clinics, settings for ambulatory procedures, long-term care facilities, or in the home.

Because of the breadth and complexity of the literature on leadership, the authors narrowed the focus to leadership at two distinct levels of health care organizations. First, the literature on executive leadership was reviewed, with a particular focus on the relationship between the chief executive officer (CEO) and chief nurse officer (CNO), to examine leadership by individuals responsible for setting the organization's vision and direction related to quality of care and patient safety. Second, an exploration of the literature related to the leadership exerted by nurses and physicians as co-leaders of the patient care areas—that is, the type of leadership provided by co-leaders who are responsible for actualizing the vision and creating the local environment in which care is provided—was conducted.

A search of the relevant literature yielded little useful information on either of these leadership topics. Studies relating to the CNO or the individual in an equivalent position focused on hospital directors,[3] nursing home administrators,[4] CEOs and boards of directors,[5] and CNOs,[6–29] with no empirical evidence regarding the CEO-CNO relationship. Thus, the focus on the CNO shifted to reporting findings regarding the CNO's leadership style and its impact on the organization.

On the second level, that of nurse-physician co-leadership, there was a similar void in the literature. Thus, this chapter describes the very few studies that have examined nurse-physician co-leadership and reports findings from interventional studies on the broader context of nurse-physician collaboration and its impact on quality and safety of patient care. Collaboration is certainly a precursor to nurse-physician co-leadership.

Research Evidence

Executive Level

Only two investigations were found that linked CNO leadership to quality care and patient safety. A case study was done to examine the influence of the CNO in revitalizing the flagship hospital of a large, integrated health system.[7] Features of patient safety were among the outcomes evaluated at baseline, 18 months, and 36 months. Patient falls and nosocomial bloodstream infections declined over time from baseline; patient satisfaction with nursing care improved. The other investigation examined the relationship of both leadership and communication to quality care in 15 nursing homes from four States.[4] The nursing home administrators were invited to participate, but the findings did not reflect how many actually responded. Nonetheless, clinical staff (n = 656) provided important insights regarding what

promoted the best care possible. The top three responses regarding what facilitated good care and what interfered with providing good care were communication, staffing, and leadership. The study findings were not specific, however, as to whether the participants were addressing executive leadership.

Studies involving CNOs frequently examined leadership styles and behaviors. Transformational leadership captured the interest of several investigators.[11–13, 21, 23, 24] Although these studies were often framed to indicate a preference for a transformational style, the findings reflected that leadership is complex and multidimensional. CNOs typically used combinations of transformational, transactional, and laissez-faire leadership.[13, 21, 23] Moreover, four homogeneous leadership groupings were found among 84 CNOs based on combinations of high and low transformational and transactional behaviors.[11]

The need for a comprehensive assessment of leadership was put into perspective in a study involving a random sample of 477 CNOs who were members of the American Organization of Nurse Executives (AONE).[21] Both transformational and transactional leadership had a negative relationship with alienative (unfavorable) organizational commitment among registered nurses (RNs). However, transactional leadership demonstrated a stronger ($r = –0.31$; $P < 0.01$) association with alienative organizational commitment than transformational leadership ($r = –0.24$; $P < 0.05$).

Other styles of leadership were also assessed; however these findings could not be explicitly linked to CNOs. Rather, the investigators considered leadership from nurse administrators, allowing the possibility that participants may have reflected on leadership from nurse managers. Nevertheless, authoritarian leadership interfered with work empowerment.[20] Conversely, connective leadership—which was largely composed of the elements of transformational leadership—was predictive of empowerment.[18] A study involving 6,526 RNs from Canada illustrated the need to examine the full repertoire of leadership styles.[30] A heretofore unrecognized leadership style—resonant leadership—lessened the impact of restructuring.

Another approach to assessing CNO leadership was to compare how CNOs perceived their leadership with how various other individuals perceived the CNO leadership style. These studies, involving CNO direct reports,[11] the individuals to whom CNOs reported (usually the chief operating officer, COO),[13] nurse managers (NMs),[15, 19, 21] staff nurses,[21] and influential colleagues,[14, 17] further verified the complexities of leadership. For example, although there were discrepancies between CNOs and their direct reports regarding how often CNOs used transformational leadership, the direct reports were more satisfied with the CNO leadership style than the CNOs expected.[13] Based on data from the same study, however, no differences in ratings of work group effectiveness were found, among the three groups (CNOs, direct reports, CNO supervisors).

NMs (n = 87) who agreed with their CNOs' (n= 22) leadership style were more likely to be satisfied with their jobs.[15] In another study conducted in a 700-bed acute care setting during an organizational transition, a rating scale and interviews were used to identify the executive behaviors that were most important to NMs.[19] Although it was not clear whether CNOs per se were considered, communication and high visibility on work units were the top 2 of the 10 most desired behaviors.

A study of nurse leadership in four hospitals—two with Magnet status and two without Magnet status—found that leadership affected staff nurse job satisfaction.[25] Based on survey responses from 305 staff nurses and interviews with 16 nurse leaders, some of whom were CNOs, the investigator concluded that staff nurses were more satisfied when nurse leaders were

visible and responsive, when they supported autonomous decisionmaking, and when there was adequate staffing.

Another group of studies examined skills essential to being a successful CNO, especially given how the role is changing.[8, 10, 17, 27, 28] For example, in a study conducted in one U.S. city involving CNOs and female leaders in other fields, six categories of essential leadership skills were identified: (a) personal integrity, (b) strategic vision/action orientation, (c) team building/communication, (d) management and technical competence, (e) people skills, and (f) personal survival skills.[10] A Delphi study conducted in 22 European countries identified 16 relevant CNO qualities.[17] Communication ranked first, followed by teamwork, leadership, strategic thinking, political astuteness, professional credibility, integrity, personal qualities, innovation, decisionmaking, promotion of nursing, research skills, physical characteristics, information handling, good management, and conflict resolution. The rankings from a European study differed from rankings derived from a U.S. study in which clinical knowledge ranked first of 14 items, communication ranked eighth, and teamwork was not in the rankings.[8] Attributes of successful nurse leadership in acute care settings were compared between 16 leaders at Magnet (n = 7) and non-Magnet hospitals (n = 9).[27, 28]

Additionally, researchers have found that organizational characteristics such as culture and size may alter the expression of leadership.[13, 27] Gender is another factor that has been assessed regarding CNO leadership. In one study, gender was deemed irrelevant because of the effective way in which the hospital leadership teams interacted.[27]

A final set of studies concerning CNOs provided evidence using qualitative methods.[6, 9, 16, 24, 26, 29] Some of these studies were conducted to delineate key executive leadership characteristics.[24, 26] For example, based on interviews with 10 CNOs, key characteristics included knowing how to use power; being visible; having a vision for the organization; motivating staff; empowering staff; and being open, honest, and personable.[24] Similarly, 16 nurse leaders—some of whom were CNOs—from four acute care hospitals were interviewed to identify effective leadership traits.[26] The categories that emerged were (a) core principles and value system guiding leadership (e.g., leading to serve, striving for excellence, a passion for nursing); (b) use of quantitative data to influence decisionmaking; and (c) collaborative teamwork among patient care staff to provide excellent care, and among management to support one another and staff. Findings from other qualitative investigations included a serendipitous finding about obstacles CNOs face in all aspects of their work;[9] determining CNO leadership behaviors across three hierarchical domains of leadership: strategic, organizational (administrative management), and production (creating goods and services);[16] how the merger of business (managed care) and medicine widened the gender gap in health care leadership;[6] and thought processes used by expert CNOs in making decisions.[29]

Nurse-Physician Co-Leaders

While there is a growing body of research described later in this chapter on the impact of collaboration between nurses and physicians who are caregivers,[31–45] there is a notable absence of research on the impact of a collaborative relationship between the nurse and physician co-leaders of patient care units. Presented in this section is a brief history of the concept of partnered leadership and a description of the one study found on this specific type of nurse-physician relationship.

The importance of a focus on collaboration and partnered leadership between nurse and physician is not a new concept, but rather one that has been in the literature for more than 25

years. In 1981, the National Commission on Nursing urged trustees and administrators to "promote and support complementary practice between nurses and physicians" and to "examine organizational structure to ensure that nurse administrators are part of the policymaking bodies of the institution and have authority to collaborate on an equal footing with the medical leaders in the institution"[46] (p. 62). Similarly, the Joint Commission (formerly the Joint Commission on Accreditation of Healthcare Organizations, JCAHO) required that activities of critical care units be guided by a multidisciplinary approach, including nursing and medical input.[47] Shortly thereafter, the American Association of Critical Care Nurses and the Society of Critical Care Medicine jointly developed a position statement outlining 10 principles for optimizing resources in critical care units. While all of the principles reflect a commitment to medical and nursing co-leaders, the following two are particularly relevant[48] (p. 43).

- #1—Responsibility and accountability for effective functioning of a critical care unit must be vested in physician and nurse directors who are on an equal decisionmaking level.
- #10—Close collaboration between the directors is essential for successful management.

More recently, Gilmore[49] has advanced the concept of *productive pairs*. He noted that as organizations become increasingly complex with rapid change, leaders are less able to possess all of the knowledge and expertise needed. Thus, a model of leadership that is based on a partnership between two individuals who share common goals and come from different, yet complementary, disciplines could be very effective.

Productive pairs possess several characteristics: separate, yet complementary, bodies of knowledge; understanding and valuing each other's areas of expertise; enough time or history together to explore the interdependencies; trust of one another that enables direct, frank exploration of issues; a commitment to the partnership and avoidance of efforts at triangulation; and a shared passion for a common goal or vision.

One study that specifically examined how physician leaders and nurse administrators worked together was by Tjosvold and MacPherson.[50] Physician and nursing administrator pairs were interviewed on how they worked together in managing areas within the hospital. Incidents they used to describe their relationship were coded as cooperative, competitive, or independent, and then related to outcomes.

Incidents in which goals were cooperative were ones in which physicians and nurse administrators discussed their issues constructively, had positive effect, strengthened their relationship, made progress on the task, promoted the organization's effectiveness, developed confidence in future work, and fostered quality care. Incidents in which goals were competitive were negatively related to productive interaction and outcomes. When the partners felt competitive, they were unable to exchange ideas openly, initiatives did not progress, and the relationship and quality of care were compromised. Constructive controversy (open-minded discussion, occurring within a strong cooperative context, or various perspectives that allow disagreement and exploration in a respectful manner) enabled the pairs to discuss their views productively and resulted in constructive outcomes. On the other hand, when constructive controversy occurred in a competitive context, problems ensued, such as resistance, a close-minded discussion of ideas, and an impaired working relationship.

Nurse-Physician Collaboration

As a backdrop for considering collaboration between nurse and physician leaders of the team, we examined the research on collaborative relationships between nurses and physicians.

Collaboration is the "process of joint decision making among independent parties involving joint ownership of decisions and collective responsibility for outcomes. The essence of collaboration involves working across professional boundaries"[31] (p. 186). Assumptions have been advanced that greater collaboration between nurses and physicians results in improved quality of patient care.

One of the first, and most often cited, studies on collaboration was conducted by Knaus, Draper, Wagner, and Zimmerman in 1986.[32] These researchers analyzed patient outcomes in 13 intensive care units (ICUs) and found a significant relationship between the presence of excellent interaction and coordination of care among nurses and physicians and improved patient outcomes. In subsequent work, Shortell, Zimmerman, and Rousseau [38] looked at communication and coordination in 42 ICUs, but they were unable to differentiate ICUs according to risk-adjusted survival. However, these researchers noted that communication and coordination helped decrease length of stay.

Baggs and others[34, 35] investigated the perceptions of physician-nurse collaboration and either negative outcomes (e.g., death or readmission to the ICU) or the transfer of patients from the ICU to an area of less intensive care. In the first study of one ICU,[34] these researchers found that the more collaboration nurses reported, the lower the risk of a negative patient outcome. In the second study in three different types of ICUs,[35] reports of collaboration by nurses in the medical ICU correlated significantly with patient outcomes: When the nurse reported full collaboration, the patient's risk of negative outcome was 3 percent; when the nurse reported no collaboration, the patient's risk increased to almost 14 percent. These findings were not observed in the surgical ICU or the community hospital ICU. Interestingly, in both of the studies, the reports of collaboration by attending physicians and residents were not associated with patient outcomes in any site. Differences in perceptions about collaboration have been found by other researchers as well, with physicians consistently perceiving higher levels of collaboration than nurses.[33, 40, 43] A study by Hojat and colleagues[39] in Mexico, however, found the opposite.

Evidence-Based Practice Implications

Executive Level

It is very difficult to link leadership to patient safety because the evidence pool is quite limited. Across studies of CNO leadership, weak designs prevail and the specific topics studied are very diffuse. As a result, it is difficult to make statements to guide practice.

A modest body of evidence is accruing about leadership styles. These studies illustrate that multiple styles of leadership may be operationalized concurrently. Evidence related to transformational leadership suggests that researchers need to consider multiple types of leadership and how the types work together, helping to limit bias created by studying only transformational leadership—or advocating for transformational leadership as a superior style. The evidence simply does not support that view.

Nurse-Physician Collaboration

On behalf of the Cochrane Collaboration, Zwarenstein and Bryant[51] completed an international review on collaboration and found several hundred studies on the topic. After examining the abstracts, these colleagues reviewed the full text of 31 studies and found three studies that were "methodologically adequate and evaluated relevant interventions"[51] (p. 4), although one study eventually had to be excluded because it was difficult to sort out the impact of combined interventions.[52] The first retained study by Curley and colleagues[53] used a randomized, controlled method to examine the impact of interdisciplinary rounds on aspects of inpatient care. These researchers found a shorter length of stay (5.46 vs. 6.06 days) and lower total charges ($6,681 vs. $8,090) for patients receiving care from the interdisciplinary team.

The second retained study at a Thai academic hospital[54] compared average lengths of stay for females in a control ward with those for females in a second ward in which frequent rounding and weekly team case conferences occurred. There were no significant differences found, although patients in the interventional ward had shorter lengths of stay, when patients who died while in the hospital were excluded. These studies are reported in Evidence Table 2.

The inclusion criteria for the Cochrane Collaboration report were very restrictive and the results do not provide health care leadership with enough relevant information to guide quality improvement projects. However, a recent critical review[55] was completed that incorporated a wider range of methodological designs to help illuminate findings from experimental research on the impact of nurse and physician collaboration on quality and safety of patient care.

The review was limited to outcome-based experimental studies completed in the United States that focused on the acute care setting and nurse-physician collaboration. Seventeen studies met the inclusion criteria,[31, 37, 53, 56–69] and the findings from this review demonstrated that outcomes could be grouped into three categories: professional outcomes, organizational outcomes, and patient outcomes.

Professional outcomes were measured in several different ways, but the most frequent evaluation was in communication skills. Other areas measured were teamwork, leadership, job satisfaction, and collaboration. Organizational outcomes were very straightforward and consisted of only three major types: length of stay (LOS), readmission rates, and hospital costs. Eight of the studies that were reviewed focused on patient outcomes. Patient care outcomes ranged from anxiety, depression, and pain to functional status, length of time on a ventilator, and diabetes management. Usually the data collected were from medical records and interviews with patients or their proxies and could be considered reasonably reliable.

The types of interventions used to improve collaboration had four basic threads: interdisciplinary rounding, development of protocols, staff education of patient care guidelines, and easier access to information at the patient's bedside. These threads are closely related to the attributes of collaboration: people working together, cooperation, sharing responsibility in decisionmaking, communication, and coordination of care.

The studies that surveyed health care providers' perceptions used a little broader spectrum of interventions. Similarities were in the use of patient rounds, patient care guidelines, and increased access to patient information. But these studies employed other interventions that included such things as establishing contacts with key stakeholders to discuss roles and responsibilities, appointing more physician helpers (NPs), appointing medical directors, providing classes on the processes of communication and teamwork, and restructuring of the organization to decentralize professionals. One study,[61] which identified nine significant

findings, employed a high-quality, randomized controlled design that used five interventions to achieve its results: (1) daily review by medical director of medications and procedures; (2) daily rounds by multidisciplinary teams; (3) daily assessments by nurses; (4) protocols to improve patients' self-care; and (5) early, ongoing emphasis on returning home. The design and interventions of this complex study were well thought out, and the study subsequently demonstrated significantly improved patient outcomes in very elderly (older than 70 years), frail patients, as well as improvement in organizational outcomes. Details of the 17 studies are in Evidence Tables 2 and 3.

It is apparent that there is a dearth of methodologically sound studies on nurse-physician collaboration. While nurses and physicians universally acknowledge the importance of collaboration, we actually know very little about what it is, how it works, and whether it makes a difference. Furthermore, we have some evidence to suggest that nurses and physicians define collaboration differently and use different criteria to assess whether it's present.[33, 40] To a large extent, this is because collaboration is part of a complex set of related concepts, often defined and operationalized very differently, e.g., as teamwork,[36, 70, 71] collegiality,[45, 72] communication,[73–75] trust,[31, 76] and coordination.[32, 38]

Additional challenges to establishing a strong evidence base include the following:

- Current studies focused on only one of several possible interconnecting factors. Without adequate theoretical frameworks or sophisticated methodology, it is difficult to sort out the contributions of individual factors in a complex situation.
- Studies typically focused on interventions within one or a few patient care areas, and usually within one institution.
- Outcomes measured tended to be objective and easily quantifiable, such as length of stay,[53] cost,[53] mortality,[32, 34, 35, 38, 57] or readmission rates,[34, 35] which are certainly important. However, we also need more studies on some of the more qualitative outcomes, such as patient satisfaction and morbidity, staff morale and retention, and patient safety.

Findings indicated only one study that specifically targets the physician and nurse as co-leaders,[50] and this was a correlational study in British Columbia. A second study, by Boyle and Kochinda,[74] implemented a collaborative communication intervention to ICU nursing and physician leaders, along with several other identified leaders such as the clinical nurse specialist, in two diverse ICUs, using a pretest–post-test, repeated measures design. The intervention included a series of educational and experiential modules, yielding improved communication skills, leader satisfaction, and perceived problem-solving ability. Though this study included nursing and physician leaders, several other individuals were included in the intervention and did not target or emphasize the special role of the clinical co-leaders.

Why are there so few studies examining the relationships between and impact of co-leaders in health care, given the extensive emphasis on leadership in health care today? Dougherty and Larson[77] noted that most research done on collaboration was conducted by nurses, and thus, the idea of examining aspects of a partnership wasn't equally valued. Fagin[78] noted that physicians are not interested in interprofessional relationships in general, and that health professions' curricula do not include sufficient content in this area, although thoughts are changing as the result of a number of national initiatives to promote interprofessional education and common competencies.[79–82] Two other factors that contribute to this gap are that (1) the role of medical director as co-leader of a clinical area is not a widespread phenomenon and, if in place, is usually seen in ICUs, emergency rooms, and other specialty areas; and (2) funding by the National

Institutes of Health and other major funding agencies follows the biomedical model of health care research.

What We Do Not Know—Research Implications

Executive Level

Although there is a strong belief that executive leadership is essential to underpin patient safety, it is difficult to support that idea from an empirical base. The strongest statement that can be made based on empirical studies is that it is unwise to view transformational leadership as a preferred style, particularly when this style is assessed independent of other leadership styles and organizational variables. We actually know very little about leadership—what works, what does not, and leadership style impact on patients, staff, and the organization. Ironically, although leadership is a topic of tremendous interest, little empirical evidence exists.

Nurse-Physician Collaboration

While the impact of collaboration between nurses and physicians has been studied, we have scant strong, empirical evidence that collaboration makes a difference. What is needed are consistent definitions of the concept, use of tools with appropriate psychometric properties to measure the concepts, interventional studies, and sampling from more than one or a few organizations.

There is much work to be done, and there are a number of helpful resources for getting started. The recent work of Gene Nelson, Paul Batalden, and their colleagues[83–85] at Dartmouth and elsewhere on clinical microsystems provides a framework for examining the role of leadership in the patient care area. Ingersoll and Schmitt[86] wrote a comprehensive review of the literature on work groups and patient safety that highlights teamwork, collaboration, communication, and other relevant concepts. Dougherty and Larson[77] recently reviewed the scope, psychometrics, and use of five instruments that have been used to measure nurse-physician collaboration; while the instruments differ significantly from each other, the authors concluded that they offer a good starting place for aiding future research.

A final comment and return to an original point: In addition to research needed on nurse-physician collaboration, significant attention must be paid to examining the experience and impact of nurses and physicians functioning as co-leaders of clinical areas. What are the factors that enhance their ability to model collaboration and co-create healthy work environments that benefit patients, families, and all members of the health care team? What are the barriers? What are individual, institutional, and societal strategies that can be implemented to a healing environment for patients, families, and all caregivers?

Acknowledgments

Tremendous gratitude is expressed to the staff of the Armed Forces Medical Library for their considerable support of this work. They conducted the database searches and assisted in acquiring numerous papers considered in the review of leadership at the executive level.

Evidence Table 1. Findings on Impact of CNO Leadership Style

Source	Safety Issue Related to Clinical Practice	DesignType	Study Design, Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Dunham-Taylor 2000[13]	Leadership	Cross-sectional (4)	Design: Level 3. Outcomes: CNO leadership style, work group effectiveness.	National study from all States; 396 CNOs, at least 3 direct reports for each CNO (N = 1,115), CNO's boss (N = 360); most CNOs were married (77%) females ((93%) in their 40s (54%) with a master's degree (61%). On average, they had 24 years experience in nursing and 9 years in executive positions. Direct reports and boss characteristics were not described except to note that most bosses were COOs.	Comparing scores on leadership styles, workgroup effectiveness.	There was a significant difference in how CNOs rated themselves and the ratings from their direct reports for transformational, transactional, and laissez-faire leadership. No statistically significant differences were found among CNOs, their direct reports, and CNO bosses in regard to work group effectiveness. Staff were more satisfied with the CNO leadership style than the CNO expected. Organizational characteristics played a role with more transformational CNOs in organizations that were participative.

Source	Safety Issue Related to Clinical Practice	DesignType	Study Design, Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Leach 2005[21]	Leadership	Cross-sectional (4)	Design: Level 3. Outcomes: Organizational commitment which was assessed according to 3 types-moral (normative, internalized identification), calculative (remunerative or compliance), and alienative (negative resistance).	A national random sample of CNO AONE members working in hospitals and a convenience sample of NM (n = 148) who reported to the CNO and 651 staff nurses who reported to a participating NM. CNOs from 35 States returned 102 usable surveys. All but one CNO were women. They had more than 15 years experience in nursing, and 70% had more than 15 years experience in management. Almost 80% had master's degrees. NMs were mostly women (95%). Most had been in nursing for more than 15 years (75%), most had more than 15 years experience in management, and 40% held a master's degree or higher. The staff nurses were mostly women (64%), and most had 11 or more years experience in nursing (62%). Almost 40% had a BSN.	Leadership and nurses' organizational commitment.	CNOs and NMs had a leadership profile that illustrated elements of both transformational and transactional leadership. Both styles of leadership showed a negative and statistically significant relationship with alienative organizational commitment. Both leadership styles were positively and statistically significantly for CNOs and NMs. No relationship was found between NM and staff nurse organizational commitment.

Evidence Table 2. Cochrane Collaborative Results: Randomized Controlled Trial Focused on Increasing Collaboration between Nurses and Physicians

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Curley 1998[53]	Collaboration	Randomized controlled trial–6 month prospective trial, with patients randomly admitted to different doctor groups (Firms).	Variables measured were length of stay (LOS), hospital charges, provider satisfaction, ancillary service efficiency, readmission rates, and quality of patient care. Using hospital billing system, medical records, and surveys.	Medical unit inpatients at large county hospital affiliated with university; used a 30-bed nursing unit; each firm had 25 attending physicians and 25–30 residents. 1,102- total number of patients: 535 in control group 567 in intervention group	Interdisciplinary rounds—MDs, RN (patient care coordinator), pharmacist, nutritionist, and social worker daily rounding; orders written during rounds; chart taken with MD on rounds.	Significant increase in provider satisfaction and perceived collaboration in the areas of understanding patient's plan of care, communication, and teamwork. Some decreases in LOS, readmission rates, and hospital costs.

Evidence Table 3. Outcome-Based, Experimental Studies Focused on Increasing Collaboration between Nurses and Physicians

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Inouye 1993[56]	Nurse-physician collaboration	Prospective cohort study with stratified and matched cohort analysis; not randomized.	Variables measured were functional decline—overall; functional decline—matched cohort analysis; using interviews; self reported activities of daily living (ADLs); mini-mental exam; confusion assessment; physical exam; and medical records for risk assessment.	Medicine units. Huge differences in baseline data. Required matched cohorts to further analyze data. 216 total 85 intervention 43 RN/MD group 42 RNonly group 131 control 66 matched cohorts	Identification and surveillance of frail older people. Twice weekly rounds of the geriatric care team. Nursing-centered educational program.	Improvement in functional decline significant only after using matched-cohort analysis.
Gallager 1998[57]	Nurse-physician collaboration	Retrospective and prospective study, convenience sample, repeated measures done quarterly; for 11-month period.	Variables measured were frequency of blood glucose monitoring; nutrition assessment; insulin management; change to glucose intolerance enteral formula as recommended by protocol; using medical records review.	All tube-fed patients admitted to a 16-bed ICU, community hospital; 65 eligible 35 participants who met criteria.	Interdisciplinary collaboration in study design, organization, and implementation of a performance improvement initiative using the Plan/Do/Check/Act process: a group formed; critical blood glucose levels defined; interventions defined.	Improvement in BG monitoring, nutrition assessment, insulin management, and hyperglycemia control.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Lassen 1997[58]	Nurse-physician collaboration	Design – retrospective and prospective comparisons of patient charts 1 year prior to intervention, right after intervention, and then 1 year after intervention, for a 3-month period of time during each interval.	Variables measured were quality of patient care; costs; length of stay (LOS), number of antibiotics received, and readmissions rates. Using medical records review.	350-bed tertiary hospital. All children admitted with sepsis during study period.	Protocol development for management of rule-out sepsis – Education of RNs and MDs in the nursery for 3 months.	Decrease in patient anxiety and confusion; significant decrease in cost and LOS, and mixed results in readmission rates.
Jordan-Marsh 2004[59]	Nurse-physician collaboration	Pre- and post-intervention data collection, total 14 quarters; 2–8 were implementation, 9–13 were maintenance.	Variables measured were documentation of pain; evaluation of effectiveness; improved pain management measured as doses of analgesia; improved pain management measured by analgesia type. Using chart audit (10% of charts each month), pharmacy records of drugs dispensed to ward, and census.	Patients on a pediatric ward in large urban hospital. Between 715 and 840 patient days per quarter.	Multifocal approach for QI-Referral book; resident experts; flow sheet; classes, policy, and protocol; rounds weekly; interdisciplinary plans; change nurses' scope of practice to include giving morphine IV; agenda item for P&T Comm; etc.	Decreased reports of pain by patients; increased evaluation of effectiveness; and improvement of pain management.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Kollef 1997[60]	Nurse-physician collaboration	Randomized controlled trial during a 4-month period; stratification according to ICU site.	Variables measured were duration on mechanical ventilation; need for reintubation; LOS; hospital mortality rate; and cost. Using medical records review.	In medical ICU and surgical ICU in 2 teaching hospitals; 4 units total. 377 total 179 intervention group (protocol directed) 178 control group (physician directed)	Protocol-directed weaning from mechanical ventilation developed by medical director; education of nursing and respiratory staff before implementation.	Significant decrease in duration on mechanical ventilation; decreased costs and LOS; and mixed results with readmission rates.
Landefeld, 1995[61]	Nurse-physician collaboration	Randomized control trial – randomly assigned to acute care program for elderly or usual care.	17 different measures looking at ability to perform ADLs – using different time frames, controlling for risk factors; plus LOS and costs. Using interviews, medical records and Universal Bill (1982).	>70 yr, admitted to general medical unit 651 total 327 intervention group 324 control group	Daily review by medical director of meds and procedures; daily rounds by multidisciplinary team, daily assessments by nurses; protocols to improve self-care; early, ongoing emphasis on returning to home.	Numerous quality of patient care outcomes were significant; also found a decrease in cost and LOS, and a mixture of results for readmission rates.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Henneman. 2001[37]	Nurse-physician collaboration	Pre- and post-quasi-experimental; compare patient outcomes 1 year before and 1 year after intervention.	Variables measured were length of time of mechanical ventilation; length of time in the ICU; cost and complications. Using Medical records; mortality rates, readmission rates to any ICU; staffing patterns, years of experience of nursing and respiratory therapy staff, and management choices.	8-bed medical ICU; no differences between control and experimental groups 207 total 77 control group 124 intervention group	Multidisciplinary rounds every morning; assessment data and progress available in medical record (both groups); assessment data and weaning progress flow sheet on board and flow sheet at patient's bedside (for intervention group only).	Significant decrease in length of time on ventilator; significant decrease in LOS; some decrease in hospital costs; and mixed results for readmission rates.
Vazirani 2005[62]	Nurse-physician collaboration	Quasi-experimental; 1 control and 1 intervention unit; over a 2-year period.	Variables measured were collaboration with MDs; NPs, RNs; communication; LOS; cost and readmission rates. Using surveys of nurses (biannually); attending MD (every 2 weeks), and residents (every month).	2 acute care inpatient medical units; no crossover between units with MDs or RNs; staffing and demographics of patients and nurses same between units. House staff – 111 (58%) Attending physicians – 45 (69%) Nurses – 123 (91%)	Appointment of an NP; appointment of hospitalist medical director; institution of daily multidisciplinary rounds–lasted 15 minutes per team.	Significant increase in perceived collaboration. (RNs had better communication only with NPs; MDs had better communication with fellow MDs and NPs, and increased collaboration amongst themselves.) Some decrease in LOS and hospital costs; and mixed results for readmission rates.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Trey 1996[63]	Nurse-physician collaboration	Descriptive, retrospective	Variable measured was clarity of roles. Using nurse manager's report.	Ambulatory care center of a large teaching hospital. Nurses, surgeons and anesthesia staff; no size given	Clarification, discussion, and resolution of ambiguous roles. Job descriptions of nurse manager and medical director were written and implemented.	Nurse manager reported that intervention helped nurses identify MD and RN responsibilities.
Dechairo-Marino 2001[64]	Nurse-physician collaboration	Pre- and post-test, intervention study – convenience sample. Surveyed at baseline and 1 month prior and 3 months after completion of interventions.	Variables measured were perceived collaboration scores and satisfaction with decisionmaking. Using Bagg's Collaboration and Satisfaction about Care Decisions questionnaire (adapted version).	RNs working on 3 medical-surgical units and 2 ICUs; 87 pretest 65 post-test; approx 50% response rate: 60% attendance rate for intervention.	Activities – developed the Operating obtained endorsement; incorporated principles into unit activities; offered 4 hour, one session class re: concepts.	Significant increase in perceived level of collaboration and the nurses' satisfaction with decisionmaking process.
Boyle 2004[65]	Nurse-physician collaboration	Quasi-experimental, prospective, intervention study. Intervention group – Pretest–post-test, followup immediately after intervention. Control group (unit staff) – F/U pretest and 6 months after intervention to explore penetration.	Variables measured were communication skills and leadership skills; situational stress and personal stress. Using collaboration skill simulation vignettes, ICU nurse-physician questionnaire, and ICU outcomes.	2 ICU units used; both had same leadership, staffing levels, and technology. Unit A = 4 beds with only 11 diagnoses; 9 nurses; 3 MDs. Unit B = 22 beds with 162 diagnoses; 38 nurses; 14 MDs. 10 leaders for both units.	6 modules on Interaction Process – 23.5 hours using adult learning methods; 2 4-hr sessions over 8 months. Participants also received coaching and reinforcement between sessions.	Significant improvements in communication skills and leadership skills and leadership characteristics exhibited; significant improvement in professional satisfaction in relationship to personal stress and situational stress; mixed results with all other parameters measured.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Wyly 1996[66]	Nurse-physician collaboration	Descriptive study of quality improvement project.	Variables measured were satisfaction with workshop and staff's plan to use elements in their work. Using surveys.	600 staff nurses	2-day training workshop, creating a learning climate that facilitates participation. Focused on Interdisciplinary teams; high-risk infant and family interventions in the neonatal ICU and through transition to community.	High satisfaction with workshop and high level of intent to use elements in their work.
Foley 1997[67]	Nurse-physician collaboration	Pre- and post-test; control and intervention groups; tested 2 months after intervention; convenience sample;	Variables measured were communication skills with physicians and interactions with patients. Using Nurse-Physician-Patient Interaction/Communication Survey and demographics.	Control group from 2 units, intervention group from another unit 66 total 28 intervention group 38 control group	Nurses engage in 2 different 15-minute videotaped case scenarios using standardized patients and standardized physicians, 1 week apart; rate themselves on a "Performance Assessment Checklist."	No significant results in nurses' communication skills with patients and physicians.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Narasimhan 2006[68]	Nurse-physician collaboration	Prospective, quasi-experimental, with testing at baseline, 1 week, 6 weeks, 9 months after implementation of intervention.	Variables measured were staff's level of understanding goals for the day; communication; desire to continue to use worksheet; and belief the worksheet had a positive effect on patient outcomes. Using surveys.	16-bed medical ICU, closed unit RNs – baseline – 21 6 wk – 14 9 mo – 18 MDs – baseline – 12 6 wk – 14 9 mo – 17 Response rate not given.	Daily goals worksheet that included consents, tests, medications, sedation, analgesia catheters, consults, nutrition, mobilization, family discussions, and dispositions (not part of the Medical Record).	Increased perception of collaboration (i.e., understanding patient goals and communication process) for both RNs and MDs.
Lorenzi 1993[69]	Nurse-physician collaboration	Single group pre- and post-test design, repeated measures at baseline, 3 months, and 6 months.	Variables measured were job satisfaction; level of nurse-physician collaboration; broad knowledge base of sickle-cell; and demographics variable (years of experience and present employment status). Using knowledge-based test, job satisfaction tool, and surveys.	42 eligible 18 participants 40% response rate	Education program for nurses; 10 hours of sickle-cell disease process, treatment, interventions, and relaxation techniques; Implementation of a comprehensive guideline for the care of sickle-sell patients.	Significant improvement in collaboration with MDs, and an increase in job satisfaction for RNs. Demographic variables were significant for years of experience and present employment status.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Liedtka 1998[31]	Nurse-physician collaboration	Postintervention survey.	Variables measured were differences and similarities of nurses', physicians', and administrators' perceptions of factors correlated with successful collaboration. Using questionnaires and interviews.	Large, academic health center, 3 service lines, and 3 professions surveyed 346 eligible 124 participants 36% response rate	Organization restructure to service lines; Implementation of a new organizational structure that has nonnursing professionals report to unit managers instead of central department.	Increased perception of factors that are correlated with successful collaboration in RNs, MDs, and administrators.

Chapter 20a. [Vignette] Transforming Health Care for Patient Safety: Nurses' Moral Imperative To Lead

Diana J. Mason

Background

On July 16 and 17, 2004, the *American Journal of Nursing*, University of Pennsylvania School of Nursing, Hospital at the University of Pennsylvania, and Infusion Nurses Society held an invitational State of the Science Symposium on Safer Medication Administration in Philadelphia. Funded by a small conference grant from the Agency for Healthcare Research and Quality (AHRQ grant no. 1 R13 HS14836-01) and educational grants from industry, the meeting brought together diverse health care professionals and groups —nurse clinicians, educators, administrators, and researchers; pharmacists; physicians; industry representatives; consumers; and professional organizations—to examine the current research on safe medication administration, barriers to improving the integration of this research into practice, and recommendations for overcoming these barriers.

Research Priorities and Barriers

The participants identified the following research priorities[1] (p. 8–9):

1. How do safety climate, error reporting, and root-cause analysis affect patient safety, quality of care, and both patient and clinician satisfaction?
2. How can individuals and organizations integrate and sustain best practices to detect, reduce or eliminate, and mitigate the errors that occur?
3. What patient-centered approaches result in medication error reduction in ambulatory and long-term care settings?
4. How do current practices and near misses make medication administration safer?
5. What is the impact of safer medication administration practices on health care costs and patient outcomes?

The participants identified the following barriers to safer medication administration[1] (p. 6–7):

1. There is a lack of a "just culture of safety" in many health care facilities.
2. There is a lack of interdisciplinary collaboration and communication.
3. Nurses' work environments do not support safety.
4. Voices of frontline nurses are missing in decisionmaking and systems design related to medication safety.
5. There are difficulties in translating research into practice.
6. Policies to effect medication safety are not driven by evidence.
7. There is insufficient funding for research on medication safety.

Note that the use of technology to reduce medication errors—or the lack of such technology—is not specified as a research priority or as a barrier to improving care. This may seem curious since health care systems are lagging behind other industries in the development and use of technology for reducing error, but its absence highlights other concerns. For example, while it is often assumed that technology will help only to reduce errors, there is evidence that it

sometimes introduces errors, often because of factors such as inadequate training of the users of the technology and poor communication.[2–4] At a national nursing conference in 2003, some of the companies that make bar-coding technology and advanced intravenous pumps (referred to as "smart pumps" because of their ability to track and report data about their use) noted that nurses often develop work-arounds when they believe that the technology is not efficient. For example, one company representative said that some nurses using his company's bar-coding technology would print out a list of all of the unit's patients with their bar-codes, then swipe these bar-codes—instead of the one on the patient's wristband—against the medication bar-codes, clearly defeating the purpose of the bar-coding technology. In the nurses' eyes, they were making more efficient a process that they viewed as cumbersome and time consuming.

Technology's absence from the research priorities and barriers also reflects the pressing reality of working nurses: too many work in environments that give lip service to patient safety, but seldom recognize that nurses are the key to quality and safety. Technology alone will not make patients safer. We must focus on decisionmaking and communication if patients are to be safer.

Defining "Error"

While companies work on developing cutting-edge technologies and health care facilities focus on root-cause analyses and systems of care, Cook and colleagues[5] found that health care workers don't even agree upon what constitutes an error.[*] In the landmark report, *To Err Is Human: Building a Safer Health System,* error is defined as a "failure of a planned action to be completed as intended or the use of a wrong plan to achieve an aim"[6] (p. 3). But Cook and colleagues found that nurses, physicians, pharmacists, and administrators don't all embrace this definition. Their findings suggested that the staff may "fail to appreciate complex, less easily categorized" errors. Indeed, many reported that they were reluctant to identify diagnosis and treatment errors as such. In fact, one glaring theme of this research was that nurses' actions can lead to errors, but physicians make "practice variances." These "practice variances" were also referred to as "suboptimal outcomes" or "differences in clinical judgment," not errors. Some of the practice variances or suboptimal outcomes included

- Delays in treatment
- Use of outmoded treatments
- Failure to employ necessary diagnostic tests
- Failure to act on the results of tests
- Errors in administration of treatment
- Failure to communicate with staff and patients

Note that this variance in the definition of error occurred despite respondents reporting that their facilities were genuinely concerned about safety (90 percent of all respondents) and didn't punish people who reported safety discrepancies (94 percent).

Assigning Responsibility for Patient Safety

One conclusion that can be drawn from the study is that nurses are viewed as having the responsibility, but not the authority, for ensuring patient safety. In a prior study, Cook and Hoas[7]

[*] While this was a multimethod study conducted in rural hospitals, reviewers of the paper noted that the findings were consistent with what existed in their regions of the country that were urban and suburban.

found that only 8 percent of physicians viewed nurses as key members of the decisionmaking team in their institutions. And in their 2004 study, Cook and colleagues[5] reported that 96 percent of nurses and more than 90 percent of all others viewed nursing as having primary responsibility for patient safety. How can nurses be responsible for patient safety if they don't feel safe in challenging a physician's order?

Cook and colleagues[5] found that nurses were reluctant to discuss physician "practice variances" or errors with them because of nurses' perceived lack of authority to question the physician, a desire to maintain collegial relationships with physicians, prior experience with being rebuffed by a physician when the nurse questioned a medical practice, and a lack of support from administration when nurses do question or challenge physician practice.

The administrators' views of the situation supported the nurses' perceptions. Administrators believed that administrators had a limited role in questioning medical practice because of their own lack of clinical expertise. "According to many administrators, the responsibility for determining that an error has occurred rests with the physician"[5] (p. 36, 39). And pharmacists concurred that, while they were confident in their ability to recognize errors, they acknowledged that "differences among the four professions concerning definitions of error and scope of practice limit their ability to record problems as errors or initiate procedural changes"[5] (p. 39).

The participants in the study by Cook and colleagues[5] acknowledged that a lack of consensus about what constitutes an error leads to an underreporting of errors. As one nurse participant noted, "The physician told me it's not an error, so we don't need to file an incident report"[5] (p. 40), illustrating the relationship between agreed-upon definitions of error and the willingness to document, correct, or prevent errors. How can safe systems of care be developed to avoid more complex errors involving diagnosis and treatment if physicians define such mistakes as "practice variances" rather than errors, and others are not willing to correct this misconception?

Communication

Interdisciplinary communication is crucial to patient safety. In 1986, Knaus and colleagues[8] reported in the *Annals of Internal Medicine* that nurse-physician communication was the single most important predictor of mortality rates in 13 intensive care units in academic medical centers. But the study did little to prompt a concerted effort to improve such communications. Rosenstein and O'Daniel[9] reported on a convenience survey of 1,500 VHA[†] nurses and physicians. The survey found that 75 percent of respondents had witnessed "disruptive behavior" by physicians, and 68 percent had witnessed such behavior by nurses. Furthermore, 17 percent reported that adverse events occurred as a result of the disruptive behaviors. Some of the participating physicians said that nurses' reports of the patients' conditions are sometimes frustratingly inadequate.[9] On the other side, nurses reported that they will not call abusive physicians about their patients. Consider the following quotes from nurses in this study"[9] (p. 61-62):

- Delay in patient receiving meds because RN was afraid to call the MD.
- Most nurses are afraid to call Dr. X when they need to, and frequently won't call. Their patients' medical safety is always in jeopardy because of this.
- Adverse event related to med error because MD would not listen to the RN.

[†] VHA, formerly Voluntary Hospital Association, is a national consortium of nonprofit hospitals and medical practices.

- RN did not call MD about change in patient condition because he had a history of being abusive when called. Patient suffered because of this.
- RN called MD multiple times re: deteriorating patient condition. MD upset with RN calling. Patient eventually had to be intubated.
- Poor communication post-op because of disruptive reputation resulted in delayed treatment, aspiration, and eventual demise.

The Moral Imperative

Why and how is the moral imperative to act in the best interests of the patient lost in the turf battles and rigid organizational hierarchies that exist in most health care facilities? Health care leaders must come to grips with this question if patients' lives are to be spared and we are to live by the adage of "First, do no harm." These are long-standing issues, but the current focus on patient safety provides nurses with the opportunity to call for, demand, and lead organizational and interdisciplinary changes that will put patients first.

Current initiatives that are focusing on improving team communication, improving patient safety and quality, and ensuring that nurses are at the tables where quality of care and patient safety are discussed—whether within health care facilities, in national patient safety initiatives, or in public policy arenas—are encouraging. For example, the Robert Wood Johnson's Nursing Initiative embraces the idea that nurses are the key to quality. One project under its initiative is Transforming Care at the Bedside (TCAB), a joint project of the foundation and the Institute for Healthcare Improvement that focuses on empowering the bedside nurse in medical-surgical units. Using a rapid-cycle feedback method of quality improvement, interdisciplinary teams at select hospitals have examined interventions to improve the quality of care, such as rapid-response teams to assist nurses on these units to evaluate and intervene appropriately on patients with deteriorating conditions, and color-coded systems to alert administrators when staff are overloaded on a unit to the point of jeopardizing patient safety. For more information on TCAB, go to http://www.ihi.org/IHI/Programs/StrategicInitiatives/TransformingCareAtTheBedside.htm.

While such initiatives are extremely important to the health of nursing and patients, leading changes to promote patient safety requires more than empowering nurses on the unit level. Nurses must be knowledgeable about the factors that lead to errors, be willing to act to fix the problems contributing to the errors, call for public policies that will support safer work environments, conduct research on the compelling questions that touch on nurses' contributions to patient safety, and make personal commitments to modify their own behaviors that may contribute to unsafe care. In this latter case, consider some of the research on nurses' work hours. Rogers and colleagues[10] reported in *Health Affairs* on a study of 363 nurses who volunteered to keep diaries on their workhours and errors. Eighty percent of the nurses reported working longer than their designated shift, with 40 percent of the shifts being more than 12 hours. About two-thirds worked overtime 10 or more times during the 28-day period of data collection, and one-third worked overtime every day. The nurses reported that they committed 199 errors and 213 near errors. In fact, 30 percent reported making at least one error, and 32 percent at least one near error. The researchers found a significant increase in risk of error after 12.5 hours worked, when working more than 40 hours in a week, and when working overtime. While those who volunteered for the study may have been more motivated to report on extended work schedules that were unsatisfactory to them, the study provided beginning data for understanding the relationship between workhours and errors.

In April 2006, Trinkoff and colleagues[11] reported on a work patterns survey of randomly selected nurses in two States funded by the National Institute for Occupational Safety and Health, adding to our understanding of the extent to which nurses are working unsafe hours and schedules. A significant portion of the respondents worked more hours than has been recommended by the Institute of Medicine: 28 percent worked 12 or more hours per day, including 52 percent of hospital staff nurses; 33 percent worked more than 40 hours a week; and 17 percent worked mandatory overtime. Furthermore, 19 percent of respondents worked more than one job. In this group, 37 percent worked 12 or more hours a day, 45 percent worked more than 40 hours a week, and 18 percent worked 6 or 7 days a week.

The Institute for Women's Policy Research[12] notes that hospitals have resorted to unsafe staffing practices (understaffing, overtime, use of contingency workers, and one-time bonuses for new hires) instead of wage increases in response to their inability to recruit sufficient numbers of nurses. Yet nurses who volunteer to work two jobs or extended work hours are associated with fatigue and subsequent errors, compromising patient safety. Nurses must continue to push for institutional and public policies that will support safer work environments, including adequate staffing ratios (for example, through legislating minimum ratios or transparency in public reporting of ratios, and through union contracts that set ratios or require that bedside nurses be involved in staffing decisions), elimination of mandatory overtime, and whistle-blower protections.

Conclusion

The current spotlight on patient safety provides nurses with an opportunity and the moral responsibility to call for changes in health care facilities' policies and operations that we know are detrimental to the safety of patients. The challenge is for all nurses to seize this opportunity. TCAB and other quality improvement initiatives provide nurses with the support and tools for leading changes in their workplaces. Nurse administrators must model leadership behavior if their staffs are to lead on the unit level. Nurses have a moral imperative to act on behalf of their patients. Anything less violates the patient advocacy mantle that we claim as a core nursing role.

Chapter 20b. [*Vignette*] Who Should Lead the Patient Quality/Safety Journey?

Joanne Disch

Batalden and colleagues[1] remind us that improving quality and safety for patients and families requires leaders to lead—and that the words *leader, leading,* and *leadership* stem from *laitho* or *laithan,* meaning "way," "journey," or "to travel."[2, 3] Much has been written about the need for and characteristics of leadership for this journey.[4–8] This section challenges Chief Nurse Executives (CNEs) to lead the journey and highlights how patients, their families, and health care organizations would benefit immeasurably if CNEs stepped forward and accepted this leadership role. There are many examples across the country where this has been exquisitely demonstrated.

The CNE should lead the journey because the nursing profession has been at the forefront of assuring quality and safety. Before the first Institute of Medicine study,[9] or the *Chicago Tribune* article with the headline "Nursing Mistakes Kill Thousands,"[10] or the National Patient Safety Foundation, or the Institute for Healthcare Improvement, there were nurses at all levels in hospitals and health care organizations concerned about patient safety and quality of care. For decades, nursing leaders like Marie Zimmer and Norma Lang have developed and tested quality indicators. For generations, nurses have taken seriously their Code of Ethics and their role as one who "promotes, advocates for, and strives to protect the health, safety and rights of the patient."[11] Florence Nightingale reminded us that "the very first requirement in a hospital [is] that it should do the sick no harm"[12]—and proceeded to set up systems and practices that are still being used today to enhance the quality and safety of patient care.

The CNE should lead the journey because nurses understand what the issues are. While many physicians, administrators, policymakers, and others have come to realize only recently that health care is frighteningly unsafe, nurses have been raising concerns for many years. Nurses do not need to be alerted to the dangers of malfunctioning equipment, or the likelihood of medication error when getting medications ready and being interrupted 16 times, or the safety threat when orientation to the new computer system is inadequate, or the potential for serious injury to the patient and self when struggling to lift a 287 pound patient. Nurses are there 24/7 and, through the nursing lens, recognize the system issues, dangerous shortcuts, work-arounds, and waste.

The CNE should lead the journey because nurses have workable solutions. We recognize the problems, and we also have solutions. We blend practical wisdom with scientific knowledge and finely-honed interpersonal skills or, as a Boston cab driver once noted, we're "caring, shrewd, and a little bit crazy." We see the big picture and the details—the interconnectedness among departments and professions. We understand everything that needs to be done to complete the job, whatever it is. We are holistic—whether it be caring for a patient in the context of family, or coming up with a solution to a problem that incorporates the concerns of everyone involved. And nurses are resourceful. Who else can coordinate the administration of three antibiotics, two units of packed cells, and four units of platelets; cajole the pharmacist to bring up a missing drug; hunt down the needed blood filter, extra IVAC, flexicare mattress, cardiac chair for a wife; and find a nurse to work an extra 12-hour shift for nights—all within an 8-hour period?

As leaders within their organizations, CNEs have the background, perspective, and platform to help their organizations seriously tackle safety issues that jeopardize patient care and that face nurses and their colleagues daily. They can

- Create a healthy culture that promotes safety, inquiry, continuous learning, and collaboration.
- Design systems and processes that help people do their best work and deliver quality care (safe, timely, effective, efficient, equitable, patient-centered).
- Acquire and align resources to get the work done and achieve organizational goals.
- Assure the existence of a professional practice environment that values evidence as a basis for decisionmaking and the ongoing development of everyone.
- Implement quality and safety programs that are effective, supported, embedded in the culture, and get the job done.

What Are the Barriers to CNEs Taking on This Particular Leadership Journey?

Barriers can exist at the organizational or individual level. These include

- *Organizations* that rely on hierarchical structures with a traditional complement of leaders, and that sustain a culture that resists change and blames individuals for system failures.
- *Organizational leaders* who impose arbitrary solutions and/or weigh financial imperatives more heavily than quality/safety concerns.
- *CNEs themselves* who retreat behind balance sheets and abdicate their role as senior patient care officers and architects for a truly professional practice environment for nurses.

In addition, a number of other factors make this journey difficult, such as a lack of resources, insufficient time, pressures from competing priorities, and the complexity of the health care system.

Evidence and Collaboration Will Enable This Journey To Be Taken Successfully

- **Evidence** that clearly outlines strategies that improve safety and quality while using reasonable levels of resources. The idea that quality is more expensive is wrong, and more is not always better, e.g., when patients get extra doses of medications, or two x-rays when one is ordered, or extra days in the intensive care unit when transfer orders are held up. CNEs can extract excellent, evidence-based strategies from this book and build the business, legal, and ethical case for safety and quality.
- **Collaboration** among nurses, physicians, other care providers, staff, boards of trustees, and organizational leaders who share a passion and commitment for a safer health care experience. The vast majority of individuals in health care want to collaborate, but don't always know how to do it. Most often, the CNE has the knowledge, perspective, and aptitude to skillfully bring people together to achieve common goals— in this case, quality and safety for patients, their families, and caregivers.

Chapter 20c. [Vignette] Creation of a Patient Safety Culture: A Nurse Executive Leadership Imperative

Victoria L. Rich

Background

In 2004, the Healthcare Leadership Alliance, which includes the American Association of Nurse Executives and other health care executives, identified a core set of competencies for executive leaders in health care.[1] The identified core competencies for nurse executives in health care were: (a) leadership, (b) business skills and principles, (c) communication and relationship management, (d) professionalism, and (e) knowledge of the health care environment. Patient safety is identified as a key element of concern in the health care environment. Within the context of the core five competencies listed above, seven imperatives were identified to develop a patient safety culture: [1]

- To support the development and implementation of an organization-wide patient safety program
- To design safe clinical systems, processes, policies, and procedures
- To monitor clinical activities to identify both expected and unexpected risks
- To support a nonpunitive reporting environment and reward systems for reporting unsafe practices
- To support safety surveys, responding and acting on safety recommendations
- To ensure staff is clinically competent and trained in their roles in patient safety
- To articulate and take action in support of the Joint Commission's National Patient Safety Goals

These imperatives are the necessary building blocks the nurse executive must communicate to foster the development of a culture of proactive patient safety. This vignette will first review the historical background of the evolution of a patient safety proponent. From lessons learned in the redesign of an entire hospital culture, a model "Systemic Mindfulness Model of Proactive Patient Safety" is presented. Using a corkscrew metaphor and systems theory, the model suggests that all levels and professions of the health care culture must become aware and responsible to achieve meaningful medical error reductions. Practical suggestions are then offered, which derive directly from the model for achieving and maintaining a culture of proactive error reduction. The skillful acquisition of the five core competencies and the implementation of the seven patient safety imperatives are necessary for these practical suggestions to be truly effective.

A Culture of Systemic Mindfulness

A systemic mindfulness culture is grounded in professional experience of the vice president of patient care at the University Community Hospital (UCH) in Tampa, Florida, from 1996 to 2002. Prior to this tenure, the sentinel event of wrong-leg amputation in the now-famous case of Willie King occurred in 1995.[2] This patient safety crisis, in concert with the drug overdose death

of Betsy Lehman in Boston in the same year, ignited public and regulatory agencies to question the safety of hospitals.[2] In 1996, the Joint Commission (formerly the Joint Commission for Accreditation of Healthcare Organizations) developed the Accreditation Watch and encouraged the use of root-cause analysis.[3] Subsequently, the Institute of Medicine's 2000 report, *To Err Is Human*, which estimated that 44,000 to 98,000 deaths in hospitals occurred each year due to medical errors, forced the issue of patient safety into public awareness.

The organizational culture of UCH in 1996, 1 year following the Willie King tragedy, was defensive and insular to any outside feedback or systems redesign. Nursing practice was fragmented, and identifying and firing the one employee—usually a nurse—responsible for a medical or nursing error was the way mistakes were handled.

Due to the negative publicity that the wrong-leg amputation created for the hospital, patients were unsure of the care they would be given, and trust by local, State, and Federal health care agencies was at an all-time low. Multiple inspections occurred by the Florida Agency for Health Care Administration, Joint Commission, Health Care Finance Administration, and Federal Drug Administration due to the numerous complaints and accusations. Malpractice claims increased and hospital administrators became adept at giving legal depositions and writing corrective action plans for the above-mentioned regulatory agencies.

Strong beliefs in patient advocacy and safety, in conjunction with a few visionary colleagues, supported the work required to make necessary changes, relying on critical-thinking skills, strong nursing educational background, personal tenacity, and self-reflection. It was not a time to second-guess personal decisions to practice at UCH, but to become part of a culture of change. Doctors, nurses, administrators, and all other employees at UCH seemed truly dedicated to providing safe patient care. Due to the wrong-site event, the culture needed leaders unscathed by the actual 1995 event to assist in reprioritizing basic patient care measures to reestablish the trust of the community. The punitive treatment of the entire hospital community by the regulators and media essentially destroyed the pride and self-confidence of the entire medical and hospital staffs.

To make matters worse, a nurse in the UCH emergency room administered a medication that was contraindicated for a patient with an aspirin allergy, culminating in the patient's death. During this time, the Joint Commission encouraged the use of the root-cause analysis process; hence, UCH was required to conduct one of the first root-cause analyses of a medical error. A root-cause analysis was conducted with key pharmacy personnel and administrators, an approach that was both overwhelming and enlightening. More questions than answers were discovered as a result of the root-cause drill-down process. The Joint Commission provided further direction, and the hospitals' chief operating officer and chief nurse officer were invited to fly to Chicago to discuss questions with the major creator of the root-cause analysis process, Dr. Richard Croteau.

Patient safety science is an important base of knowledge for nursing leadership. Patient safety conferences where Dr. Lucian Leape, Don Berwick, and Michael Cohen and their book, "New Look in Patient Safety," provide important understanding of latent errors and system dynamics in medical errors.[4–7] An important insight into the most salient insight in the journey was that the causes of medical errors were complex and did not occur in any predictable and linear way. Rather, a systems approach to patient safety and the impact of leadership and communication on the safety processes was needed—instead of focusing solely on the one person who presumably made the error. Yet, the scarcity of nursing scholars and executives assuming leadership in the development and design of patient safety science was evident; which may be why physicians, pharmacists, quality officers, administrators, sociologists, and information experts became the pioneers for this new frontier in health care.[8]

The extensive experience gained by the entire UCH multidisciplinary team in the 3 years from 1996 to 1999 culminated in a true success story. The 1999 Joint Commission triennial visit resulted in UCH earning Accreditation with Accommodation with no citations. This achievement remains a career hallmark.

Development of the Systemic Mindfulness Model of Proactive Patient Safety

The experiential journey of managing contradiction, chaos, and complexity in patient safety informed the development of the Systemic Mindfulness Model of Proactive Patient Safety.[9, 10] This model, displayed in Figure 1, resembles a corkscrew and suggests that risk and safety are embedded in all systems of the health care environment, from the blunt end (leadership) to the sharp end (clinical interventions). In addition, the pathway to patient safety risk reduction is not linear. Movement and change in each level of the corkscrew are complex, circular, and continuous.[11, 12] Furthermore, such complex circularity is by nature interdisciplinary in medical systems in which critical safety systems are embedded at each level of the system, and in which each level interacts with other levels, making each turn of the corkscrew an appropriate field of study for the researcher.[10] The goal of the model is to provide a framework for moving a health care culture from a pathological or bureaucratic organization to a generative patient safety culture. Basic definitions are provided for clarification:

- *Systemic mindfulness* is being aware of the current moment-to-moment, lived experience by observing and attending to the changing scope of thoughts, feelings, and sensations. This results in alertness to what is happening in the here and now.[13–16] In the health care genre, systemic mindfulness refers to focused attention at each level of the health care system on how its functions affect patient safety.
- *Blunt end of a system* refers to those people in the organization such as administrators, members of the board of trustees, and health care leaders farthest removed from individual contact with the patient and patient system who nonetheless affect the patient safety processes through policies, technological and economic decisions, and cultural leadership.[5]
- *Sharp end of a system* refers to those who are closest to the moment-by-moment interactions with the patient and the patient's family. Nurses, doctors, pharmacists, technicians of various medical specialties, and support personnel such as dieticians work at the sharp end.[5]
- *Culture* is defined as a system of shared beliefs, values, customs, behaviors, and material objects that interact to produce attitudes and behavioral norms that determine how health care providers do things. Culture includes almost any form of behavior that is learned rather than instinctive or inherited.[17]
- *Generative* or *informed safety culture* exists when bidirectional communication is open and honest, trust exists for all levels of the organization, and messengers are trained and rewarded for improving systems. The system is just in the treatment of employees, reporting of errors is valued, and lifelong learning from mishaps is identified and appreciated.[18–20]
- A *pathological organization* is one in which messengers are reprimanded or ignored, change is extremely difficult, and powerful people are honored.[19, 20]

- A *bureaucratic culture* is highly compartmentalized and failure is known by only a few. Bidirectional communicational processes do not exist.[19, 20]

Figure 1. Systemic Mindfulness Model of Proactive Patient Safety Using a Corkscrew Metaphor

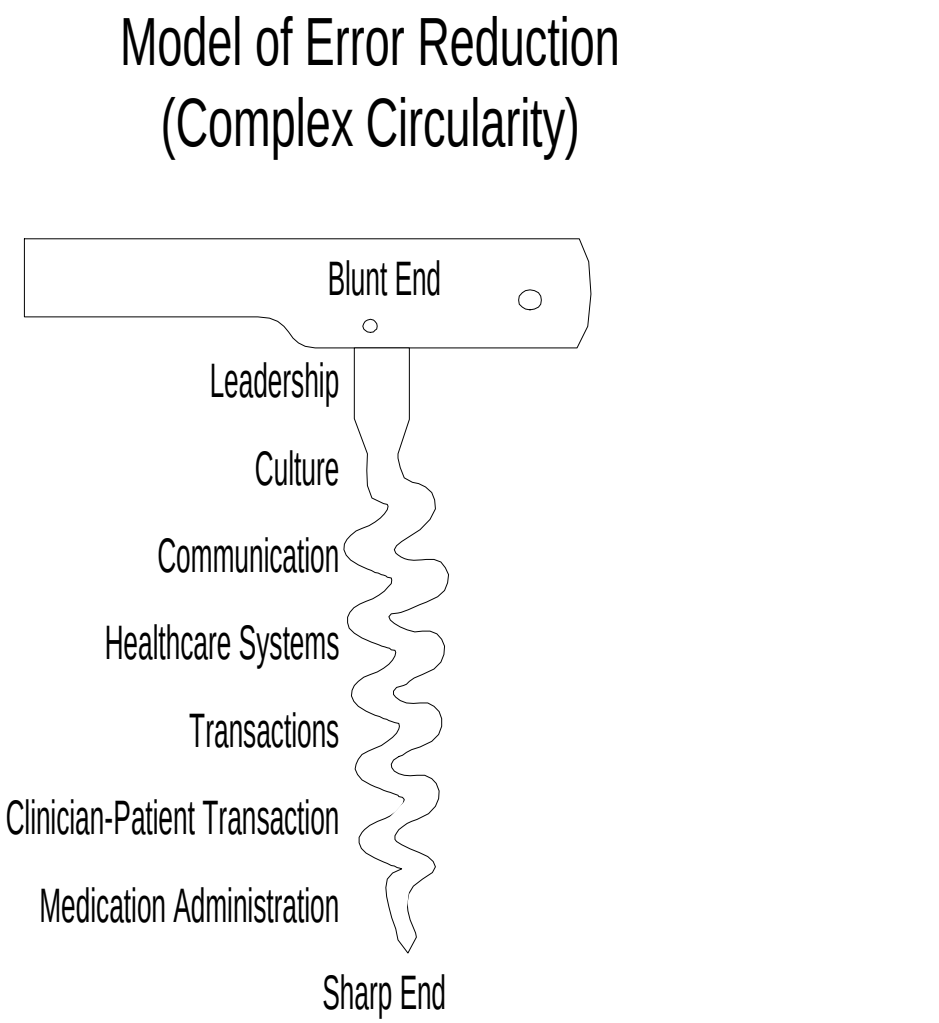

Figure 1. Systemic Mindfulness Model of Proactive Patient Safety Using a Corkscrew Metaphor

The corkscrew metaphor (shown in Figure 1) also signifies that the journey to an error reduction culture is never static, but constantly turning and twisting, and that a steady state of patient safety can never be obtained without a systemic mindfulness value system that holds both the sharp and blunt ends personally and professionally accountable for patient safety. As mentioned, there are seven imperatives that the nurse leader must implement to develop a patient

safety culture.[1] These imperatives must be initiated by the nurse executive leadership and communicated from top to bottom.

However, communication between the blunt and sharp ends of the system must be bidirectional. If nurses feel comfortable reporting near misses in a nonpunitive environment, new communication channels are developed and new practice procedures are put in place by leadership. Moreover, decisions made at one level of the system affect all other levels. For example, a decision to decrease staff made at the leadership level will necessarily affect health care system transactions and nurse–patient interactions by increasing caseloads and responsibilities, and thereby potentially increase medical error risk.[21]

Communication affects health care transactions among health care personnel. For example, it is imperative that the list of a patient's medications that is gathered at admission be communicated effectively to subsequent providers as the patient is transferred between settings and practitioners extending all the way to discharge.[10]

Croteau[22] refers to the general principles of proactive risk reduction necessary at the sharp end of care to mitigate error. Leadership involves staff in the development and implementation of the following principles: (a) retraining and counseling, (b) redoing policies and changing practices, (c) creating redundancy and double checks, (d) putting in fail-safe systems such as backup systems, and (e) purchasing more technological solutions.

In summary, the premise behind the model is that each level identified in the spiral must be addressed and managed to ensure patient safety. A generative culture of systemic mindfulness and professional accountability is imperative at all levels of the system for system-wide effectiveness. This infers that everyone's job is patient safety in all health care system transactions; this safety mission involves the entire health care team, from the nurse and physician to the valet parking attendant.

Handling a Medical Error

A generative culture for nursing is created by the chief nurse executive, mindful of patient safety. Leadership guidelines to adhere to when an error or near miss occurs are as follows:

1. Interview all clinicians involved in the error and be sensitive to not only the overt, explicit information about the experience, but also implicit knowledge such as coping style, fatigue, and personality traits such as attitudes of overconfidence and underconfidence in clinical knowledge.
2. Assess if the error is one of three types: (a) s*kill-based*—occurs when the competency of the nurse is identified as a component of the error, (b) *rule-based*—results from a failure to follow policy and procedure, or (c) *knowledge-based*—due to a knowledge deficit or assumption that known knowledge is correct when it is not.[18]
3. If an error occurs, provide administrative leave with pay during the investigation and offer psychological counseling. Invite the nurse to be involved in the root-cause analysis to express what happened and why. The nurse executive or designee should be present to provide professional support and leadership to all team members. Remember that the involved clinician is often overlooked and can become the second victim. Shame and guilt can become disabling.

The information gained through this process can be used to further explore the latent errors within each level of the system. Nurses learn to use 'work-arounds' and peer support to compensate for poorly designed systems or lack of resources. These 'work-arounds' become

common practice. A hallmark of identifying causes of system errors or near misses is to interview nurse clinicians involved in the mishap about their actual thoughts and resultant behaviors during the time of the event. This process should be accomplished prior to the root-cause analysis so that information obtained can be utilized in remedial actions and self-reflections of the people involved.

Changing and Holding Generative Culture Gains at the Nurse-Patient Transactional Level

There are a number of processes that can be used to retain gains made through the change process that move the culture to one of patient safety. For example, decisions to improve patient safety by leadership must be communicated through each level of the system from leaders in allied professions, to health care transactions among health care professionals, to clinician-patient interactions, to the administration of a specific health care intervention. These changes not only need to be implemented effectively, but also maintained over time in the face of other changes such as staff and nurse manager turnover.

1. Foster a just culture that enables reporting of all errors and rewards actions to proactively avoiding future errors:
    a. Provide opportunities for staff to share near-miss scenarios with one another without breaking patient confidentiality.
    b. Reward nurses who speak up and identify errors or near misses. As a nurse executive leader, it is important to personally meet with staff that speak out and present them with a thank you note and/or a small gift such as movie tickets.
    c. Learn the art of storytelling. Become a raconteur. In nurse executive leadership meetings with staff, tell the story of a root cause, what was discovered and what practice changes are needed. Initiate a bidirectional dialogue with staff to get honest feedback. Validate disparate opinions and explain alternative solutions.
    d. Review, on an annual basis, all root-cause analyses to assure that identified corrective strategies are still in existence and are providing continued safety nets.
    e. Proactively identify unit trends in near misses, nurses' expressed concerns, vacancy and turnover increases, increased patient volume, and acuity. The perfect storm could be brewing.
    f. Administer punishment when willful misconduct, reckless behavior, and unjustified deliberate violation of the rules were significant factors in causing the error.
2. Identify and develop nurses as patient safety experts:
    a. Create employees who function as surveillance and reconnaissance officers who are trained in patient safety principles and are well versed in the Joint Commissions' National Patient Safety Goals. Give these patient safety disciples titles such as "deltas" and provide a formalized structure for ongoing communication, empowerment, and recognition.
    b. Include patient safety functions in everyone's job description.
    c. Consider a patient safety clinical specialist who provides oversight for nurse/patient safety processes such as clinical alarms, code carts, and telemetry outcomes.[23, 24]
3. Ensure staff have the needed tools and resources to improve patient safety:

a. Implement computerized occurrence reporting that is anonymous and easy to complete. Report aggregate data at designated times to determine areas of concern.

b. Spread positive gossip and the rationale for the purchase of new safety equipment or process changes that have been implemented. Include nurses in decisions. Celebrate acquisition of new technologies and changes as key components to creating safe environments for both the patient and nurse.
c. Develop a scorecard for each nursing unit, reporting clinical outcomes and adherence to patient safety goals such as patient identification. Establish achievable targets to share with all staff on a monthly basis.
d. Create evidence-based nurse safety practices that are unit-specific and review and update on a yearly basis with staff.
e. Establish a communication officer for nursing and publish a monthly newsletter that includes patient-nurse safety updates from both internal and external avenues. Circulate to all nursing units the *Institute for Safe Medication Practices* (ISMP) monthly newsletter.[25]
f. Expect new technology to create new, unexpected errors and perform a failure mode and effects analysis prior to implementation or early on in the adoption phase.[26, 27]
g. Invite industry partners to open forum lunches with staff nurses to discuss design and operative concerns of safety devices. Effectuate changes with health care vendors and purchasing agents.

4. Develop clever reminders for nursing staff that validate their importance in safety, both for their patients and themselves. An example is the following message attached to the back of the employee identification badge:

> Mindful Practice
> It doesn't matter how good we are if we are not paying attention.
> - Stop—Stop and become focused on the task at hand.
> - Look—Look and see the uniqueness of the patient.
> - Listen—Listen to what you have been taught about safe patient care.

5. Enable patient safety through effective leadership:
   a. Address in senior leadership lack of professionalism and diminished respect in the workplace. Remember, it takes a village to change a culture.
   b. Provide leadership, direction, and passionate commitment for rapid response team implementation. Communicate successful outcomes to not only nursing and medical staff, but to all stakeholders. Take charge as a nurse executive to promote the successes.[28]
   c. Be the moral conscience for the patient at the senior leadership table, especially if a balance of safety practices and financial imperatives is needed. Sometimes compromise is not acceptable when it concerns patient or nurse safety.
   d. Develop translational research mechanisms and business acumen to effectively articulate the business case for patient safety.

e. Keep informed on technology and innovations in patient safety and support them vehemently if outcomes appear justified.
f. Emulate authentic leadership traits using skilled communication messages of truth, trust, balance, respect, and confidentiality.[29]

6. Enable patients and their families to be part of patient safety improvements:
   a. Invite preselected patients, families, and/or consumers to speak directly to nurses about their perceptions of care given, as well as the lived experience of near misses or medical errors.
   b. Empower patients on admission by giving them safety information regarding issues such as making sure identification bands have correct information, observing and expecting clinicians to wash hands, mark surgery sites, etc.
   c. Remember medical errors are always matters of the heart. Everyone is impacted, not just the patient and family, but the nurse or clinician involved in the error—the second victim.

The development of an informed patient safety culture has evolved since 1995 through the passionate leadership of many stakeholders in both the public and private sectors, including the Joint Commission and the development of its National Safety Goals.[7, 8] However, the health care industry still struggles to gain the trust of patients. Consumer groups are encouraging patients to have a patient advocate accompany them to the hospital.[30]

The patient safety leadership skills identified by the Leadership Alliance for Nurse Executives[1] should be addressed by practicing the strategies described as necessary for creating a generative culture at all levels of the health care system from leadership to the nurse-patient transaction (see Figure 1). Patient safety is dependent upon the safe practices of nurses. Nurse executives must be the moral conscience for the patient and assure that wherever nursing care is practiced, it is practiced with a mindful approach. Nurses must have the time to think critically and not be interrupted or easily distracted. Every newly designed system will never be fail-safe if the nurse does not have time for that final safety net at the sharp end of the care delivery system. The authentic executive nurse leader in the 21st century must lead in spite of contradictions and complexity and build bridges to all stakeholders as we walk on them together.[31]

Research Implications

Despite the advances in the science of patient safety, a significant reduction in the frequency of medical errors has yet to be accomplished.[30] Process enhancements such as double checks, redundancy, and fail-safe procedures, have not led to the elimination of administering the wrong drug or the wrong dose. Research from the field of human factors has shown that attention, perception, and cognition are all fallible. Reality is influenced by expectation. Routines and similarities may result in not being able to recognize differences. Fatigue, stress, and strong emotions such as anger and frustration, affect perceptions and thoughts. The next frontier in patient safety is now researching how human factors affect performance. As such, mindfulness may contribute to preventing common errors of attention and perception, but it is not known whether mindfulness can be a learned skill. Each time a nurse administers a medication, an MRI is performed, and the operating room personnel complete the sponge count, can they learn to bring full awareness to their task?

Another set of questions involves new technology. How will the work of the future nurse be redesigned to assure that barcoding, hand-held devices, bedside computerized documentation,

computerized physician order entry, e-ICUs, smart infusion systems, and voice-activated communication tools are all interconnected to result in a decrease in errors and better patient outcomes? Paradoxically, these strategies may introduce new sources of error.

Conclusion

Well-publicized medical errors during the mid-1990s created a health care crisis involving patient safety. As the public and the profession have become more cognizant of the problem, demands for system redesign to significantly reduce medical errors have occurred. This vignette suggests that it is imperative for all nurse leaders and the chief nurse executive, in particular, to become prime architects in creating a culture of patient safety by employing the core competencies of leadership, communication, professionalism, business skills, and knowledge of the health care environment.

Personal experience in redesigning a hospital safety culture, following a significant medical error, contributed to learning that the science of medical error reduction is complex and involves multiple levels and systems of the health care environment. More specifically, reducing medical errors is not a matter of finding and punishing the one person thought responsible for the error. Rather, chief nurse executives must recognize that medical errors occur because of complex reasons that are not entirely predictable. All departments of the hospital environment with direct or indirect patient contact must be accountable if patient safety goals are to be achieved.

To assist in this process, the Systemic Mindfulness Model of Proactive Patient Safety model suggests using a corkscrew metaphor where each multiple level of the health care system interacts in complex ways to affect patient safety. Decisions made at one level can affect all other levels and alter the dynamics of the patient safety culture. To be effective, all staff need to be aware of their role in the patient safety process and how they can best promote and maintain a patient safety culture.

Chapter 21. Creating a Safe and High-Quality Health Care Environment

Patricia W. Stone, Ronda Hughes, Maureen Dailey

Background

Maintaining a safe environment reflects a level of compassion and vigilance for patient welfare that is as important as any other aspect of competent health care. The way to improve safety is to learn about causes of error and use this knowledge to design systems of care to "… make errors less common and less harmful when they do occur"[1] (p.78). As a result, researchers, policymakers, and providers have intensified their efforts to understand and change organizational conditions, components, and processes of health care systems as they relate to patient safety.

Health care is the second-fastest growing sector of the U.S. economy, and nursing is the largest occupation within the industry, with more than 2.4 million jobs and the highest projected growth.[2] As noted in recent reports by the International Council of Nursing and the Institute of Medicine, one of the reasons for the current and future shortages of nurses relates to the work environment.[3, 4] Improving the environment in which nurses work may attract new students to nursing as well as engage current professionals in developing innovative models of care delivery that will help retain and nurture future generations of nurses. Most important, improving the work environment may also improve the quality and safety of patient care.

High turnover has been recognized as a problem in many service industries, including health care.[5] In U.S. hospitals, nursing turnover has been reported to range from 15 percent to 36 percent per year.[6] These turnover rates are much higher than those for other health care professionals, which are estimated to average 2.3 percent per year.[7] Past estimates of the cost to replace one medical-surgical registered nurse (RN) range between $30,000 and $50,000; and replacement costs for critical care nurses are closer to $65,000.[8] More recently, Jones[9] estimated the total turnover costs of one hospital-based RN to range from $62,000 to $67,000 depending on the service line. While these cost estimates rely on nurse manager reports of decreased productivity, clearly there are avoidable organizational monetary and human costs related to high turnover of desirable employees. Using multiple databases in an academic medical center, other analysts found the low-end estimate for the cost of employee turnover accounted for greater than 5 percent of the annual operating budget.[10] Clearly, understanding organizational aspects that promote a stable workforce is important.

Besides the obvious harm to patients, preventable adverse health care events related to patient safety have major financial consequences for the patient, the provider, the insurer, and often the family and/or caregivers. Using Agency for Healthcare Research and Quality (AHRQ) patient safety indicators, researchers estimated the excess length of stay for postoperative sepsis to be approximately 11 days at a cost of almost $60,000 per patient.[11] While in some instances there is extra payment made by insurers to hospitals for these adverse events, it has been estimated to be considerably less than the total cost of the resources used.[12] Furthermore, with increased discussions about pay-for-performance and mandatory reporting of certain adverse patient safety events, providers may have increased financial as well as other incentives to

improve patient safety.[13] Therefore, understanding organizational aspects that promote patient safety is also very important.

Throughout the body of patient safety and occupational health literature, authors refer to concepts of organizational climate and culture as well as safety climate and culture. Culture broadly relates to the norms, values, beliefs, and assumptions shared by members of an organization or a distinctive subculture within an organization.[14, 15] Organizational culture is typically thought of as evolving over the course of time and difficult to change. Organizational climate refers to members' shared perceptions of organizational features like decisionmaking, leadership, and norms about work, including opportunities for advancement and collaboration.[16] Organizational climate has been likened to a weather pattern.[17] For example, Clarke[18] pointed out that organizational climate refers to an atmosphere, which is a moveable set of perceptions related to working and practice conditions, many of which can be directly influenced by managers and organizational leaders. There are other microclimates; for example, safety climate is the current landscape of employees' perceptions and attitudes about safety, such as state of current safety initiatives and safety behaviors.[19]

Additionally, a number of safety climate scales have been developed in the fields of occupational health and patient safety. In occupational health, attributes of a safe climate in hospitals have been found to include senior management support for safety programs, absences of hindrances to safe work practices, availability of personal protective equipment, minimal conflict, cleanliness of work site, good communication, and safety-related feedback.[20] A positive safety climate has been significantly correlated to reduced risk of work injury and exposure.[20] In patient safety, attributes of a safe hospital environment have been identified as a positive work environment, supportive supervisor/manager, improved interdisciplinary communications, and increased safety event reporting.[21] Obviously these microclimates overlap. Additionally, they should be synergistic and correlate with the overall organizational climate. Indeed, a positive organizational climate is most likely an essential antecedent to the development of a strong safety climate.

As part of AHRQ's The Effect of Health Care Working Conditions on the Quality of Care research portfolio (RFA HS-01-005), a team of interdisciplinary scholars developed a model depicting aspects of organizational climate and their relationship to worker and patient outcomes.[22] These investigators tested the model in various settings (i.e., ambulatory care, home health, long-term care, Veterans Health Administration facilities, and acute care hospitals) and identified important organizational structures (leadership and infrastructure) and processes (supervision, work design, group behavior, and quality/safety emphasis). Using this model as the organizing framework, this chapter reviews the evidence examining the impact of organizational climate on patient and employee outcomes. It is important to note that we are focusing on the broad concept of organizational climate. Another chapter in this volume focuses specifically on safety culture and climate. Based on the evidence on organizational climate and the relationships with patient outcomes, job satisfaction, and turnover, we have developed a new conceptual model of organizational attributes and outcomes.

Research Evidence

Overall 14 studies were reviewed. In four of the published studies, the researchers focused only on patient outcomes,[23–26] with one of the teams reporting the results related to worker turnover and job satisfaction in other publications.[27, 28] Two of the research teams published

results related to patient outcomes and worker outcomes in single manuscripts.[29, 30] The majority of the manuscripts reviewed focused on worker outcomes. In the following section, the studies focusing on organizational climate and patient outcomes are synthesized, followed by a synthesis of the evidence linking organizational climate with turnover and job satisfaction.

Organizational Climate and Patient Outcomes

Table 1 describes the primary research (six studies) found investigating organizational climate and patient safety outcomes. The attributes of organizational climate measured varied. Some researchers focused on quality,[23] measures of morale, and consensus of depersonalization,[24, 29] while others used a composite organizational climate measure, which focused on nurses' perceptions of the work environment.[25] The patient outcomes were also varied and specific to the setting. For example, in one study the measure of patient safety was nurse-reported medication errors;[24] another research team measured self-report service quality.[29] All other research teams used some form of existing administrative data to measure patient safety outcomes, with one team using clinical and laboratory data elements collected for participation in the Centers for Disease Control and Prevention's National Healthcare Safety Network.[25] The National Safety Network hospitals collect standardized nosocomial infection data. The settings studied also varied across projects and were primary care sites, rural hospitals, outpatient social services, specialized hospital settings (e.g., emergency departments and intensive care units) and the Veterans Health Administration. All studies used cross-sectional designs with the exception of one group reporting on the evaluation of a quality-improvement project.[23] Despite these varying measurement issues, settings and populations, and research designs, positive organizational climates were generally found to improve patient safety.

Organizational Climate, Turnover, and Job Satisfaction

Table 2 provides the results of the current evidence found examining the relationships among organizational climate and worker outcomes (i.e., turnover and job satisfaction). Ten studies were found, half of which included both job satisfaction and turnover. Again, the organizational climate attributes varied from morale to composite measures of organizational climate.[28, 30] The study populations were mainly nurses (60 percent), but outpatient caseworkers and mental health providers were also studied. Most studies (80 percent) were conducted in the United States, but nurses employed in Australia,[31] Begium,[32] and Hong Kong[33] were also studied. The majority of the studies were cross-sectional, with only one pre-post test intervention study.[34] All of the researchers reported that positive organizational climates were related to increased worker satisfaction. The results related to turnover were not quite as strong, and researchers in one study found that job satisfaction mediated the effect of organizational climate on turnover.[35]

Evidence-Based Practice Implications

Overall, there is an emerging evidence base pointing to the need for positive organizational climate. For the most part, the research findings were consistent; patient and employee outcomes were affected by organizational climate. However, the strength of the relationship between organizational climate and job satisfaction was stronger than the relationship between organizational climate and turnover. Furthermore, the evidence base regarding organizational

climate and patient safety outcomes was scant, with only six studies found, and only three of those studies focused on patients in acute care settings. Despite these limitations, the consistency of the findings point to the importance of organizational climate on patient and employee outcomes.

Based on this review and our previous work,[22] we developed the conceptual model displayed in Figure 1. The structural characteristics of the setting may serve as enabling factors for outcomes. These first and foremost include senior leadership. Other important enabling factors are related to the infrastructure (such as technology available) and communication systems. We call these enabling factors structural characteristics because they are not easily changed. These enabling factors influence the settings' microclimates, which may be grouped into three main foci: employee/staff, patient, and organizational. It is important to understand these microclimates are not conceptualized as mutually exclusive or independent. We believe these microclimates interact with each other and are synergistic. For example, a setting that focuses on occupational safety may also focus on evidence-based, patient-centered care; additionally, collaboration and communication among providers and patients may be important shared components of each microclimate. The microclimates influence the actions of the staff, patient, and often the family and/or caregivers, which in turn have an impact on the outcomes. Again, the outcomes are conceptualized at three different levels: the employee, the patient, and the organization. The list of specific outcomes under each category is representative of the category, but it is not exhaustive. For more complete lists of patient safety outcomes, the reader should refer to AHRQ's Patient Safety Indicators and the National Quality Forum's consensus standards for nursing-sensitive care.[36, 37]

Based on the literature reviewed and the conceptual model developed, there are a number of practice recommendations at all levels of nursing (e.g., nursing leaders, nurse managers, staff nurses, and educators). The existence of a relationship between a positive organizational climate and both worker and patient outcomes means that facilities need to be aware of the importance of assessing and periodically reassessing the climate within their organization. There are published reviews of instruments used to assess organizational climate.[38] Additionally, data regarding the climate should be correlated with outcomes along all three of the foci (employee, patient, and organizational).[39] The recommended frequency of conducting these analyses is not clear, but such assessment and reassessment should be part of a continuous quality-improvement process, and it seems reasonable that employee surveys should be conducted at least annually. Nurse educators need to develop and evaluate safety and leadership curriculum.[40, 41] Additionally, as we rapidly increase the information technology available in health care, we must ensure that this infrastructure promotes patient safety, increases efficiency, and contributes to nursing knowledge.[42]

Nursing leaders and managers need to be cognizant of the job satisfaction of all employees on an ongoing basis, specifically as low satisfaction can be linked to burnout, intention to leave, and even higher rates of job turnover or loss to the nursing profession (i.e., early retirement or transfer to another career). With the high costs of nursing turnover, efforts to increase job retention levels are likely to be financially beneficial.[9, 10]

Despite the scant evidence linking organizational climate—broadly defined—and patient safety, the evidence supporting the significant relationship between a climate of safety—a specific component of organizational climate—and patient safety is growing, given increased utilization of safety climate surveys. (This is discussed further in the next chapter.) It is likely then that development and utilization of readily available tools to assess organizational climate

will expand the evidence base and provide key information to leaders and managers to improve job satisfaction, interdisciplinary teamwork, and retention, ultimately improving the quality of health care delivery. Indeed, the usefulness of this information would likely be considerably improved if it were linked with ongoing patient-safety monitoring and quality-improvement activities within the organization. Organizational climate is more malleable and open to change than the more-entrenched aspects of culture. Thus, data-driven leaders can be proactive by assessing both worker perceptions and outcomes to ensure safety processes are adhered to more consistently (i.e., less violations or work-arounds); this should improve all outcomes. For staff and future staff, nurses' job satisfaction is key to not only providing quality care, but to having lower levels of occupational stress and higher levels of occupational safety, both of which are discussed in other chapters within this book.

Research Implications

This review identified a number of gaps in the research evidence. First and foremost, as interventions are developed to improve the organizational climate, rigorous research and evaluation studies need to be conducted. It is important to note, however, that this type of research will not often lend itself to randomized controlled trials. Other epidemiological designs that control for confounding variables and ensure comparability between groups will most likely be needed. Second, future research aimed at understanding the impact of human capital variables (i.e., stability of the workforce, education, etc.) on patient outcomes and system efficiencies is warranted. Furthermore, consistency in measurement tools would help advance the field and assure that study results are more consistent and comparable.

Lastly, more cost analyses need to be conducted to make the business case for improving the organizational climate in nurses' work environment and improving patient, employee, and organizational outcomes. The model provided presents various aspects of organizational climate that may be measured in different research projects, across a research portfolio, and in various settings. It is doubtful that any one study would include all aspects presented in this model. Rather, the researcher may use this model to select the organizational aspects and outcomes most appropriate to their research aims.

Organizational climate is one of the overarching aspects found in the work environment. However, it is not the only aspect related to patient safety and worker satisfaction and turnover. Other environmental aspects include actual workload, such as nurse-to-patient ratios in acute and long-term care and caseloads in outpatient settings; scheduled work hours (e.g., shift length, nights versus days); mandatory overtime; information systems for decision support to prevent errors of commission and omission; and human factor engineering solutions. The impact of these other aspects of the work environment is discussed elsewhere in this volume.

There are both strengths and limitations to this review. In our search for evidence we attempted to be comprehensive. However, we may have missed some studies. Additionally, only primary studies published in English after the year 2000 were audited.

Conclusion

Gradually, evidence is accumulating that links work environments to behavior, attitudes, and motivations among clinicians. These behaviors and orientations can, in turn, affect quality processes and outcomes. A growing number of studies in health care show that members of

organizations are more satisfied when they work in climates that have more supportive and empowering leadership and organizational arrangements, along with more positive group environments (often reflecting elements of group support and collaboration). Moreover, although the research base is not as strong, there is emerging evidence that these same organizational attributes impact employee turnover and, most important, patient safety. Improving the organizational climate is likely to improve patient safety and decrease overall health care costs. However, future research studying specific interventions and their cost effectiveness is needed.

Search Strategy

A systematic review of the literature was conducted focusing on relationships among organizational climate and three outcomes: patient safety, nurse turnover, and job satisfaction. Medline and AHRQ's Patient Safety Network (PSNET: www.psnet.ahrq.gov) searches were conducted using the key word "organizational climate," then cross-referenced with "patient safety" and "patient outcomes," "satisfaction," as well as "turnover" and "intention to leave." More than 200 titles were examined. Abstracts were examined by two nurse researchers if the article was published in 2000 or after, written in English, and pertained to health care organizations. Manuscripts were obtained and reviewed if they were primary reports of research findings. Editorials were excluded. Reference lists were also reviewed for key articles.

Publications that presented primary research findings and had sample sizes of greater than 30 respondents were organized into two tables presenting evidence on the relationships between organizational climate and (1) patient outcomes, and (2) worker satisfaction and retention of workers. Each study was audited for the following elements: the organizational climate attributes studied, the design type, the outcome measures (patient or worker), study setting and population, study intervention, and key findings. All studies were reviewed by two authors. Following the guidelines put forth by AHRQ, the study design types were categorized using the "type of evidence" criteria.

Evidence Table 1. Organizational Climate and Patient Outcomes

Source	Organizational Climate Attributes	Design Type	Patient Safety Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Cretin 2001[23]	Importance of improving quality of care, current status in quality improvement, climate for guideline implementation, attitude toward practice guidelines, and motivation for guideline implementation	Quality improvement projects/ research	Primary care followup, physical therapy or chiropractic care, specialist care	U.S. Army Medical Department: 4 facilities in the Great Plains Region served as demonstration sites, and there were 5 comparison facilities. 31,273 new low-back pain patients	Integrated model guideline implementation system: Evidence-based practice guidelines, education/training, toolkit, and interdisciplinary team approach	Significant downward trend in the percentage of the patients referred to physical therapy/chiropractic care (10.7%–7.2%) at demonstration sites as compared to comparison sites. No discernable reduction in specialty care referrals or primary care followup visits at the demonstration sites as compared to comparison sites.
Fogarty & McKeon 2006[24]	Workplace morale, supervisor leadership, participative decisionmaking, role clarity, professional interaction, appraisal and recognition, professional growth, goal congruence, workplace distress, and excessive work demands	Cross-sectional study	Medication error index	11 rural hospitals in Australia 176 nurses	Not applicable	Self-report medication errors positively correlated to composite measure of organizational climate ($r = 0.75$, $P \leq 0.01$). However, this relationship was mediated by health care worker psychological well-being, and distressed employees were more likely to report medication errors.
Glisson & James 2002[29]	Employee consensus of depersonalization, emotional exhaustion, and role conflict	Cross-sectional study	Service quality measured by perceptions of case managers	33 child welfare and juvenile case management teams in 30 counties (4 urban and 26 rural) in 1 southeastern State in the U.S.	Not applicable	Case managers and teams with more constructive cultures reported a higher service quality ($P \leq 0.05$); organizational climate was not significantly related to service quality.

Source	Organizational Climate Attributes	Design Type	Patient Safety Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Stone 2007[25]	Composite measure of organizational climate	Cross-sectional study	Central line bloodstream infections (CLBI), ventilator-associated pneumonia (VAP), catheter-associated urinary tract infections (CAUTI), 30-day mortality and decubiti (pressure ulcers)	51 adult intensive care units in 31 U.S. hospitals 15,902 patients 1,095 nurses	Not applicable	Results were inconsistent. Organizational climate was significantly positively related to CLBI and significantly negatively related to CAUTI ($P \leq 0.05$).
Warren 2007[30]	Organizational climate as measured by 4 metafactors: employee focus, support, professional demands, and pay satisfaction	Cross-sectional study	1. Management of 2 chronic diseases (diabetes and chronic obstructive pulmonary disease [COPD]) 2. Prevention Index (PI): Summary of prevention care delivery (vaccination, tobacco prevention, disease, and risk factors screening) 3. Surgical outcomes using the National Surgical Quality Improvement Program (NSQIP) measures postsurgical morbidity and mortality	74,662 employees from the U.S. Veterans Health Administration	Not applicable	Positive associations between employee focus and COPD, diabetes, and prevention index ($P \leq 0.05$).

Source	Organizational Climate Attributes	Design Type	Patient Safety Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Wright 2003[43]	Fairness and equity, role ambiguity, role overload, role conflict, workgroup cooperation and facilitation, growth and advancement, job satisfaction, emotional exhaustion, personal accomplishment, and depersonalization	Cross-sectional study	Frequency of staff members' clinical work with patients with psychiatric problems	1 general hospital emergency department (ED) in a U.S. urban Midwest location 131 ED staff (medial, nursing, and psychiatric workers)	Not applicable	Workgroup cooperation and facilitation is positively associated ($P \leq 0.05$) with frequency of clinical work with patients.

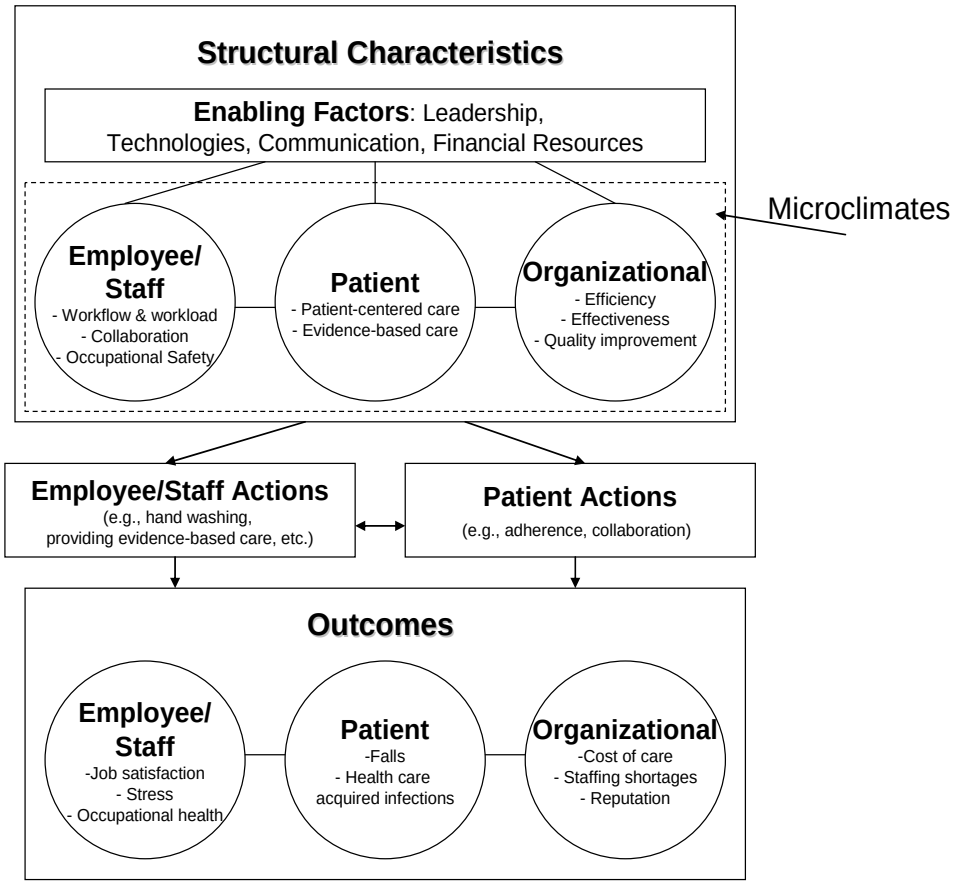
Evidence Table 2. Organizational Climate and Worker Outcomes

Source	Organizational Climate Attributes	Design Type	Worker Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Aarons & Sawitzky 2006[35]	Demoralizing climate	8	Job satisfaction, 1-year turnover	322 pediatric, adolescent, and family mental health providers in 49 public sector programs in California	Not applicable	The effect of organizational culture on job satisfaction and other work attitudes was partially mediated by the organizational climate in structural equation modeling. Worker attitudes significantly predicted turnover 1 year later.
Albion 2003[44]	Workplace morale, supervisor leadership, participative decisionmaking, role clarity, professional interaction, appraisal and recognition, professional growth, goal congruence, workplace distress, and excessive work demands	4	Job satisfaction, intention to leave	1,097 regional Health Service District employees in Australia	Not applicable	Nurses reported lower organizational climates on all scales except professional interaction ($P < 0.05$). Nurses reported significantly lower job satisfaction than administrators, medical professionals, or operational staff. Nurses working in large hospital reported significantly lower job satisfaction and higher intention to leave ($P < 0.05$).
Dunham-Taylor 2000[45]	Transactional leadership, laissez-faire leadership	4	Staff satisfaction	396 nurse executives and 1,115 staff who report to them	Not applicable	Staff satisfaction in the workplace was correlated with transformational leadership ($r = 0.79$, $P < 0.0001$). Staff satisfaction decreased as staff rated the leader as being more transactional ($r = 0.37$, $P < 0.0001$) or using a more laissez-faire leadership style ($r = 0.71$, $P < 0.0001$).
Glisson 2006[34]	Depersonalization, emotional exhaustion, role conflict, and role overload	6	Turnover	235 caseworkers and 26 case management teams that provide child welfare and juvenile justice services	Availability, responsiveness, and continuity (ARC) intervention	In hierarchical linear models analyses, it was found that the ARC intervention reduced turnover by 2/3 and improved organizational climate.

Source	Organizational Climate Attributes	Design Type	Worker Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Glisson & James 2002[29]	Employee consensus of depersonalization, emotional exhaustion, and role conflict	4	Job satisfaction, 1 year turnover	33 child welfare and juvenile case management teams in 30 counties (4 urban and 26 rural) in 1 southeastern State in the U.S.	Not applicable	Case managers and teams with more constructive cultures experienced lower turnover rates ($P \leq 0.05$); organizational climate was not significantly related to turnover. Organizational climate was significantly positively related to job satisfaction.
Siu 2002[33]	Organization, immediate upper level, coworkers, involvement, flexibility, work environment, and well-being	4	Job satisfaction	Two separate samples of Hong Kong nurses sample 1: 144 nurses sample 2: 114 nurses	Not applicable	Findings were not consistent across samples. In sample 1, environment was significantly correlated with satisfaction. In sample 2, well-being was a significant predictor of job satisfaction.
Stone 2006[27]	Professional practice, staffing/resource adequacy, nurse management, nursing process, nurse/physician collaboration, nurse competence, and positive scheduling climate	4	Intention to leave	2,323 registered nurses from 66 hospitals and 110 critical care units	Not applicable	Organizational climate factors that had an independent effect on ICU nurse intention to leave due to working conditions were professional practice, nurse competence, and tenure ($P < 0.05$).
Stone 2007[28]	Composite measure	4	Intention to leave	837 nurses employed in 39 adult critical care units from 23 hospitals		Organizational climate is an important determinant of intention to leave. Higher wages did not reduce these intentions; therefore, it was concluded that increased pay alone without attention to organizational climate is likely insufficient to reduce nurse turnover.

Source	Organizational Climate Attributes	Design Type	Worker Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Stordeur 2006[32]	Meaning of work, relationships with nursing management, relationships with team, relationships with doctors, relationships with administration, quality of leadership, social support from superior, social support from colleagues, days dedicated for professional development, satisfaction with handover shifts	4	Intention to leave, job satisfaction	2,065 registered nurses in 12 Belgian hospitals	Hospitals with high and low turnover were compared	Relationships with nursing management; work ability; and satisfaction with working time, handover shifts, and schedules were also better in attractive hospitals ($P < 0.001$). Job satisfaction and commitment were higher in attractive hospitals, whereas intention to leave was lower ($P < 0.001$).
Warren 2007[30]	Organizational climate as measured by 4 metafactors: employee focus, support, professional demands, and pay satisfaction	4	Intention to leave, job satisfaction	74,662 employees from the Veterans Health Administration	Not applicable	Employee focus was most strongly associated with job satisfaction, and support was negatively associated with turnover intention ($P < 0.05$).

Figure 1. Conceptual Model of Organizational Attributes and Outcomes



Chapter 22. Practice Implications of *Keeping Patients Safe*

Ann E. K. Page

Background

Improving patient safety and other dimensions of health care quality requires change at all four levels of the health care system: (1) the experience of patients during their interactions with individual clinicians; (2) the functioning of small units (microsystems) of care delivery such as surgical teams or nursing units; (3) the practices of organizations that house the microsystems; and (4) the environments of policy, payment, regulation, accreditation, and other factors external to the actual delivery of care that shape the context in which health care organizations deliver care.[1] Several groundbreaking Institute of Medicine (IOM) reports have spurred substantial actions at each of these levels to bring about improvements in patient safety and overall quality.

These IOM reports began as the product of the unique Committee on the Quality of Health Care in America created by the IOM in 1998 in response to the accumulating number of studies documenting that the way in which health care has been delivered has not kept pace with the advances in medical technology and our growing knowledge about diseases and how to effectively treat them. The committee's first report, *To Err Is Human*, was stunning. This report documented that not only was health care often of poor quality, it was actually unsafe. The report said that between 44,000 and 98,000 deaths every year (more than deaths from breast cancer, AIDS, or motor vehicle accidents) were caused by problems in the way the health care system was designed, not from "bad" doctors, nurses, or other health care workers.[2]

The report's message and recommendations for building safer systems of care delivery across the entire U.S. health care system primarily addressed the changes needed at the fourth level of the health care system—where policy, payment, regulation, accreditation, and similar external factors shape the delivery of health care.[a] Within weeks of the report's release, the Senate Committee on Appropriations began hearings on medical errors and patient safety.

As a result of those hearings, Congress directed the Agency for Healthcare Research and Quality (AHRQ) to lead a national effort to combat medical errors and improve patient safety. AHRQ subsequently established a research and demonstration program to fund research to determine the causes of medical errors and to develop models that minimize the frequency and severity of errors; mechanisms that encourage reporting, prompt review, and corrective action; and methods to minimize paperwork.[3]

---

[a] The Committee's second report, *Crossing the Quality Chasm—A New Health System for the 21st Century*, addressed health care quality in all its dimensions: effectiveness, timeliness, patient centeredness, efficiency, and equity (in addition to safety). *Crossing the Quality Chasm* generally spoke to the first and second levels of the health care systems—the experiences of patients with their individual clinicians and the microsystems of care delivery. *To Err Is Human* and *Crossing the Quality Chasm* both directed less attention to the third level—health care organizations.

Nurse Working Conditions

Nursing personnel represent the largest component of the health care workforce. Licensed nurses and unlicensed nursing assistants represent approximately 54 percent of all U.S. health care workers (e.g., physicians, nurses, dentists, allied health professionals, technicians and technologists, and other health care assistants).[4] Registered nurses (RNs) alone constitute approximately 23 percent of the entire health care workforce—the largest portion among all health care workers. These 2.2 million RNs provide health care to individuals in virtually all locations in which health care is delivered—hospitals; long-term care facilities; ambulatory care settings, such as clinics or physicians' offices; and other settings, including the private homes of individuals, schools, and workplaces. In U.S. hospitals, approximately one of every four hospital employees is a licensed nurse.[5] Although constituting the largest contingent in the health care workforce, nurses are in short supply and competition for them is strong.

As part of its portfolio of research and demonstrations, AHRQ contracted with the IOM to study key aspects of the work environment of nurses that likely impact patient safety and identify potential improvements that would likely increase patient safety. AHRQ further directed the IOM to address three issues that have received much attention in Federal and State policy arenas: extended work hours and fatigue, mandatory overtime, and regulation of nurse staffing levels.

The report produced by the IOM in response to this charge, *Keeping Patients Safe: Transforming the Work Environment of Nurses*,[6] is significant for three reasons:

1. It documents the key role that nurses (the largest component of the health care workforce) play in patient safety and makes specific recommendations for changing their work environments to improve patient safety.
2. It highlights the role that an organization's governing boards, executive leadership, other management personnel, and practices play in patient safety by shaping organizational work environments.
3. It identifies generic workplace processes and characteristics that threaten or protect patient safety, not just with respect to nurses' actions, but by affecting the actions of all health care practitioners.

Keeping Patients Safe's recommendations are addressed to those parties that most directly shape work environments: health care organizations, Federal and State regulators, labor organizations, as well as other leaders in health care and nursing education. (The recommendations are reproduced in the section below, "Recommendations for Promoting Patient Safety in the Work Environments of Nurses.") However, individual nurses can also use the recommendations of this report to improve work environments in ways that keep patients safe from errors in their health care. The evidence presented in *Keeping Patients Safe* identifies factors that all nurses should take into consideration in selecting the health care organization in which to be employed, in participating in labor-management discussions, and in interacting in their employing organizations' efforts to reduce health care errors.

Practice Implications

Keeping Patients Safe identifies eight overarching safeguards to protect patient safety that need to be in place within all health care organizations in which nurses work: (1) organizational governing boards that focus on safety; (2) the practice of evidence-based management and leadership; (3) effective nursing leadership; (4) adequate staffing; (5) provision of ongoing

learning and clinical decisionmaking support to nursing staff; (6) mechanisms that promote interdisciplinary collaboration; (7) work design practices that defend against fatigue and unsafe work; and (8) a fair and just error reporting, analysis, and feedback system with training and rewards for patient safety (see Table 1).

Table 1. Necessary Patient Safeguards in the Work Environment of Nurses

Governing Boards That Focus on Safety
- Are knowledgeable about the link between management practices and patient safety.
- Emphasize patient safety to the same extent as financial and productivity goals.

Leadership and Evidence-Based Management Structures and Processes
- Provide ongoing vigilance in balancing efficiency and patient safety.
- Demonstrate and promote trust in and by nursing staff.
- Actively manage the process of change.
- Engage nursing staff in nonhierarchical decisionmaking and work design.
- Establish the organization as a "learning organization."

Effective Nursing Leadership
- Participates in executive decisionmaking.
- Represents nursing staff to management.
- Achieves effective communication between nurses and other clinical leadership.
- Facilitates input from direct-care nursing staff into decisionmaking.
- Commands organizational resources for nursing knowledge acquisition and clinical decisionmaking.

Adequate Staffing
- Is established by sound methodologies as determined by nursing staff.
- Provides mechanisms to accommodate unplanned variations in patient care workload.
- Enables nursing staff to regulate nursing unit workflow.
- Is consistent with best available evidence on safe staffing thresholds.

Organizational Support for Ongoing Learning and Decision Support
- Uses preceptors for novice nurses.
- Provides ongoing educational support and resources to nursing staff.
- Provides training in new technology.
- Provides decision support at the point of care.

Mechanisms That Promote Interdisciplinary Collaboration
- Use interdisciplinary practice mechanisms, such as interdisciplinary patient care rounds.
- Provide formal education and training in interdisciplinary collaboration for all health care providers.

Work Design That Promotes Safety
- Defends against fatigue and unsafe and inefficient work design.
- Tackles medication administration, handwashing, documentation, and other high-priority practices.

Organizational Culture That Continuously Strengthens Patient Safety
- Regularly reviews organizational success in achieving formally specified safety objectives.
- Fosters a fair and just error-reporting, analysis, and feedback system.
- Trains and rewards workers for safety.

Source: Committee on the Work Environment for Nurses and Patient Safety, 2004[6]**:** pages 16-17. Reprinted with Permission.

Keeping Patients Safe's 18 recommendations describe actions health care organizations, governmental policymakers, labor organizations, and other leaders in health care and nursing should take to promote patient safety in nurse work environments. While not directed principally

to individual nurses in clinical practice, the recommendations also can be used by nurses to leverage improvements in patient safety. Specifically, the recommendations have corollary questions (presented in Table 2) that nurses should ask of prospective and current employers.

Table 2. Questions Nurses Should Ask Prospective (and Current) Employers About Patient Safety

Governing Boards That Focus on Safety

1. What are the organization's most recent statistics on patient care errors, near misses, and adverse events?
2. How long has the organization been measuring these, and what do the trends show?
3. What activities does the organization have underway to improve patient safety, and what are the quantitative results of these initiatives to date?
4. Does the governing board review results of measurement of patient safety? How frequently?

Evidence-Based Management Structures and Processes

5. What mechanisms does the organization have in place to enable it to function as a "learning organization," i.e., to internally create and acquire from external sources new knowledge of better health care practices, distribute this knowledge throughout the organization, and change its policies and practices to reflect this new knowledge?

Effective Nursing Leadership

6. What person in the organization represents clinical nursing staff to the organization's governing board and management? What percent of this person's time is dedicated to improving clinical nursing care? Is this person a nurse? Of what senior management structures is this person a part?
7. How much funding and other organizational resources does nursing leadership have in its budget to support nurses' acquisition of knowledge?
8. To what nursing manager will the position in question report? What are the responsibilities of this nurse manager, and what portion of the nurse manager's time is generally spent in each of these responsibilities? What proportion of the nurse manager's time is spent providing supervisory and managerial support to clinical staff? How much time does the nurse manager spend providing direct patient care to his or her assigned caseload?

Adequate Staffing

9. What methods does the organization use to determine safe nurse staffing levels? Can you get a copy of the methodology?
10. What input do clinical nurse staff have in reviewing and modifying the staffing methodology? How frequently are the methodology and its assumptions reviewed?
11. Does the organization count admissions, discharges, and "less than full-day" patients (in addition to a census of patients at a point in time) in its estimates of patient volume for projecting staffing needs?
12. What mechanisms does the organization use to quickly secure additional staffing when need for nurse staffing is higher than anticipated—e.g., an internal float pool, use of staff from external agencies, staffing at higher levels to provide "slack" in the system, other mechanisms? Does the organization avoid use of nurses from external agencies?
13. What roles does clinical nursing staff have in determining admissions and discharges to the unit?
14. What is the nurse turnover rate for the organization? How is this calculated?
15. If an acute care hospital, what are the nurse-patient staffing levels in the intensive care units (ICUs)?
16. If a long-term care facility, is there at least one RN in the facility around the clock, seven days a week?

Organizational Support for Ongoing Learning and Decision Support

17. How does the organization support new graduate nurses and nurses new to the organization? Does it assign preceptors? How long is orientation?
18. What percent of the organization's nursing payroll is dedicated to the ongoing acquisition and maintenance of knowledge of the nursing staff?
19. To what extent does the organization annually ensure that each licensed nurse and nurse assistant has an individualized plan and resources for their educational development?
20. What types of decision support technology does the organization provide to nursing staff?
21. Does the organization use an electronic health record (EHR)? Does the EHR include decision support?

Mechanisms That Promote Interdisciplinary Collaboration

22. What mechanisms (such as interdisciplinary patient care rounds) does the organization have in place to promote interdisciplinary collaboration?
23. Does the organization provide formal education and training in interdisciplinary collaboration for all health care providers?

Work Design That Promotes Safety

24. What are the organization's policies with respect to nursing work hours? Do they prevent direct-care nurses from working longer than 12 hours in a 24-hour period and in excess of 60 hours per 7-day period under both voluntary and mandatory work hours?
25. Has the organization undertaken initiatives to design or redesign the work environment and care processes to reduce errors? What care processes did these initiatives address? Did the design of these efforts directly involve direct-care nurses?
26. Has the organization undertaken initiatives to improve hand washing and the safety of medication administration? When were they conducted and what were the results?

Organizational Culture That Continuously Strengthens Patient Safety

27. What are the organization's short- and long-term safety objectives?
28. How and how frequently does the organization review its success in meeting these?
29. What are the organization's policies and procedures for reporting errors, near misses, and adverse events in care?
30. Does the organization assure a de-identified, fair, and just reporting system for errors and near misses? How does it do this?
31. What are the organization's procedures for analyzing errors and providing feedback to direct-care workers?
32. Does the organization conduct an annual, confidential survey of nursing and other health care workers to assess the extent to which a culture of safety exists?
33. To what extent does the organization provide employee training in error detection, analysis, and reduction?
34. What rewards and incentives does the organization use to reduce health care errors?

Recommendations for Promoting Patient Safety in the Work Environments of Nurses[b]

Recommendations for Transformational Leadership and Evidence-Based Management

Creating work environments for nurses that are most conducive to patient safety will require fundamental changes throughout many health care organizations (HCOs) in terms of how work is designed, how personnel are deployed, and how the very culture of the organization understands and acts on the science of safety. These changes require leadership capable of transforming not just physical environments, but also the beliefs and practices of both nurses and other health care workers providing patient care and those in the HCO who establish the policies and practices that shape those environments—the individuals who constitute the management of the organization.

[b] Reprinted, with permission, from *Keeping Patients Safe: Transforming the Work Environment of Nurses*.[6] ©2004 National Academy of Sciences.

Leadership will need to assure the effective use of practices that (1) balance the tension between production efficiency and reliability (safety), (2) create and sustain trust throughout the organization, (3) actively manage the process of change, (4) involve workers in decisionmaking pertaining to work design and work flow, and (5) use knowledge management practices to establish the organization as a "learning organization." To this end, the committee makes the following recommendations:

Recommendation 4-1.[c] HCOs should acquire nurse leaders for all levels of management (e.g., at the organization-wide and patient care unit levels) who will:

- Participate in executive decisions within the HCO.
- Represent nursing staff to organization management and facilitate their mutual trust.
- Achieve effective communication between nursing and other clinical leadership.
- Facilitate input of direct-care nursing staff into operational decisionmaking and the design of work processes and work flow.
- Be provided with organizational resources to support the acquisition, management, and dissemination to nursing staff of the knowledge needed to support their clinical decisionmaking and actions.

Recommendation 4-2. Leaders of HCOs should take action to identify and minimize the potential adverse effects of their decisions on patient safety by:

- Educating board members and senior, midlevel, and line managers about the link between management practices and safety.
- Emphasizing safety to the same extent as productivity and financial goals in internal management planning and reports and in public reports to stakeholders.

Recommendation 4-3. HCOs should employ management structures and processes throughout the organization that:

- Provide ongoing vigilance in balancing efficiency and safety.
- Demonstrate trust in workers and promote trust by workers.
- Actively manage the process of change.
- Engage workers in nonhierarchical decisionmaking and in the design of work processes and work flow.
- Establish the organization as a "learning organization."

Because HCOs vary in the extent to which they currently employ the above practices and in their available resources, the committee also makes the following recommendation:

Recommendation 4-4. Professional associations, philanthropic organizations, and other organizational leaders within the health care industry should sponsor collaboratives that incorporate multiple academic and other research-based organizations to support HCOs in the identification and adoption of evidence-based management practices.

Maximizing Workforce Capability

Monitoring patient health status, performing therapeutic treatments, and integrating patient care to avoid health care gaps are nursing functions that directly affect patient safety. Accomplishing these activities requires an adequate number of nursing staff with the clinical

[c] For ease of reference, the committee's recommendations are numbered according to the chapter of the main text in which they appear.

knowledge and skills needed to carry out these interventions and the ability to effectively communicate findings and coordinate care with the interventions of other members of the patient's health care team. Nurse staffing levels, the knowledge and skill level of nursing staff, and the extent to which workers collaborate in sharing their knowledge and skills all affect patient outcomes and safety.

Regulatory, internal HCO, and marketplace (consumer-driven) approaches are traditionally advocated as methods to achieve appropriate staffing levels. The committee determined that each of these approaches has limitations as well as strengths; their coordinated and combined use holds the most promise for achieving safe staffing levels. The committee also took particular note of the need for more accurate and reliable staffing data for hospitals and nursing homes to help make these efforts more effective and to facilitate additional needed research on staffing. Finally, the committee identified a need for more research on hospital staffing for specific types of patient care units, such as medical-surgical and labor and delivery units. The committee therefore makes the following recommendations:

Recommendation 5-1. The U.S. Department of Health and Human Services (DHHS) should update existing regulations established in 1990 that specify minimum standards for registered and licensed nurse staffing in nursing homes. Updated minimum standards should:

- Require the presence of at least one RN within the facility at all times.
- Specify staffing levels that increase as the number of patients increase, and that are based on the findings and recommendations of the DHHS report to Congress, *Appropriateness of Minimum Nurse Staffing Ratios in Nursing Homes – Phase II Final Report*.[7]
- Address staffing levels for nurse assistants, who provide the majority of patient care.

Recommendation 5-2. Hospitals and nursing homes should employ nurse staffing practices that identify needed nurse staffing for each patient care unit per shift. These practices should:

- Incorporate estimates of patient volume that count admissions, discharges, and "less than full-day" patients in addition to a census of patients at a point in time.
- Involve direct-care nursing staff in determining and evaluating the approaches used to determine appropriate unit staffing levels for each shift.
- Provide for staffing "elasticity" or "slack" within each shift's scheduling to accommodate unpredicted variations in patient volume and acuity and resulting workload. Methods used to provide slack should give preference to scheduling excess staff and creating cross-trained float pools within the HCO. Use of nurses from external agencies should be avoided.
- Empower nursing unit staff to regulate unit work flow and set criteria for unit closures to new admissions and transfers as nursing workload and staffing necessitate.
- Involve direct-care nursing staff in identifying the causes of nursing staff turnover and in developing methods to improve nursing staff retention.

Recommendation 5-3. Hospitals and nursing homes should perform ongoing evaluation of the effectiveness of their nurse staffing practices with respect to patient safety, and increase internal oversight of their staffing methods, levels, and effects on patient safety whenever staffing falls below the following levels for a 24-hour day:

- In hospital ICUs—one licensed nurse for every two patients (12 hours of licensed nursing staff per patient day).
- In nursing homes, for long-stay residents—one RN for every 32 patients (.75 hours per resident day), one licensed nurse for every 18 patients (1.3 hours per resident day), and one nurse assistant for every 8.5 patients (2.8 hours per resident day).

Recommendation 5-4. DHHS should implement a nationwide, publicly accessible system for collecting and managing valid and reliable staffing and turnover data from hospitals and nursing homes. Information on individual hospital and nursing home staffing at the level of individual nursing units and the facility in the aggregate should be disclosed routinely to the public.

- Federal and State nursing home report cards should include standardized, case-mix–adjusted information on the average hours per patient day of RN, licensed, and nurse assistant care provided to residents and a comparison with Federal and State standards.
- During the next 3 years, public and private sponsors of the new hospital report card to be located on the Federal government website should undertake an initiative—in collaboration with experts in acute hospital care, nurse staffing, and consumer information—to develop, test, and implement measures of hospital nurse staffing levels for the public.

Moreover, the knowledge base on effective clinical care and new health care technologies is increasing rapidly, making it impossible for nurses (and other clinicians) to incorporate this information into their clinical decisionmaking and practice without organizational support. Organizational studies and research on exemplary work environments indicate the importance of investment in ongoing employee learning by employers. The committee therefore makes the following recommendation:

Recommendation 5-5. HCOs should dedicate budgetary resources equal to a defined percentage of nursing payroll to support nursing staff in their ongoing acquisition and maintenance of knowledge and skills. These resources should be sufficient for and used to implement policies and practices that:

- Assign experienced nursing staff to precept nurses newly practicing in a clinical area to address knowledge and skill gaps.
- Annually ensure that each licensed nurse and nurse assistant has an individualized plan and resources for educational development within health care.
- Provide education and training of staff as new technology or changes in the workplace are introduced.
- Provide decision support technology identified with the active involvement of direct-care nursing staff to enable point-of-care learning.
- Disseminate to individual staff organizational learning as captured in clinical tools, algorithms, and pathways.

Finally, in response to evidence on inconsistent interprofessional collaboration among nursing staff and other health care providers, the committee makes the following recommendation:

Recommendation 5-6. HCOs should take action to support interdisciplinary collaboration by adopting such interdisciplinary practice mechanisms as interdisciplinary rounds, and by providing ongoing formal education and training in interdisciplinary

collaboration for all health care providers on a regularly scheduled, continuous basis (e.g., monthly, quarterly, or semiannually).

Design of Work and Workspace To Prevent and Mitigate Errors

Nurses' work processes and workspaces need to be designed to make them more efficient, less conducive to the commission of errors, and more amenable to detecting and remedying errors when they occur. The work hours of a minority of nurses, in particular, are identified as a serious threat to the safety of patients. The effects of fatigue include slowed reaction time, lapses of attention to detail, errors of omission, compromised problem solving, reduced motivation, and decreased energy for successful completion of required tasks. Other safety-sensitive industries have acknowledged and taken action to defend against these effects by limiting the number of shifts or hours worked in a week.

Changing work patterns will require attention from HCOs, regulatory bodies, State boards of nursing, schools of nursing, and nurses themselves. Accordingly, the committee makes the following recommendation:

Recommendation 6-1. To reduce error-producing fatigue, State regulatory bodies should prohibit nursing staff from providing patient care in any combination of scheduled shifts, mandatory overtime, or voluntary overtime in excess of 12 hours in any given 24-hour period and in excess of 60 hours per 7-day period. To this end:

- HCOs and labor organizations representing nursing staff should establish policies and practices designed to prevent nurses who provide direct patient care from working longer than 12 hours in a 24-hour period and in excess of 60 hours per 7-day period.
- Schools of nursing, State boards of nursing, and HCOs should educate nurses about the threats to patient safety caused by fatigue.

Enabling nursing staff to collaborate with other health care personnel in identifying high-risk and inefficient work processes and workspaces and (re)designing them for patient safety and efficiency is also essential. Moreover, documentation practices are in great need of redesign. However, this cannot be accomplished solely by nursing staff and internal HCO efforts. As many documentation practices are driven by external parties, such as regulators and oversight organizations, these entities will need to assist in the redesign of documentation practices. To address these needs, the committee makes the following recommendations:

Recommendation 6-2. HCOs should provide nursing leadership with resources that enable them to design the nursing work environment and care processes to reduce errors. These efforts must directly involve direct-care nurses throughout all phases of the work design and should concentrate on errors associated with:

- Surveillance of patient health status.
- Patient transfers and other patient hand-offs.
- Complex patient care processes.
- Non–value-added activities performed by nurses, such as locating and obtaining supplies, looking for personnel, completing redundant and unnecessary documentation, and compensating for poor communication systems.

Recommendation 6-3. HCOs should address handwashing and medication administration among their first work design initiatives.

Recommendation 6-4. Regulators, leaders in health care; and experts in nursing, law, informatics, and related disciplines should jointly convene to identify strategies for safely reducing the burden associated with patient and work-related documentation.

Creating and Sustaining a Culture of Safety

Employing a nursing workforce strong in numbers and capabilities and designing their work to prevent errors will not be sufficient to fully safeguard patients. The largest and most capable workforce is still fallible, and the best-designed work processes are still designed by fallible individuals. Patient safety also requires an organizational commitment to vigilance to prevent potential errors, and to the detection, analysis, and redress of errors when they occur.

A variety of safety-conscious industries have made such a commitment and achieved substantially lower rates of errors by doing so. These organizations place as high a priority on safety as they do on production; all employees are fully engaged in the process of detecting high-risk situations before an error occurs. Management is so responsive to employees' detection of risk that it dedicates time, personnel, budget, and training resources to bring about changes needed to make work processes safer. Employees also are empowered to act in dangerous situations to reduce the likelihood of adverse events. These attitudes and employee engagement are so pervasive and observable in the behaviors of these organizations and their employees that an actual *culture of safety* exists within the organization. These organizational cultures are effective because they (1) recognize that the majority of errors are created by systemic organizational defects in work processes, not by blameworthy individuals; (2) support staff; and (3) foster continuous learning by the organization as a whole and its employees.

HCOs should redouble their efforts to create such cultures of safety within their work environments. Such efforts require a long-term commitment because they necessitate changes in the attitudes and behaviors of both organizations and people. Time is needed to enact an initial change, evaluate, refine, and enact further change. Strong organizational leadership is also essential. The safety of patients needs to be a stated and visible priority, with every organizational member understanding that each is fallible, even with the best of intentions, as are the processes used. Moreover, establishing a fair and just culture in responding to errors reduces workers' fear and disincentives to report errors and near misses. As a result, nursing staff is more inclined to be vigilant for errors and near misses, with a view toward learning from each event and strengthening the culture of safety accordingly. Action also is needed from State boards of nursing and Congress to enable strong and effective cultures of safety to exist. To these ends, the committee makes the following recommendations:

Recommendation 7-1. HCO boards of directors, managerial leadership, and labor partners should create and sustain cultures of safety by implementing the recommendations presented previously and by:

- Specifying short- and long-term safety objectives.
- Continuously reviewing success in meeting these objectives and providing feedback at all levels.
- Conducting an annual, confidential survey of nursing and other health care workers to assess the extent to which a culture of safety exists.
- Instituting a de-identified, fair, and just reporting system for errors and near misses.
- Engaging in ongoing employee training in error detection, analysis, and reduction.

- Implementing procedures for analyzing errors and providing feedback to direct-care workers.
- Instituting rewards and incentives for error reduction.

Recommendation 7-2. The National Council of State Boards of Nursing, in consultation with patient safety experts and health care leaders, should undertake an initiative to design uniform processes across States for better distinguishing human errors from willful negligence and intentional misconduct, along with guidelines for their application by State boards of nursing and other State regulatory bodies having authority over nursing.

Recommendation 7-3. Congress should pass legislation to extend peer review protections to data related to patient safety and quality improvement that are collected and analyzed by HCOs for internal use or shared with others solely for purposes of improving safety and quality.

Research Implications

Finally, the committee notes that changing health care delivery practices to increase patient safety must be an ongoing process. Research findings and dissemination of practices that other HCOs have found successful in improving patient safety will help HCOs as learning organizations add to their repertoire of patient safety practices. This report calls attention to several areas in which, at present, information is limited about how to design nurses' work and work environments to make them safer for patients. Research is needed to provide better information on nursing-related errors, means of achieving safer work processes and workspace design, a standardized approach to measuring patient acuity, information on safe staffing levels for different types of patient care units, effective methods to help night shift workers compensate for fatigue, information on what limits should be imposed on successive days of working sustained work hours, and collaborative models of care. Accordingly, the committee makes the following recommendation:

Recommendation 8-1. Federal agencies and private foundations should support research in the following areas to provide HCOs with the additional information they need to continue to strengthen nurse work environments for patient safety:

- Studies and development of methods to better describe, both qualitatively and quantitatively, the work nurses perform in different care settings.
- Descriptive studies of nursing-related errors.
- Design, application, and evaluation (including financial costs and savings) of safer and more efficient work processes and workspace, including the application of information technology.
- Development and testing of a standardized approach to measuring patient acuity.
- Determination of safe staffing levels within different types of nursing units.
- Development and testing of methods to help night shift workers compensate for fatigue.
- Research on the effects of successive work days and sustained work hours on patient safety.
- Development and evaluation of models of collaborative care, including care by teams.[d]

Conclusion

Nurses are in a key position to improve patient safety, not just through their individual patient care actions as clinicians, but by exercising their leverage as much-desired employees in the labor marketplace. If nurses ask the above questions of their prospective employers, and incorporate the responses they receive into their selection of their place of employment, they will be able to exert significant influence within the health care system, as health care organizations come to appreciate the ability to recruit nurses as an additional important reason for making the types of organizational changes needed to provide safe patient care.

Chapter 23. Patient Acuity

Bonnie M. Jennings

Background

For more than 50 years, researchers have worked to develop staffing methodologies to accurately indicate the number of nurses needed to give good care to patients.[1] By the 1980s, patient classification systems (PCSs) were in common use to predict patient requirements for nursing care. These requirements, or patient acuity, could then be used to manage nursing personnel resources, costs, and quality.[2, 3]

PCSs have numerous limitations, however. Paramount among these are (a) validity and reliability are infrequently monitored;[4, 5] (b) the tools are often complex and require considerable time to complete;[4] (c) they lack credibility among staff nurses and administrators;[5, 6] (d) they are not designed to detect census variability throughout the day from patient movement due to admissions, discharges, transfers, and short-stays;[7, 8] and (e) their focus on tasks shortchanges the cognitive work and knowledge inherent to expert nursing care and sophisticated surveillance.[9, 10]

As restructuring and mergers escalated in the 1990s, issues of patient acuity once again moved to the foreground. Patients were said to be sicker and leaving health care facilities more quickly. Concerns about rising patient acuity continue into the new millennium because of the relentless change that is now common in health care. Moreover, acuity is one of many elements that comprise the often used but not yet well specified concept of workload.[11, 12]

Research Evidence

In assessing the research conducted between 1995 and 2005 about patient acuity, three things stand out. First, most of the research reports are about developing or comparing instruments to measure patient acuity. Unlike early PCSs that were designed for medical-surgical patients in acute care facilities, these instruments are tapping into other care settings such as long-term care,[13–17] home care,[18, 19] emergency departments (EDs),[20–28] and neurological rehabilitation centers,[29–33] to name but a few. There is little evidence, however, regarding the extent to which these tools are being used.

Second, most reports simply mention that patient acuity is increasing without supporting data. Only four studies actually examined trends in patient acuity to empirically substantiate perceptions that acuity is rising. Interestingly, these investigations were all conducted outside the United States. PCS scores were compared over 3 months in 1996 and the same period in 1999 for critical care patients in one Australian hospital.[34] Acuity varied by shift (day, evening, night), with the evening shift demonstrating the highest patient acuity. Although the PCS scores followed similar patterns in 1996 and 1999, the PCS scores were higher for all shifts in 1999.

Monthly PCS data from 17 units in a Swedish hospital indicated that average scores in each of four acuity categories increased from 1995 to 1996.[35] The investigators concluded that patients were sicker and their treatments more time consuming. However, they also demonstrated discrepancies between actual and required staff, with the actual staff consistently lower than required. This gap has also been observed in U.S. hospitals.[6] In a Canadian study from Ontario, case-mix data were examined for all acute care hospitals from 1997 to 2002.[36] After controlling

for age, it was evident that the average inpatient case-mix index (CMI) increased by 17 percent over the 5 years of data that were examined. The least complex patients declined by 24 percent, and the most complex patients increased by 144 percent, representing an overall increase of 211 percent for the most complex patients. The fourth study examined care needs for long-term-care (LTC) residents in Alberta, Canada, between 1988 and 1999.[37] The data demonstrated an increase in residents needing greater help with activities of daily living and more intervention for difficult behaviors such as dementia.

Finally, studies were rarely designed to assess patient acuity in relation to patient outcomes. Of those shown in Table 1, three evaluated heterogeneous groupings of patients in acute care settings.[38–40] An additional three studies examined acuity in more homogeneous patient populations. One study focused exclusively on critical care patients,[41] and another considered only obstetrical care for teenagers.[42] Acuity was also examined in relation to patient outcomes in the ED.[43]

Evidence-Based Practice Implications

There is little empirical evidence about the relationship between acuity and patient safety, making the practice implications from these studies modest. Although three studies showed a positive association between acuity and adult mortality,[38, 40, 41] findings were more equivocal for the relationship between acuity and neonatal mortality rates.[42] This latter study illustrated that factors other than acuity were more predictive of outcomes, particularly weekend births and ethnicity or race. The investigators who studied critical care patients concluded that variations in mortality might be partially explained by excess workload.[40]

Findings from the studies involving a variety of inpatients were not consistent. As expected, the two studies using the same dataset[38, 40] both showed similar results—a positive relationship between acuity and adverse outcomes such as infections and decubiti, but not medication errors and falls. The third study was conducted on 32 units in a different hospital.[39] Data were collected for a full year. Although the association between hours of nursing per patient day was statistically significant ($r = .60$; $P < .05$), the relationship between acuity and adverse outcomes was not examined. Rather, acuity was a significant predictor of various self-care measures such as symptom management.

The ED study assessed patient satisfaction as the outcome measure.[43] Although this work did not provide evidence about outcomes related to patient safety, it did illustrate how patient perceptions come into play regarding features of care delivery. Patients whose acuity placed them in the ‘emergent’ category were more satisfied with their care than patients in either the ‘urgent’ or ‘routine’ acuity groups. However, when perceived throughput time was controlled, acuity did not predict satisfaction with ED care. The importance of patient perceptions was clearly in effect in determining satisfaction.

Research Implications

At present, very little is known about the relationship between acuity and outcomes. The lack of a standardized approach to measuring acuity has broad research implications. For investigations using PCSs, reports need to include information about the psychometric properties of the tools. It would also be helpful to examine the relationship of PCS acuity to clinical outcomes using more homogeneous patient groupings.

Perhaps the most important research issues concern greater clarity about the larger concept—workload. There is an urgent need to develop a conceptual model illustrating the relationships of the various elements comprising workload as well as a standardized definition of workload. Empirical testing of the model might then better elucidate how acuity, as one aspect of workload, relates to patient safety.

It would also be very helpful if U.S. studies were conducted to ascertain whether the perceptions of increased acuity are verifiable. It would be most beneficial if these studies looked not just at acuity in the aggregate, but also at acuity for homogeneous patient populations. This could help clarify whether acuity for medical-surgical patients has escalated. Finally, it would be useful to have a sense of acuity in the outpatient setting, given how patient care has shifted. Although outpatient acuity is particularly difficult to capture, it remains a research challenge for the future.

Conclusion

Patient acuity is a concept that is very important to patient safety. Presumably, as acuity rises, more nursing resources are needed to provide safe care. Very little research has actually been conducted, however, to verify this premise. Moreover, findings from the research that has been conducted are largely inconsistent. Design issues account for these differences. In addition, it is possible that factors other than patient acuity may contribute more to patient outcomes. It remains important to derive a much better grasp of the relationship between patient acuity, outcomes, and patient safety. At present, little can be said with confidence about this association.

Search Strategy

The literature for this review was identified by searching the MEDLINE® and CINAHL® databases from 1995 to 2005 for research-based articles published in the English language. A reference librarian assisted in choosing the search terms. In the CINAHL® search, the terms were "patient acuity" or "patient classification." This yielded 345 citations. The MEDLINE® search was tried four times using various combinations of terms such as "patient acuity," "patient classification," "severity of illness index," "acute disease classification" and "diagnosis related groups." The combined efforts of the four searches resulted in identifying 98 references.

The abstracts for all 443 citations were reviewed. Of these, 104 were considered to be potential candidates for use in this review. The references that were excluded from this assessment included a wide array of topics that were irrelevant to patient acuity. The diversity of these articles is too great to provide a complete view of them, but a few examples include quality of life, menstrual cycle abnormalities, blood pressure variability, and fever management for children.

After reading the 104 candidate articles in their entirety, an additional 72 papers were omitted from the remainder of the analysis. Papers were excluded because they were more tangentially related to patient acuity (e.g., indicators of patient dependency), they were reviews of literature, or they did not focus on patients per se (e.g., a way to classify school-age children with disabilities). As a result, this review was based on findings from 32 research reports.

Table 1. Evidence on Patient Acuity

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Blegen 1998[38]	Inpatient outcomes (acuity was measured by the monthly reports derived from the hospital's acuity system)	Cross-sectional	Design: Level 3 Patient outcomes: deaths, rates of falls, medication errors, decubiti, urinary tract and respiratory infections (Level 1), complaints	42 inpatient units in an 880-bed hospital during FY 1993 (prior to restructuring); 21,783 discharged patients; 1,074 full-time equivalent nursing staff members, 832 of whom were RNs		In bivariate correlations, acuity was negatively associated with medication errors and falls, and positively correlated with infections, decubiti, complaints, and death.
Boudreaux 2004[43]	ED patients (acuity was measured by triage categories assigned by trained nurses—emergent, urgent, routine)	Cross-sectional	Design: Level 3 Patient outcomes: satisfaction (Level 4)	1,865 patients over 1 month at a large inner-city hospital ED Patients: average age 30 years; 53% female		Patients with higher acuity were more satisfied with care and perceived their throughput time more favorably; satisfaction was more closely linked to perceived throughput times than to actual throughput times or acuity.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Hamilton and Restrepo 2003[42]	Neonatal deaths preventable in the perinatal period (acuity was measured using maternal medical risk factors such as hypertension, anemia, previous birth of an infant who was preterm or small for gestational age)	Cross-sectional	Design: Level 3 Patient outcomes: mortality (Level 1)	All births to teenage mothers (< 20 years of age) in Texas in 1999 and 2000 (N = 11,749) with a focus on neonatal deaths (prior to the 28th day of life) (n = 397); mean neonatal mortality/1,000 live births = 3.6; Hispanic (56%), White (27%), African American (15%), other (2%)		Neonatal mortality rates differed significantly between weekdays and weekends (odds ratio [OR] = 1.42, 95% CI = 1.14–1.76, *P* = 0.001). When ethnicity and or race were examined with day of the week, a statistically significant difference was found for births to Hispanic teens (OR = 1.728, 95% CI = 1.275–2.342, *P* < 0.001). Differences in acuity did not fully explain higher weekend neonatal mortality rates.
Potter 2003[39]	Patient outcomes (after adjusting for acuity)	Cross-sectional	Design: Level 3 Patient outcomes: fall and medication error index (Level 1); self-reports of symptom management, self-care, health status; patient satisfaction	32 inpatient units in one hospital from 2000 to 2001; 3,418 patients		Unit data were aggregated to create yearly data due to small numbers for some variables. Acuity was a significant predictor of the self-care measures of importance and understanding, and indexes of self-care symptom management.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Reed 1998[40]	Adverse occurrences among inpatients (acuity was measured by an institutionally standardized measure; average daily acuity/month was used)	Cross-sectional	Design: Level 3 Patient outcomes: deaths, pressure ulcers, nosocomial infections, medication administration errors (Level 1), complaints	42 inpatient units in an 880-bed hospital during FY 1993 (prior to restructuring). This was a secondary data analysis of a mix of units: 5 surgical; 10 medical; 3 obstetrical; 8 pediatric; 4 critical care; 4 psychiatric; 2 eye, ear, nose; 6 orthopedic and neuroscience.		Deaths, pressure ulcers, infections, patient complaints were positively intercorrelated and positively correlated to patient acuity. When patient acuity was controlled, these adverse outcomes seemed to share a common underlying characteristic indicating something other than acuity, such as the quality of care.
Tarnow-Mordi 2000[41]	Staff workload (after adjusting for risk using the APACHE II; workload was defined by average nursing requirement per occupied bed and peak occupancy)	Prospective cohort	Design: Level 3 Patient outcome: hospital mortality (Level 1)	1,050 patients admitted to an adult ICU in Scotland between January 1, 1992, and December 31, 1995. Patients: Age, 16 to $\geq$70, with 43% of the patients in the $\geq$ 70 age group58% male		Predicted mortality was calculated using the APACHE II. The 337 hospital deaths were 49 more than predicted by APACHE II (95% CI = 34–65). Adjusted mortality was more than two times higher (OR = 3.1, 95%CI = 1.9–5.0) for patients exposed to high ICU workload.

Chapter 24. Restructuring and Mergers

Bonnie M. Jennings

Background

During the first half of the 20th century, there was a huge increase in the number of free-standing general hospitals in the United States.[1] At that time, registered nurses (RNs) typically practiced in hospitals. Consequently, there are strong parallels between the evolution of the nursing profession and the growth of hospitals as the central structure in the U.S. health care system.[2] By the 1980s, however, a variety of initiatives were implemented for the purpose of curtailing the rapid rise in health care costs.[3, 4] Based upon the assumption that hospital care was very expensive, cutting inpatient care was a central strategy in the attempt to control the cost of health care.[5] Moreover, the focus on fiscal challenges shifted the health care industry into a business mode that substantially altered the experiences of patients, as well as the roles of health care personnel.[6]

Cost-cutting initiatives over the past 20-odd years contributed to tremendous turmoil in health care. The initiatives were often introduced concurrently and without empirical evaluations to determine their effectiveness. Among the early initiatives was a prospective payment system based upon Diagnosis Related Groups (DRGs), which differed from the historical system of retrospective payments that covered all services rendered. DRGs established fixed prices for care based on set criteria, such as diagnosis, therapy, and discharge status. These fixed prices altered hospital reimbursements, which in turn changed their incentives. As a result, for example, lengths of stay were shortened. Patients with complex care needs moved through the inpatient care setting much more rapidly than in the past, giving rise to the phrase “sicker and quicker” to reflect this dramatic change. In addition, preauthorization was implemented to reduce hospital use. Together, DRGs and preauthorization provided the impetus to shift care from the hospital to the outpatient setting and the home.

Fewer inpatients required fewer staff. Reductions in hospital personnel helped to reduce labor costs; they also raised concerns about the effects of staffing on quality of care and nurses’ job satisfaction.[7] By the year 2000, although the hospital remained the primary place of employment for RNs, 40 percent of RNs worked in other settings.[8] This represented a significant shift over 25 years.

Also contributing to the turmoil in health care during the 1980s was the rapid growth in managed care. All types of managed care programs attempted to control costs by decreasing unnecessary use of health care. To support this goal, primary care physicians assumed a more dominant role in health care by becoming “gatekeepers,” allocating health care resources such as referrals to specialists.

Managed care also prompted the integration of health services and providers. Through horizontal integration, free-standing hospitals merged into multihospital systems owned by central organizations (e.g., Humana), and physicians in private practices joined group practices. Through vertical integration, a broad array of services covering the care continuum—from ambulatory care to long-term care—were pulled together into comprehensive delivery systems.[4] Ideally, these mergers helped to streamline functions, reduce administrative redundancy, and negotiate reduced rates when purchasing supplies, equipment, and pharmaceutical products.

These often radical changes proceeded, however, with little empirical evidence to guide them. Evaluations were uncommon, and those that were conducted could not keep pace with the speed of changes resulting from restructuring and mergers. A report from the Institute of Medicine[9] concluded that despite enormous organizational turmoil, little progress was made toward restructuring health care systems in ways that meaningfully addressed quality and cost concerns. Likewise, a critical review of restructuring studies found mixed signals about what was accomplished through these organizational changes.[3] According to Aiken and colleagues[10] (p. 463), "What we know about changes in organization and structure and the potential for those changes to affect patient outcomes pales by comparison to what we do not know."

Assessments about how restructuring and mergers affected patients and staff are more a look through the rearview mirror because they occurred after the fact. Nonetheless, the findings are informative, especially when considered in the context of current changes such as recent growth in hospital construction.[11] Today, ongoing change, not stability, is the order of the day for health care. Lessons from the past can be used as a platform for more proactive responses to future changes.

Research Evidence

The findings from studies of restructuring can be grouped in numerous ways. A summary of the findings is presented in Table 1. These studies represent work conducted internationally, but predominantly in the United States and Canada. Most of the evidence came from assessments of restructuring in acute care settings.[10, 12–48] Although hospital restructuring altered care delivered in other settings, little research was found that looked outside acute inpatient care. Exceptions were assessments of outpatient care following restructuring in the Department of Veterans Affairs (VA),[49, 50] an evaluation of increasing home care needs in Canada,[51] and an examination of overcrowding in an emergency department following restructuring.[52]

Studies typically addressed employee perceptions of restructuring. Overall, the changes that occurred through restructuring processes were viewed unfavorably. Most studies considered the effect of restructuring on staff nurses.[10, 12–21, 23, 25–27, 29–31, 34, 35, 38–44, 47, 48] Other health care professions such as physical therapists[33] and social workers[36] also explored how restructuring affected their respective roles. A few investigations considered restructuring from the perspective of nurses in administrative positions at the patient unit and executive levels.[12, 22, 24, 32, 38, 43] One investigation examined the views of top and middle managers from various disciplines at one VA hospital, as well as physicians and patients.[53] A pair of related investigations considered restructuring as viewed by chief executive officers.[45, 46] An important finding among these studies was that although strong leadership is essential in times of change, staff nurses' assessment of nurse managers' abilities declined considerably between 1986 and 1998, as did the perception of nurse executive power.[10]

Few studies explored ways to mitigate the deleterious effects of restructuring. There is beginning evidence, however, that empowerment[32] and leadership style[20] may reduce burnout and increase job satisfaction. One study explicitly examined rebuilding after restructuring.[24] Staffing changes were central to the rebuilding efforts, especially increases in licensed personnel and senior support staff, and decreases in part-time, temporary, agency, and contract nurses. In three studies that examined cost, results reflected increased costs at both the unit level[13] and the hospital level[45, 46] suggesting that restructuring did not achieve its intended purpose.

The majority of studies examined the relationship between restructuring and job satisfaction. Regardless of professional discipline, there was a decline in job satisfaction after restructuring.[13, 15, 18–21, 23, 30, 32, 33, 36, 45] Aspects of burnout were also frequently explored.[19–21, 32, 48] Findings consistently showed burnout was increasing, particularly emotional exhaustion, which is viewed as the core feature of burnout. Along with evaluating psychological health, studies began to detect a relationship between restructuring and increased musculoskeletal injuries.[14, 29, 42]

Restructuring can occur within a single institution, while mergers involve integrating two or more institutions. A cluster of studies explicitly addressed various aspects of mergers.[54–62] Findings from three studies verified that the success of mergers was enhanced by engaging staff from the merging institutions in the process.[54, 56, 57] Other investigations evaluated various responses of nursing staff to mergers.[58–60] In a merger involving three hospitals, for example, Jones[59] found that uncertainty about job status and feeling unappreciated minimized nurses' organizational commitment. Other studies examined mergers from the standpoint of factors effecting financial performance,[61] midwifery practice,[62] and the integration of two emergency departments.[55]

A number of investigations relied exclusively on qualitative methods to explore restructuring and mergers.[16, 17, 25, 27–29, 32, 34, 40, 53, 54, 60, 62] Themes across these studies help to edify potential sources of job dissatisfaction and burnout. For example, participants commented that restructuring altered work relations in undesirable ways,[16, 25, 27, 53, 62] including relations with management,[32] that contributed to staff distrust of the employing organization.[25, 54] Participants also identified changes in work life related to increased responsibilities, decreased resources, and overall busyness.[25, 27, 29, 32, 34, 62]

In two studies, themes emerged indicating that staff viewed restructuring as detrimental to the quality of care.[27, 32] In another two investigations, in which both patients and health care professionals were interviewed, findings indicated that patients had fewer complaints about the changes than did the hospital staff.[34, 53]

A few studies considered the effects of restructuring on quantifiable patient outcomes;[10, 13, 18, 30, 37, 42, 49, 50] two of these investigations related to outpatient care.[49, 50] The paucity of studies exploring patient outcomes related to restructuring illustrates that staff response has been the focus of most restructuring and merger studies. Although no causal connections have been demonstrated, beliefs and assertions hold that staff characteristics do affect patient outcomes. For example, recent findings show emotional exhaustion among nurses is associated with higher patient morality.[63]

Nevertheless, the staff-focused studies do not help to inform patient care per se. Moreover, the concerns addressed a decade ago by Ingersoll[26] persist—many studies are reported in journals geared to audiences that are more interested in application than scientific rigor. There is a continued need for studies with more sophisticated designs to better inform the science of patient safety. These needs expose the potential for better informing practice by combining health services research techniques with nursing research inquiries.

Table: Summary of Research Evidence Related to Restructuring and Mergers

Care setting	• Most studies evaluated restructuring and mergers in acute care settings.
Effect on costs	• Increased unit level costs. • Increased hospital level costs.
Effect on staff nurses	• Decreased job satisfaction. • Increased burnout, especially emotional exhaustion. • Increased musculoskeletal injuries.
Common sources of job dissatisfaction and burnout	• Undesirable changes in work relations, including relations with administrators, that fostered organizational mistrust. • Increased work responsibilities. • Decreased resources.
Ways to reduce the undesirable effects of restructuring and mergers	• Empowerment. • Empathetic leadership style. • Staffing changes—more licensed personnel and senior support staff; fewer part-time, temporary, agency, and contract nurses.
Effect on patient outcomes	• Results are conflicting about patient mortality. • Indicator data (e.g., falls, nosocomial infections, medication errors) vary over time, making it important to track trends. • Indicator data differ when assessed at the hospital level, the unit level, and by unit type (e.g., medical or surgical). • Overall, the evidence is scattered and inconsistent.

Evidence-Based Practice Implications

The 11 studies in Table 2 illustrate findings pertinent to patients as well as staff regarding likely connections between restructuring and patient safety. The setting for studies that met inclusion criteria was most often acute care,[10, 18, 20, 21, 32, 43, 46, 48] with research focused on outpatients[40, 50] and home care[51] also represented. Overall, however, the evidence is scattered and, at times, inconsistent. As a consequence, there are few solid implications for practice.

Patient mortality showed conflicting results. Increases in mortality were found in aggregated data from hospitals throughout the United States,[10] and decreases were found based on data from more than 2,000 patients at a single hospital.[18] A study of VA outpatients showed no statistically significant differences in mortality between patients who saw a physician for symptoms and patients who were not seen.[50]

Indicator data for falls, medication errors, nosocomial infections, and intravenous complications were examined in an 18-month longitudinal study of four medical-surgical units at one hospital.[18] The four indicators were assessed for more than 2,500 patients at four points in time. Although descriptive data reflected patternless variations in the indicators, all indicators were increasing at 18 months. The investigators noted, however, that when indexed by rate of occurrence per 100 patients, all four indicators either improved or remained unchanged.

Sovie[43] collected data from 29 university teaching hospitals in eight of the nine U.S. census regions. More than findings about the individual patient outcomes, this study illustrated important variations depending upon how data were aggregated. That is, data aggregated at the hospital level differed from data at the unit level. More striking, findings varied by unit type—medical or surgical. For falls, pressure ulcers, and urinary tract infections (UTIs), the rates were always lower on surgical units than medical units. This may have important implications for practice related to staffing considerations.

Berlowitz[49] led a study of pressure ulcers among residents of long-term care units at 150 VA medical centers nationwide. This study illustrated that, as care shifted from a focus on hospital-based specialty care to outpatient primary care, pressure ulcers increased, even after risk adjustment. Conversely, in a study from a single VA facility in California, Rubenstein and colleagues[50] demonstrated that the shift to outpatient care yielded improvements in continuity of care and preventive care related to smoking, exercise, detection of depression, and the number of individuals with hypertension receiving treatment.

The final study involving a patient focus examined home care needs for patients after hospitals closed beds.[51] Not only did more patients need care after discharge, but service intensity also increased. The intensity diminished in the second week after discharge. Although findings from single studies do not warrant practice changes, the effects of restructuring on home care needs remains an important consideration for patient safety.

The studies that evaluated various staff response to restructuring displayed a much clearer pattern to their findings—restructuring was associated with negative effects on staff.[21, 32, 48] Interested in mitigating these effects, Cummings and colleagues[20] tested a model that examined leadership style. Empathy was a critical leadership competency that served to offset the negative effects of restructuring. It was characterized by individuals who listened and responded to employee concerns.

Finally, Walston and colleagues[46] evaluated changes in hospital costs during restructuring efforts. They found that restructuring altered work processes by changing the workflow and job responsibilities. This exerted a negative influence by increasing hospital costs relative to competitors.

Research Implications

Given the current evidence, we know that reducing inpatient care as the central strategy for controlling the cost of health care has not succeeded. We know that staff report being dissatisfied with their job conditions. We also know there is no consistent pattern in the few studies that have examined the effect of organizational change on patient outcomes. Furthermore, we know that change in health care organizations is likely to continue.

Consequently, there are large gaps in knowledge about restructuring and mergers. It is not feasible to provide a comprehensive list of areas for future study. However some general notions can be outlined. A fundamental premise is that health care leaders must seriously consider which changes to implement and the best processes for introducing changes into their organizations. In addition, they need to evaluate changes—not just implement them. The evaluations need to be sufficiently comprehensive so that organizational goals (e.g., costs) do not overshadow examination of the effects of change on staff and patients. These studies also need to be longitudinal, to track the effects of restructuring over time. This strategy will help to fill the void about the effects of restructuring on patient safety.

Moreover, if existing care delivery structures are not effective, then a central question concerns how best to organize care. For example, if the Institute of Medicine's aims for the 21st-century health care system are still appropriate,[9] then what structures will lead to care that is safe, effective, patient-centered, timely, efficient, and equitable? Continuity of care before and after restructuring and mergers is an aspect of care that could benefit from in-depth exploration because it could contribute to improvements in each of the desired aims. Acute care, outpatient

care, and home care have all been affected by restructuring. What mechanisms could be introduced to enhance continuity from unit to unit and across the care continuum?

Many studies of restructuring follow a sociological view of organizations; a psychological framework has been used less often. Human relations—among both staff and patients—are central to caregiving organizations. Kahn[64] asserts that interpersonal transactions are at the core of caregiving organizations. He believes that resilient organizations have members who are able to learn and grow, even in difficult environments. Resilient organizations are better able to absorb stress and maintain the capacity to function effectively. Therefore, regardless of the structure, health care organizations would benefit from investigations that examine interpersonal conditions at work. Interventions could then be developed to help staff improve relationships with one another and work together more effectively. To date, studies have not examined the effects of restructuring on the dynamics among caregivers and between caregivers and patients. In addition, leadership as a linchpin of relationships between staff and administrators begs to be better understood.

From the perspective of patient outcomes, however, we know very little. There is no discernible pattern in existing findings; there is no meaningful statement that can be made. The impact of restructuring on patient safety remains unknown. Measurement and methods questions are important considerations to enhance that understanding—which indicators to use, how they are defined, how they are measured, what the unit of analysis is. Decreased resources, including sufficient staff, surfaced as a concern in studies of restructuring. It would be beneficial to assess different care structures, determine the work that needs to be done, determine who needs to do it, provide the proper type and number of staff to do the work, and then assess which organizational structures yield the best opportunity for providing safe care to patients.

It would also be extremely useful to pursue a series of qualitative studies to better depict the current state of health care organizations. Data could be collected from staff at all levels of individual organizations as well as vertically and horizontally integrated systems of care. Data could also be collected from patients getting care in different venues, including the home. Family member perspectives would be valuable, too. Such studies would be very complex and difficult, but they could elucidate key issues and concerns. These could then be used to construct interventions or guide future restructuring efforts.

This is just the beginning of an almost endless list of ideas that could be studied to advance the understanding of restructuring and mergers. Future endeavors need to be more proactive in assessing organizational change early in the change process. They also need to approach questions over time, using a comprehensive set of variables, as well as sophisticated methodological and statistical techniques, to truly advance the understanding of restructuring on the staff as well as patient safety.

Conclusion

As reflected in the Table (see above), most studies of restructuring and mergers have been conducted in acute care settings. Many of these studies have examined the effects of restructuring and mergers on cost, staff nurses, and patient outcomes. In the aggregate, restructuring and mergers did not achieve the desired reductions in cost. However the upheaval accompanying restructuring efforts and mergers can be related to lower job satisfaction among nurses and increased burnout. The effects of restructuring and mergers on patient care, however,

are more difficult to understand because the evidence varies over time, by hospital or unit, and by unit type.

There is convergence in findings about sources of job dissatisfaction and burnout related to restructuring and mergers. Organizational and unit leaders would be wise to carefully assess work relations, work responsibilities, and the availability of resources, all of which may be sources of dissatisfaction and burnout. It would also behoove the leaders to consider the evidence that illustrates ways to minimize the undesirable effects of restructuring and mergers. These include empowerment, empathetic leadership, and staffing changes that increase the number of licensed nurses who are employed by the institution.

Search Strategy

A reference librarian assisted in running database searches in both MEDLINE® and CINAHL® to identify literature for this review. Both databases were searched from 1995 to 2005, using the same two MESH headings: hospital restructuring and health facility mergers. The searches were limited to research reports published in the English language. A total of 149 potential publications were identified, 56 in MEDLINE® and 93 in CINAHL®. Based upon an assessment of the abstracts, 67 of the publications were regarded as being suitable for inclusion in this review. The 82 papers that were omitted were a combination of brief reports or abstracts, topics not suitable to this review (i.e., mental health triage tools), and doctoral dissertations.

After reading the 67 publications in their entirety, 14 were omitted from further consideration. Some of these papers, for example, were only tangentially related to restructuring and mergers, a few were redundant publications, and others were about instrument development. This review is therefore based on 53 research reports.

Acknowledgment

Tremendous gratitude is expressed to the staff of the Armed Forces Medical Library, Falls Church, VA, for their considerable support of this work. They conducted the database searches and assisted in acquiring numerous papers considered in this review.

Evidence Table: Restructuring and Mergers

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Aiken 2000[10]	Staffing	Cross-sectional	Design: Level 4; Patient outcomes: mortality (Level 1)	Hospitals throughout the United States, 646 CEOs, 2,000 nurses, patient data from American Hospital Association and Health Care Financing Administration databases	Restructuring: personnel reductions via attrition (69%), cross-training (84%), skill mix reductions (60%), reassignment of support services (60%), redistribution of patients on nursing units (42%); reduction of management positions (54% by layoffs, 70% by attrition)	57% of hospitals had restructured; 12 magnet hospitals showed more declines than improvements in the nursing practice environment between 1986 and 1998; RN staffing and mortality were negatively correlated (r = –0.49, P = 0.02 based on 1997 data from 22 magnet hospitals; r = –0.18, P = 0.02 for 314 hospitals).
Berlowitz 2001[49]	Outpatient care	Retrospective cohort	Design: Level 4, Patient outcomes: risk-adjusted development of stage 3 or 4 pressure ulcers (Level 1)	Department of Veterans Affairs (VA) long-term care units at about 150 VA medical centers nationwide between 1990 and 1997; 274,919 observations of 103,499 VA residents who were without a pressure ulcer (PU) at an index assessment: 97% were men, average age was 71 years	Reorganization beginning in 1995 to shift from a hospital-based, specialty-focused system to one based on primary care delivered in outpatient settings	Before the change (1990–1994), risk-adjusted rates of PUs declined by 27%. Rates began increasing in 1997. By 1997 rates were similar to those in 1990. The proportion of new PUs that were severe increased significantly from 1995 to 1997 (P = 0.01, average 45%). 11 patient characteristics were significantly associated with PU development (e.g., mobility, dependency on transferring, toileting; P < 0.001).

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Bryan 1998[18]	Patient-centered care	Cross-sectional, Same variables measured at 4 points in time using different patients (preimplement-ation, 6, 12, and 18 months after)	Design: Level 3, Patient outcomes: mortality, falls, medication errors, nosocomial infections, IV-related complications (Level 1), patient satisfaction	Four medical-surgical units in one Pennsylvania hospital: patients at baseline = 2,700 6 months = 2,500 12 months = 2,756 18 months = 2,672	Hospital redesign using patient-centered concepts—facility changes (e.g., alter location and number of work stations and supply areas), enhanced information systems (e.g., redesigned patient call system), total redesign of work processes (e.g., redesigned staff roles to use multiskilled personnel)	Mortality ratios declined from baseline, although an increase was evident in the last year of reported data; rate of occurrence per 100 patients for falls, medication errors, nosocomial infections, and IV-related complications improved or remained unchanged since restructuring (0.4-3/100 patients before and 0.2-2/100 after); patient satisfaction improved on 3 of the 4 units, but the pattern of change differed among all units.
Cummings 2005[20]	Leadership	Cross-sectional	Design: Level 3, 15 nursing outcomes: e.g., emotional health; physician-nurse teamwork; nurse workgroup collaboration; satisfaction with time to spend with patients, supervision, financial rewards, one's job; perceived quality of care as measured by unmet patient needs (Level 3)	Acute care hospitals in Alberta, Canada; 6,526 registered nurses (53% response rate)	Leadership styles: resonant (visionary, coaching, affiliative, democratic), dissonant (pace setting, commanding), mixed.	Hospital restructuring led to reported increases in unmet patient needs among all nurses surveyed. Resonant leadership lessened the intensity of the impact of restructuring on unmet care needs, emotional exhaustion, emotional health, and workgroup collaboration. Dissonant leadership intensified the effects of restructuring. Other causal relationships were discovered among nursing outcome variables that were mitigated by resonant leadership.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Cummings 2003[21]	Effects on nurses who remained employed while others lost their jobs	Systematic literature review	Design: Level 1, effects of restructuring on nurses remaining employed in hospitals (Level 3)	Published research—84 papers were screened for inclusion criteria: 22 papers were included in the review (18 of 24 quantitative papers and 4 of 9 qualitative papers)	Hospital restructuring effects on nurses (RNs and LPNs)	Decreased job satisfaction complicated recruiting and retaining nursing staff; increased emotional exhaustion and work absences; perceived and actual increased workload; perceived increase in patient acuity; impaired ability to communicate important patient information; loss of work group cohesion.
Keller 2004[51]	Hospital bed closures	Cross-sectional	Design: Level 4; outcomes: rate of home care, service intensity	Kingston, Ontario, Canada; closure of 134 acute care beds in 2 tertiary teaching hospitals in 1997; hospital patients ages 45 and older, discharged to a home setting between 1996 and 2000, covered by the provincial health insurance plan and admitted to the local Community Care Access Center within 5 days before or after hospital discharge (*n* = 1,651)	Delivery of home care by registered nurses (RNs) and registered practical nurses (RPNs)	Patients needed continued care after discharge. Age-gender standardized rates for home care showed a 10% increase between 1996 and 1997, with people 13% more likely to receive home care in 1997 (OR 1.13, 95% CI 1.05–1.22). Between 1996 and 2000, there was a 4% net increase in the age-gender standardized rate of admission to home care services. Service intensity and volume were measured at weeks 1, 2 & 1 month—total visits and visits/patient increased from 1996 to 1999; the total volume of nurse visits was highest in 2000; the intensity of nursing care eased in the second week after discharge.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Laschinger 2004[32]	Nurse managers' health	Cross-sectional	Design: Level 3, outcomes: empowerment, burnout (emotional exhaustion [EE]), job satisfaction, mental and physical health (Level 3)	Acute care hospitals in Ontario, Canada; random sample of 500 nurse managers; 286 usable surveys were returned (62%); first-line managers (*n* = 202), 95% female, average age 48, average years nursing experience 25, average years managerial experience 10, 42%, were baccalaureate prepared; middle managers (*n* = 84), 96% female, average age 49, average years nursing experience 27, average years managerial experience 14, 43%, were master's prepared	Restructuring	First-line and middle nurse managers perceived their work environments as being only modestly empowering but reported high levels of psychological empowerment. EE was high (reflecting burnout), energy levels were low, physical and depressive symptoms were infrequent. Predictive models showed structural empowerment was a significant predictor of EE in both groups of managers. Managers are at risk of developing EE, the core component of burnout, if they do not have needed information, resources, and support to perform their roles.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Rubenstein 1996[50]	Outpatient care	Cross-sectional with data collected at 3 points in time—1989, before implementation; 1992, early in implementation; and 1993 after implementation	Design: Level 3, outcomes: mortality (Level 1), continuity, preventive care, access, workload (Level 3)	A VA medical center in California; data for practice-based comparisons came from 1,262 veterans in 1992 and 1,373 in 1993 (697 were from a new cross-sectional sample and 676 were from the original cohort); data for visit-based comparisons came from 1,407 veterans in 1992 and 643 in 1993 (92.3% of the new clinic cross-section). Patient survey responses were linked to computerized utilization and mortality data.	Implementation of the Primary Ambulatory Care and Education (PACE) program, a medical-center-wide interdisciplinary matrix management system and training program; put in place in 1990–1991.	There were no statistical differences in mortality between patients who saw a physician for symptoms vs. patients who did not. From 1992 to 1993, improvements were found for continuity of care, preventive care related to smoking and exercise ($P < 0.05$), and detection of depression ($P < 0.001$). Hypertensive patients receiving antihyperten-sives increased as well (8.6%, $P < 0.01$). Access diminished—21% of patients with serious symptoms did not see a physician in 1992, rising to 42% in 1993. Time to talk with patients and explain health problems and medications improved ($P < 0.05$).

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Sovie 2001[43]	Nursing structure and processes	Cross-sectional	Design: Level 3, outcomes: *structure* (full-time equivalents for each type of nursing staff; skill mix, hours worked per patient day [HPPD] for all staff); *process* (management practices and organizational processes, e.g., autonomy, decisionmaking); *outcomes* (annual rates for nosocomial pressure ulcers [NPUs], urinary tract infections [UTIs], falls, (Level 1); patient satisfaction with pain management, education, attention to needs, nursing and the hospital, preparation for discharge (Level 3)	29 university teaching hospitals with > 300 acute operating beds in 8 of 9 U.S. census regions; chief nurse executives (CNEs) at each hospital (all were women with graduate degrees, 15 had doctorates), patients and nursing staff (registered nurses [RNs], licensed practical nurses [LPNs], unlicensed assistive personnel [UAP]) from a medical unit and a surgical unit at each hospital (RN participants: *n* = 1,687 in 1997, 1,256 in 1998; 92–93% female, 57–58% married, 53% BSN degrees, mean age 37, mean years in nursing 11)	Restructuring had been in progress in 50% of the hospitals for over 4 years prior to data collection. The goal of restructuring was to achieve reductions in operating costs.	Less management support was available to patient care staff: expanded CNE responsibilities (97%), nursing departments downsized (82%), nurse manager positions reduced in 91% of the hospitals and span of control increased to more than one nursing unit. There were fewer RNs and more UAPs; outcomes were affected by RN HPPD and HPPD by all staff; increased RN HPPD were associated with lower falls and higher patient satisfaction with pain management; increased HPPD by all staff were associated with lower UTI rates; no single staffing pattern resulted in best value; outcomes differences for medical and surgical units reflected the importance of unit-level evaluations.
Walston 2000[46]	Changed work processes and design	Cross-sectional	Design: Level 3, outcomes: changes in hospital cost per adjusted patient day relative to the hospital's market area (controlling for bed size and other factors) (Level 3)	All U.S. general medical/ surgical hospitals in urban areas with > 100 beds (*N* = 2,306); CEOs surveyed November 1996 through July 1997	Reengineering (60% rate of adoption in sample)	Negative influence on a hospital's competitive position (hospital costs were increased relative to competitors); use of integrative strategies (e.g., project teams, deep CEO involvement) may moderate the negative effects of reengineering.

Source	Safety Issue Related to Clinical Practice	Design Type	Study Design, Study Outcome Measure(s)	Study Setting & Study Population	Study Intervention	Key Finding(s)
Woodward 1999[48]		Cross-sectional at 3 points in time over 2 years	Design: Level 3, outcomes: work environment, emotional distress, personal resources, perceptions of patient care and the hospital as an employer (Level 3)	One large teaching hospital in Ontario; 900 randomly sampled employees, 881 of whom were eligible, 730 of whom were employed 2 years later, 47% responded in all time periods. Respondents to all 3 surveys included 220 health care professionals, 40 service/technical staff, 66 secretarial personnel, 20 business staff.	Re-engineering	Statistically significant changes ($P \leq 0.001$) were found for job demands (increased), coworker and supervisor support (decreased), less role clarity and teamwork, and more job insecurity. Psychological distress as measured by anxiety, depression, and emotional exhaustion showed an overall increase ($P < 0.001$). Perceptions of care quality and the hospital's work environment also diminished ($P \leq 0.001$).

Chapter 25. Nurse Staffing and Patient Care Quality and Safety

Sean P. Clarke, Nancy E. Donaldson

The importance of nurse staffing to the delivery of high-quality patient care was a principle finding in the landmark report of the Institute of Medicine's (IOM) Committee on the Adequacy of Nurse Staffing in Hospitals and Nursing Homes: "Nursing is a critical factor in determining the quality of care in hospitals and the nature of patient outcomes"[1] (p. 92). Nurse staffing is a crucial health policy issue on which there is a great deal of consensus on an abstract level (that nurses are an important component of the health care delivery system and that nurse staffing has impacts on safety), much less agreement on exactly what research data have and have not established, and active disagreement about the appropriate policy directions to protect public safety.

The purpose of this chapter is to summarize and discuss the state of the science examining the impact of nurse staffing in hospitals and other health care organizations on patient care quality, as well as safety-focused outcomes. To address some of the inconsistencies and limitations in existing studies, design issues and limitations of current methods and measures will be presented. The chapter concludes with a discussion of implications for future research, the management of patient care and public policy.

Background

For several decades, health services researchers have reported associations between nurse staffing and the outcomes of hospital care.[2–4] However, in many of these studies, nursing care and nurse staffing were primarily background variables and not the primary focus of study.[5] In the 1990s, the National Center for Nursing Research, the precursor to the National Institute of Nursing Research, convened an invitational conference on patient outcomes research from the perspective of the effectiveness of nursing practice.[6] It was hoped that as methods for capturing the quality of patient care quantitatively became more sophisticated, evidence linking the structure of nurse staffing (i.e., hours of care, skill mix) to patient care quality and safety would grow. However, 5 years later, the 1996 IOM report articulating the importance of nurses and nurse staffing on outcomes concluded that, at that time, there was essentially no evidence that staffing exerted an effect on acute care hospital patients' outcomes and limited evidence of its impact on long-term care outcomes.[1]

There has been remarkable growth in this body of literature since the 1996 IOM report. Over the course of the last decade, hospital restructuring, spurred in part by a move to managed care payment structures and development of market competition among health care delivery organizations, led to aggressive cost cutting. Human resources, historically a major cost center for hospitals, and nurse staffing in particular, were often the focus of work redesign and workforce reduction efforts. Cuts in nursing staff led to heavier workloads, which heightened concern about the adequacy of staffing levels in hospitals.[7, 8] Concurrently, public and professional concerns regarding the quality and safety of patient care were sparked by research and policy reports (among them, the IOM's *To Err is Human*[9]), and then fueled by the popular

media. A few years ago, reports began documenting a new, unprecedented shortage of nurses linked to growing demand for services, as well as drops in both graduations from prelicensure nursing education programs and workforce participation by licensed nurses, linked by at least some researchers to deteriorating working conditions in hospitals.[10, 11] These converging health care finance, labor market, and professional and public policy forces stimulated a new focus of study within health services research examining the impact of nurse staffing on the quality and safety of patient care. An expected deepening of the shortage in coming years[12] has increased the urgency of understanding the staffing-outcomes relationship and offering nurses and health care leaders evidence about the impacts of providing care under variable nurse staffing conditions. This chapter includes a review of related literature from early 2007.

Identifying Nurse-Sensitive Outcomes

The availability of data on measures of quality that can be reasonably attributed to nurses, nursing care, and the environments in which care is delivered has constrained research studying the link between staffing and outcomes. While nurse leaders have been discussing the need to measure outcomes sensitive to nursing practice back to at least the 1960s, widespread use of the terms "nurse/nursing-sensitive outcomes" and "patient outcomes potentially sensitive to nursing" is a relatively recent development. Nurse-sensitive measures have been defined as "processes and outcomes that are affected, provided, and/or influenced by nursing personnel, but for which nursing is not exclusively responsible."[13, 14] While some scholars feel the term "nurse-sensitive measure" is fundamentally incorrect because patient outcomes are influenced by so many factors, health care is practiced in a multidisciplinary context, and few aspects of patient care are the sole purview of nurses, there is a broad recognition that some outcomes reflect differences in the quality of nursing care patients receive and therefore presumably respond to the characteristics of the environments in which care is provided (including staffing levels).

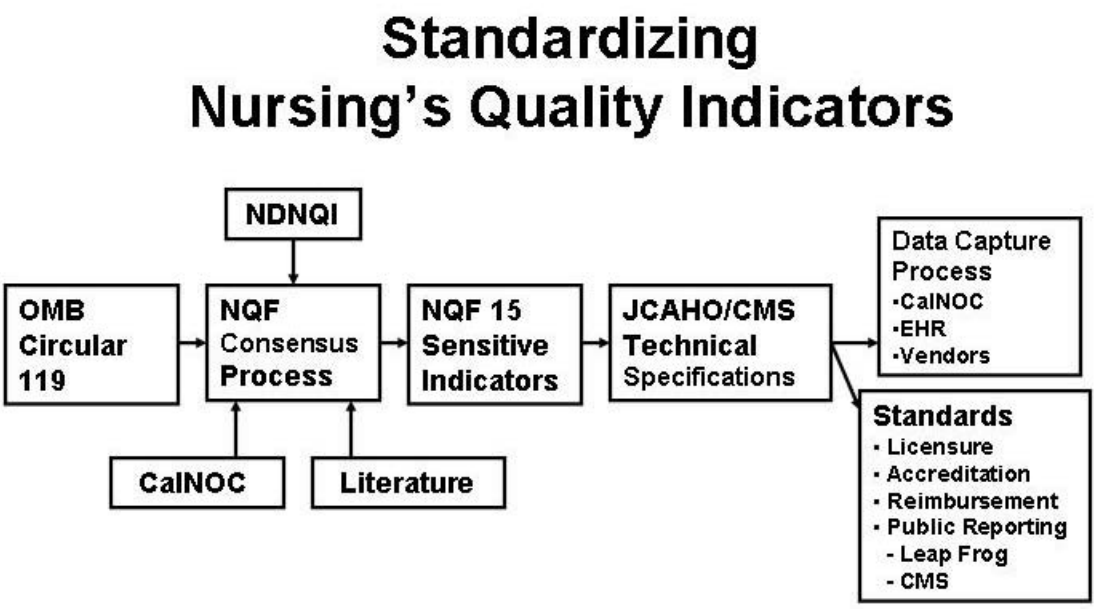
No matter what label these measures are given, measures that have conceptual and clinical links to the practice of nursing and are sensitive to variations in the structure and processes of nursing care are an essential ingredient in this area of research. Data sources from which to construct these measures must be identified, and exact definitions indicating how measures are to be calculated must be drafted. This is particularly critical if different individuals or groups are involved in compiling quality measures. There have been calls for standardization of measures of the quality of health care for some time,[1, 15] along with outcome measures related to the quality of nursing care. Inconsistent definitions have slowed progress in research and interfered with comparability of results across studies. A paper, now under review, examines and compares common measures of adult, acute care nurse staffing, including unit-level hospital-generated data gleaned from the California Nursing Outcomes dataset, hospital-level payroll accounting data obtained from the California Office of Statewide Health Planning and Development, hospital-level personnel data submitted to the American Hospital Association, and investigator research data obtained from the California Workforce Initiative Survey. Findings reveal important differences between measures that may explain at least some inconsistencies in results across the literature (Spetz, Donaldson, Aydin, personal communication February, 2007).

Efforts to address the standardization imperative began with the American Nurses Association's (ANA) first national nursing quality report card initiative. This initiative began with a literature search to identify potential nurse-sensitive quality indicators. Next, expert reviewers examined and validated a smaller, selected group of indicators and measures from

among these.[16] The ANA then funded six initial nursing quality report card indicator feasibility studies, which developed and refined these first sets of measures, documenting the quality of nursing care in acute care settings. The California Nursing Outcomes Coalition (CalNOC) was among the first State-based feasibility projects conducted by the ANA that ultimately served as the basis for the National Database for Nursing Quality Indicators (NDNQI) established in 1997. Maintaining an informal collaboration with the NDNQI, CalNOC continues to function as a regional nursing quality database, and more recently, CalNOC methods have been adapted by both the emerging Military Nursing Outcomes Database and VA Nursing Outcomes Database projects. All four groups currently collect and analyze unit-level data related to the associations between nurse staffing and the quality and safety of patient care. Together, they have formed an unofficial collaborative of nursing quality database projects.[17–21]

The most recent initiative in standardizing staffing and outcomes measures for quality improvement and research purposes was undertaken by the National Quality Forum (NQF). The mission of the NQF is to improve American health care through consensus-based standards for quality measurement and public reporting related to whether health care services are safe, timely, beneficial, patient centered, equitable, and efficient. To advance standardization of nurse-sensitive quality measures and respond to authoritative recommendations from multiple IOM and Federal reports,[9, 15, 22] the NQF convened an expert panel and established a rigorous consensus process to generate the Nation's first panel of nursing-sensitive measures for public reporting. The aim of the expert panel was to explicate and endorse national voluntary consensus standards as a framework for measuring nursing-sensitive care and to inform related research. Potential nursing-sensitive performance measures were subjected to a rigorous and systematic vetting under the terms of the NQF Consensus Development Process, which included a thorough examination of evidence substantiating each measure's sensitivity to nursing factors, alignment with existing requirements being made of providers, and validation/recommendations of advisory bodies to Federal agencies. As illustrated in Figure 1, the resulting first 15 NQF nursing-sensitive measurement standards were informed by earlier work by the NDNQI and CalNOC, as well as measures arising from formal research studies.

Figure 1. Standardizing Nursing's Quality Indicators



Notes: CMS = Centers for Medicare and Medicaid Services; EHR = electronic health record; JCAHO = Joint Commission on Accreditation of Healthcare Organizations, now known as the Joint Commission; OMB = Office of Management and Budget.

These measures represent a first (but by no means final) attempt to make nurse-sensitive outcomes visible to the broader community of payers and policymakers. The first 15 voluntary consensus standards for nursing-sensitive care intended for use in public reporting and policy initiatives included[23]

1. Failure to rescue
2. Pressure ulcer prevalence
3. Falls
4. Falls with injury
5. Restraint (vest and limb) prevalence
6. Urinary catheter-associated urinary tract infections (intensive care unit, ICU)
7. Central line catheter-associated bloodstream infections (ICU)
8. Ventilator-associated pneumonia (ICU)
9. Smoking cessation counseling for acute myocardial infarction
10. Smoking cessation counseling for pneumonia
11. Smoking cessation counseling for heart failure
12. Skill mix
13. Nursing hours per patient day
14. Practice Environment Scale-Nursing Work Index
15. Voluntary turnover

A Framework Relating Nurse Staffing to Patient Care Quality and Safety

Figure 2 illustrates a set of conceptual relationships between the key variables in this review, including influences on staffing levels and factors influencing outcomes. These relationships form a set of interrelated pathways that link nurse staffing to patient care quality, safety, and outcomes. Notable is that each of the elements enclosed in a box—specifically administrative decisions, quality of nursing care, care needs, and safety and clinical outcomes—is influenced by a host of factors that are not detailed in the diagram and could each be the subject of its own literature review.

Figure 2. Nurse Staffing, Quality of Care, and Outcomes

- Staffing levels are set by administrators and are affected by forces that include budgetary considerations and features of local nurse labor markets. Administrative practices result in a structure of the nursing staff of an agency (nature of supervision) and staff or staff hours assigned to different subunits in a facility. These practices also affect the mix and characteristics of the nurse workforce, the model of care used in assigning staff and in providing care, and a wide range of workplace environments that affect how nurses practice. Other characteristics of the workplace environments noted in the literature included the physical environment, communication systems and collaboration, information systems, and relevant support services. All of these factors ultimately influence the "dose" or quantity of nursing time, as well as the quality of nursing care.
- Variables included in the category of care needs of the patient include the acuity and complexity of the patient's health status, as well as the patient's comorbid medical conditions, functional status, family needs/resources, and capacity for self-care. The vulnerabilities of patients for adverse events varies and changes over the course of a hospital stay or episode of care.
- The quality of nursing care relates to the appropriate execution of assessments and interventions intended to optimize patient outcomes and prevent adverse events. For

example, the extent to which nurses assess the risk for falls in hospital patients upon admission, implement evidence-based fall-prevention protocols, and sustain such preventive interventions could each be developed into measures of nursing care quality. The quality of nursing care also includes attention to safety issues, for example, the accuracy of medication administration. Safe care also entails consistent monitoring tailored to patients' conditions to guarantee early recognition of patient deterioration and, if problems are identified, benefit from a rapid, appropriate interdisciplinary team response to these issues.[24]

The quality of care that nurses provide is influenced by individual nurse characteristics such as knowledge and experience, as well as human factors such as fatigue. The quality of care is also influenced by the systems nurses work in, which involve not only staffing levels, but also the needs of all the patients a nurse or nursing staff is responsible for, the availability and organization of other staff and support services, and the climate and culture created by leaders in that setting. The same nurse may provide care of differing quality to patients with similar needs under variable staffing conditions and in different work environments.

- Safety outcomes include rates of errors in care as well as potentially preventable complications in at-risk patients. Safe practices that avoid errors and foreseeable complications of care can be thought of as either a basic element of or a precondition for delivering high-quality care, but are generally thought of as only one component of quality.
- Clinical outcomes (endpoints) of importance vary from patient to patient or by clinical population and include mortality, length of stay, self-care ability, adherence to treatment plans, and maintenance or improvement in functional status. Serious errors or complications often lead to poor clinical outcomes. So far, very few positive clinical outcomes have been studied by staffing-outcomes researchers, probably because of limited measures and data sources.

The sheer number of variables and myriad linkages depicted suggest why precise evidence-based formulas for deploying nursing staff to ensure safe, high-quality patient care are impossible based on the knowledge on hand. In fact, such prescriptions may never be possible. Certainly, evidence-based guidelines for allocating resources to ensure optimal outcomes in acute care and other health care settings cannot be offered until working environments, staffing (beyond head counts and skill mix), patient needs, processes, and outcomes of care can be measured with precision.

Research investigating links between hospital nurse staffing and patient outcomes began with studies examining patient mortality. Reviews now include research examining a broad range of outcomes, including specific adverse events other than mortality. Although many studies support a link between lower nurse staffing and higher rates of negative nurse-sensitive safety outcomes,[25–27] reviews of two decades of research revealed inconsistent results across studies.[25–30]

State of Science on the Relationship Between Nurse Staffing and Patient Outcomes

Before examining the state of the scientific literature on the relationship between nurse staffing and clinical outcomes, it is important to consider common challenges of research in this arena. Investigators face at least two fundamental problems when designing staffing-outcomes studies: first, finding suitable data sources and measures for staffing and patient outcomes, and

second, linking the two types of variables to reach valid conclusions. As noted earlier in this chapter, because of limitations in measures, data sources, and analytic methods, researchers generally ask a different question in their studies (Is there a correlation between staffing and patient care outcomes?) than the questions that are of primary concern to patients, clinicians, managers, and policymakers (What staffing levels are safe under a specific set of circumstances?).[31] Nonetheless, researchers in this field deserve a great deal of credit for making creative use of a variety of data sources not originally developed for research (or research on staffing and outcomes) to generate a great deal of evidence that has fueled discussion in the practice, management, and policy communities.

Data Sources, Measures, and Challenges

As clinical trials or controlled experiments are difficult if not impossible to conduct in this area, observational designs must be optimized as much as possible. When outcomes are compared across hospitals or other health care organizations as a whole or their clinical units or microsystems, frequently the research design that results from data linkages and analyses is cross-sectional and correlational in nature. Staffing levels and patient outcomes from approximately the same time are analyzed to determine whether a correlation exists between the two. As all students of research methods know, correlational designs are more limited than experiments for determining the extent to which causal links exist between staffing levels and outcomes. Factors other than nurse staffing can vary alongside staffing levels, so whether or not certain different staffing levels directly lead to better or worse outcomes cannot be determined with certainty from correlational designs. Such factors include other aspects of the environment in which care is provided (for example the availability of supplies, quality of physician care and/or other services and supports). Statistical methods can control for obvious factors that influence or are otherwise associated with staffing levels (such as hospital size, academic affiliation, or rural-urban location). Nonetheless, it is impossible to measure and account for all possible confounding variables (or competing explanations for findings) in the typical designs of these studies. Maximizing returns on correlational research designs involving staffing requires careful selection of variables and clearly articulating the theoretical and/or empirical bases for choosing them.

Tables 1 and 2 provide brief overviews of types of measures and the questions consumers of staffing outcomes research might consider in appraising individual studies. The discussion that follows is intended to emphasize a few fundamental points before turning to the findings in the literature itself.

Table 1. A Typology of Measures in the Staffing-Outcomes Literature

Variable	Sources of Data	Types
Staffing	• Records from health care facility operations (assignment sheets, scheduling grids) • Data submitted to regulatory bodies • Surveys of staff regarding staffing levels and/or workload	**Major types** • Staff/staffed hours divided by patient/service volume • Credentials/qualifications of nursing staff (higher or lower in relation to total): licensed vs. unlicensed; level of licensure; highest degree, professional certification; years of experience • Voluntary turnover • Use of contract or agency staff **Important distinctions** • Level of measurement within the organization (whole facility/department vs. unit) • Roles of staff measured (such as staff involved in "direct patient care" vs. all nursing staff) • Time frame (shift/day/week/month/quarter/year)
Outcome	• Patient records, discharge abstracts, incident reports, or other byproducts of care delivery (including reimbursement) • Prospective surveillance for specific events (such as falls and pressure ulcers) • Surveys of patients/families and providers	Occurrence of events suggestive of poor (or less commonly, high) quality of care or nurse work-related outcomes **Level of measurement** • Individual patients/nurses • Subunits (e.g., nursing units) of organizations • Entire facilities

Table 2. Major Methodological Considerations in This Literature

Design Feature	Questions to Ask
Measurement of staffing	Do the staffing measures reflect the type and "dose" of staff actually caring for the patients being studied? Were the staffing measures collected in a consistent manner (using common definitions) across the organizational units/time periods?
Measurement of outcomes	Were outcomes assessed in comparable ways across patients and across settings (units or institutions or time periods)? Do data sources allow a distinction between complicating conditions present when care was undertaken (which should be considered in the analyses in risk adjustment (below)) from conditions that appeared during care (that are potentially outcomes of nursing care during the hospitalization)? Were outcomes assessed completely/comprehensively for all patients? What evidence is there regarding the consistency of documentation for the outcomes in question in the data sources? Does the outcome in question have a plausible association with nursing practice, or is it primarily/entirely associated with factors outside the control of providers?
Risk adjustment	Have the authors conducted fair comparisons between rates of adverse events across hospitals units or time periods by considering potentially important differences in the patients treated across those settings and/or over time?

Design Feature	Questions to Ask
Data linkage	To what extent do staffing measures represent conditions at the times and places where nursing care affecting the outcomes and measured for this study is given? Are outcomes attributed to the locations of care where nursing services actually influence the outcome, or do they also reflect the place where detection of the outcome occurs?
Control for confounding factors	Have other aspects of the environments in which patients are cared for that might affect the outcomes been measured and analyzed? E.g., availability of equipment/supplies, quality of physician care, other types of facility personnel, hospital size, academic affiliation, rural-urban location
Statistical modeling	If the study examines an outcome that is rare in the patient population, has this been considered in any modeling? How is skewness of the data managed? If the subjects of the study are grouped or nested within larger organizational units (e.g., patients within nursing units within hospitals), has this been handled by the analytic strategy? Do at least some of the analyses presented depict the complexity of associations between the factors involved through some type of statistical modeling that evaluates impacts of variables simultaneously?

Staffing

Staffing levels can be reported or calculated for an entire health care organization or for an operational level within an organization (a specific unit, department, or division). Specific time frames (at the shift level and as a daily, weekly, or yearly average) must be identified to ensure common meaning among collectors of the data, those analyzing it, and individuals attempting to interpret results of analyses.

In many cases, staffing measures are calculated for entire hospitals over a 1-year period. It is fairly common to average (or aggregate) staffing across all shifts, for instance, or across all day shifts in a month, quarter, or year and sometimes also across all the units of hospitals. The resulting measures, while giving an imprecise idea of what specific conditions nurses and patients experienced at particular points, are general indicators of facilities' investments in staffing. However, staffing levels on different units reflect differences in patient populations and illness severity (the most striking of which are seen between general care and critical care units). Furthermore, in practice, staffing is managed on a unit-by-unit, day-by-day, and shift-by-shift basis, with budgeting obviously done on a longer time horizon. For these reasons, some researchers argue that at least some research should be conducted where staffing is measured on a shift-specific and unit-specific basis instead of on a yearly, hospitalwide basis. A distinct, but growing, group of studies examined staffing conditions in subunits or microsystems of organizations (such as nursing units within hospitals) over shorter periods of time (for example, monthly or quarterly).[17, 32–34]

In addition to three sources of staffing data, there are also two basic types of staffing measures or variables. The first type divides a volume of nurses or nursing services by a quantity of patient care services. Common examples include patient-to-nurse ratios, hours of nursing care delivered by various subtypes of personnel per patient day (HPPD), and full-time equivalent (FTE) positions worked in relation to average patient census (ADC) over a particular time period. Patient-to-nurse ratios, HPPD figures, or FTE:ADC measures have the potential to both

systematically overestimate or underestimate nurse workloads and the attention given to specific patients in relation to those patients' needs, conditions, and clinical trajectories across units or institutions or over time.[31]

The second major type of measure examines the credentials or qualifications of those staff members and expresses them as a proportion of staff with more versus less training (or vice-versa). Commonly, the composition of the nursing staff employed on a unit or in a hospital in terms of unlicensed personnel, practical or vocational nurses, and registered nurses (RNs) is calculated. The specific types of educational preparation held by RNs (baccalaureate degrees versus associate degrees and diplomas) have also begun to be studied. Additional staffing-related characteristics studied include years of experience and professional certification. The incidence of voluntary turnover and the extent to which contract or agency staff provide care have also been studied. As will be discussed, the majority of the evidence related to hospital nurse staffing focuses on RNs rather than other types of personnel.

For the most common measures, ratios and skill-mix, determining which staff members should be included in the calculations is important, given the diversity of staffing models in hospitals. Most researchers feel these statistics should reflect personnel who deliver direct care relevant to the patient outcomes studied. Whether or not to count charge nurses, nurse educators involved in bedside care, and nurses not assigned a patient load (but who nevertheless deliver important clinical services) can present problems, if not in principle, then in the reality of data that institutions actually collect. Outcomes research examining the use of advanced practice nurses in acute care—for instance, nurse practitioners and nurse anesthetists—to provide types of care traditionally delivered by medical staff and medical trainees has been done in a different tradition (analyzing the experiences of individual patients cared for by specific providers) and does not tend to focus on outcomes relevant to staff nurse practice; therefore these studies are not reviewed here. No studies were found that examined advanced practice nurse-to-patient ratios or skill mix in predicting acute care patient outcomes. There have been calls to examine advanced practice nurses supporting frontline nurses in resource roles (for instance, clinical nurse specialists who consult and assist in daily nursing care, staff development, and quality assurance) and their potential impact on patient outcomes. No empirical evidence of this type was found.

Outcomes

Clearly, capturing data about patient outcomes prospectively (i.e., as care is delivered) is the best option for obtaining precise, comprehensive, consistently collected data. This approach is the most challenging because of practical, ethical, and financial considerations. However, researchers can sometimes capitalize on prospective data collections already in progress. For instance, hospital-associated pressure ulcer prevalence surveys and patient falls incidence are commonly collected as part of standard patient care quality and safety activities at the level of individual nursing units in many institutions.[18, 32] Many, but by no means all, studies in this area use secondary data not specifically intended for research purposes, such as patient medical records. Outcomes researchers often use condensed or abstracted versions of hospital patients' records in the form of discharge abstracts, which contain data extracted from health care records about clinical diagnoses, comorbidities, procedures, and the disposition of patients at discharge.[35] As there are concerns that the quality and reliability of clinical documentation varies widely,[35] one author suggested that only a form of electronic medical record that forces contemporaneous recording of assessment data and interventions will permit true performance measurement in

health care.[36] Wider application of information technology in health care settings, anticipated to facilitate care delivery and improve quality and safety, is also expected to provide richer, higher-quality data sources for strategic performance improvement that can be leveraged by outcomes researchers.

Patients are not all at equal risk of experiencing negative outcomes. Elderly, chronically ill, and physiologically unstable patients, as well as those undergoing lengthy or complex treatment, are at much greater risk of experiencing various types of adverse events in care. For instance, data on falls may be consistently collected for all hospitalized patients but may not be particularly meaningful for obstetrical patients. Accurately interpreting differences in rates across health care settings or over time requires understanding the baseline risks patients have for various negative outcomes that are beyond the control of the health care providers. Ultimately this understanding is incorporated into research and evaluation efforts through risk adjustment methods, usually in two phases: (1) carefully defining the patient populations at risk—the denominator in rates; and (2) gathering reliable and valid data about baseline risk factors and analyzing them. Without sound risk adjustment, any associations between staffing and outcomes may be spurious; what may appear to be favorable or unfavorable rates of outcomes in different institutions may no longer seem so once the complexity or frailty of the patients being treated is considered.[35]

The focus of this review is on staffing and safety outcomes. However, as was noted earlier, quality of care and clinical outcomes (and by extension, the larger domain of nursing-sensitive outcomes) include not only processes and outcomes related to avoiding negative health states, but also a broad category of positive impacts of sound nursing care. Knowledge about positive outcomes of care that are less likely to occur under low staffing conditions (or are more likely under higher levels) is extremely limited. The findings linking functional status, psychosocial adaptation to illness, and self-care capacities in acute care patients are at a very early stage[37] but eventually will become an important part of this literature and the business case for investments in nurse staffing and care environments.

Linkage

In staffing-outcomes studies, researchers must match information from data sources about the conditions under which patients were cared for with clinical outcomes data on a patient-by-patient basis or in the form of an event rate for an organization or organizational subunit during a specific period of time. Ideally, errors or omissions in care would be observed and accurately tracked to a particular unit on a particular shift for which staffing data were also available. Most, but not all, large-scale studies have been hospital-level analyses of staffing and outcomes on an annual basis and have used large public data sources.

Linkages of staffing with outcomes data involve both a temporal (time) component and a departmental or unit component. Many outcomes (endpoints) examined by staffing researchers are believed to reflect compounded errors and/or omissions over time across different departments of an institutions. These include some types of complications as well as patient deaths. Attribution of outcomes is complicated by the reality that patients are often exposed to more than one area of a hospital. For instance, they are sometimes initially treated in the emergency department, undergo surgery, and either experience postanesthesia care on a specialized unit or stay in an intensive care unit before receiving care on a general unit. If such a patient develops a pressure ulcer, at what point did low staffing and/or poor care lead to the

pressure ulcer? Unfortunately, in hospital-level datasets, it is impossible to pinpoint the times and locations of the errors or omissions most responsible for a clinical endpoint. In the end, if outcomes information is available only for the hospital as a whole (which is the case in discharge abstracts, for instance), data linkage can happen only at the hospital level, even if staffing data were available for each unit in a facility. Similarly, if staffing data are available only as yearly averages, linkage can be done only on an annual basis, even if outcomes data are available daily or weekly. Linkages can be done only at the broadest levels (on the least-detailed basis or at the highest level of the organization) available in a dataset. Many patient outcomes measures (such as potentially preventable mortality) may actually be more meaningful if studied at the hospital level, while others (such as falls) may be appropriately examined at the unit level.

One should recognize that common mismatches between the precision of staffing measures and the precision of outcome measures (i.e., the staffing across an entire year across all units in a hospital used as a predictor of outcomes for a patient treated for a short time in only a fraction of these units) compromise the likelihood that valid statistically significant associations will be found. This finding is particularly relevant when staffing statistics span a long time frame and therefore contain a great deal of noise—information about times other than the ones during which particular patients were being treated. High-quality staffing data, as well as patient assessment and intervention data—all of which are accurately date-stamped and available for many patients, units, and hospitals—will be necessary to overcome these linkage problems. Such advances may come in the next decades with increased automation of staffing functions and the evolution of the electronic medical record.

Recent prospective unit-level analyses, now possible with datasets developed and maintained by the NDNQI, CalNOC, and the military hospital systems, make it possible to overcome some of these issues. These databases, although not risk adjusted, stratify data by unit type and hospital size and have adopted standardized measures of nurse staffing and quality of care. The resulting datasets provide opportunities to study how variations in unit-level staffing characteristics over time can influence patient outcomes (for instance, pressure ulcers and falls, as discussed later). As data sources do not exist for all types of staffing and outcomes measures at all levels of hospital organization (nor will they ever), research at both the unit level and the hospital level will continue, and both types of studies have the potential to inform understanding of the staffing-outcomes relationship.

Research Evidence

Perhaps staffing and outcomes research has such importance and relevance for clinicians and educators as well as for managers and policymakers, staffing-outcomes research is a frequently reviewed area of literature. As was just detailed, a diversity of study designs, data sources, and operational definitions of the key variables is characteristic of this literature, which makes synthesis of results challenging. Many judgments must be made about which studies are comparable, which findings (if any) contribute significantly to a conclusion about what this literature says, and perhaps regarding how to transform similar measures collected differently so they can be read side by side. The review of evidence here builds on a series of recent systematic reviews with well-defined search criteria.[25, 27, 30, 38] At least one group of researchers conducted a formal meta-analysis that integrated the bulk of empirical findings in the hospital staffing literature and summarized effect sizes for specific staffing measures, outcomes, and clinical populations.[30] This review was the most up-to-date identified within this search.

Evidence Related to Acute Care Hospitals

Many researchers have identified higher levels of adverse patient events (mortality and complications, for instance) and negative nurse job outcomes (such as burnout) under poorer staffing conditions (specifically, thinner staffing coverage or fewer nurses per unit of patient care and, somewhat less commonly in these studies, lower skill mix/education level of staff). These findings have appeared in studies conducted using a variety of designs and examining hospital care in different geographical areas and over different time periods. On the whole, while some researchers have identified effects of 20 percent and greater reductions in negative outcomes associated with increased/improved (or the most generous) staffing, most studies in this literature show much smaller reductions in negative outcomes (under 10 percent and often much smaller ones) associated with the most favorable staffing conditions they observe.[30] Given the relative rarity of some outcomes, these are subtle enough changes in outcomes to require observing many thousands, if not hundreds of thousands, of patients to identify staffing effects on the reduction of negative patient outcomes. Again, because of the tremendous number of factors involved in staffing decisions and their effects on patient care, and limitations in assessing patient characteristics, the specific staffing thresholds applicable to managers' decisionmaking below which outcomes are demonstrably worse cannot be identified using this literature—a point emphasized in many reviews.[24, 26]

The evidence table summarizes four major systematic reviews of the literature, approaches, and conclusions regarding the state of the evidence for specific outcomes or outcome types. In these papers, reviewers identify specific measurement types and established criteria for study inclusion in terms of design and reporting and examined a relatively complete group of the studies one by one to provide an overview of the state of findings as an integrated whole.

The contrasts in the conclusions are interesting but are probably less important than the overall trend: research results point persuasively to a correlation of staffing with outcomes, but not all outcomes or datasets show such a connection. An additional important point is that nearly all studies connecting staffing parameters with outcomes have been conducted at the hospital (rather than the unit) level.

Recent results emerging from the Agency for Healthcare Research and Quality (AHRQ) Patient Safety Working Conditions Program (2001–2005) offer some examples of recent unit-level studies of staffing and its impacts on outcomes. In a 2-year AHRQ Working Conditions and Patient Safety study built on the work of CalNOC, Donaldson and colleagues[17] engaged acute care hospitals using ANA nursing indicators for reporting staffing, patient safety, and quality indicators in a research, repository development, and benchmarking project. Data were drawn from 25 acute care, not-for-profit California hospital participants in the regional CalNOC. The sample included urban and rural hospitals with an average daily census from 100 to more than 400 patients. Most patients' principal diagnoses were medical (66 percent). The aims of the study were to test associations between daily nurse staffing on adult medical-surgical units and hospital-acquired pressure ulcers, patient falls, and other significant adverse events, if they were of sufficient volume to analyze. A prospective, descriptive, correlational design tested associations between patient outcome measures and daily unit-level nurse staffing, skill mix, hours of care (along with hours covered by supplemental agency staff), and workload. Falls were defined as "unplanned descents to the floor." RN hours of care were significantly associated with the two focal outcomes. Unit activity index and hospital complexity (measured by bed size) were also significant predictors of falls.

In another analysis, Donaldson and colleagues[39] traced daily, unit-level direct care nurse staffing in 77 units across 25 hospitals over a 2-month period using data on staffing effectiveness (the match between hours of care and hours provided). By law in California, each hospital unit uses an institutionally selected, acuity-based workload measurement system to determine required hours of care for each patient. For each patient-care unit, the ratio of actual to required hours of care, was expressed as both a mean ratio and as a percentage of days on which required hours exceeded actual hours over the 7 days prior to a pressure ulcer prevalence study. Using Spearman rank correlations, the percentage of patients with hospital-associated pressure ulcers was significantly associated with the mean actual/required hours ratio for the prior 7 days (r's = -0.25, 63 df, $P < 0.05$), and with the percent days with the actual/required ratio <100 percent for the prior 7 days (r's = 0.25, 63 df, $P < 0.05$). Larger actual/required ratios and actual/required ratios closer to 100 percent were associated with a lower percentage of patients with hospital-associated pressure ulcers. These analyses linked unit-level staffing and safety-related outcomes data, and measured for time periods at the unit level closely and logically connected (staffing measures relevant to conditions before the outcome occurred). The findings are intriguing and suggest that the impact on patients of "short" staffing appeared a number of days later, as one would expect given the pathophysiology of pressure ulcers (since it takes a number of days of unrelieved pressure on a vulnerable area for tissue damage to occur). Both researchers and research consumers need to reflect on the time frames involved in the evolution of various outcomes when assessing the validity of data linkages across time and units. For instance, in contrast to the lags between quality problems in care and evidence of their impact on outcomes such as infections and pressure ulcers, practice conditions will tend to have more immediately observable impacts on outcomes like falls with injury and most adverse drug reactions.

Recent legislation in California that introduced mandated nurse-to-patient ratios at the unit level provides an interesting context for studying the association of staffing and outcomes. CalNOC has reported early comparisons of staffing and outcomes in 268 medical-surgical and step-down units in 68 California hospitals during two 6-month intervals (Q1 and Q2 of 2002 and Q1 and Q2 of 2004) before and after introduction of the ratios. Data were stratified by hospital size and unit type. On medical-surgical units, mean total RN hours per patient day increased by 20.8 percent, total nursing hours increased by 7.4 percent, the number of patients per licensed nurse decreased by 16.0 percent, and the portion of nonlicensed nursing hours decreased by 20.8 percent. However, there were no statistically significant changes in the rate of patient falls or pressure ulcers on these units.[40] These early data suggested that the introduction of mandated ratios may have led to changes in staffing metrics in California hospitals without yet attaining the goal of improving patient outcomes.

Summary and Comment

Researchers have generally found that lower staffing levels are associated with heightened risks of poor patient outcomes. Staffing levels, particularly those related to nurse workload, also appear related to occupational health issues (like back injuries and needlestick injuries) and psychological states and experiences (like burnout) that may represent precursors for nurse turnover from specific jobs as well as the profession.

Associations are not identified every time they are expected in this area of research. Other aspects of hospital working conditions beyond staffing, as well individual nurse and patient

characteristics, affect outcomes since negative outcomes are relatively uncommon even at the extremes of staffing and do not occur in every circumstance where staffing is low.

A critical mass of studies established that nurse staffing is one of a number of variables worthy of attention in safety practice and research. There is little question that staffing influences at least some patient outcomes under at least some circumstances. Future research will clarify more subtle issues, such as the preferred methods for measuring staffing and the precise mechanisms through which the staffing-outcomes relationship operates in practice.

Areas Where the Evidence Base Is Currently Limited

Nurse executives and frontline managers make decisions about numbers of staff to assign to the various areas of their facilities. They also establish models of care to be used in caring for patients in terms of the constellation of nursing staff and distribution of responsibilities among professional nurses and other types of nursing staff. Patients and their families want assurances that enough staff are on duty to ensure that care is safe and meets patients' needs. Policymakers want assurances that the nursing workforce in their jurisdictions is adequate; they also want to know whether or not regulatory intervention is necessary to ensure acceptable staffing levels and desirable patient outcomes. Staffing researchers are ultimately constrained by the limitations of their data in answering many questions of relevance to the real worlds of health care delivery and public policy. Investigators most commonly examined the correlations of complex patient outcomes with staffing measures derived at some distance from the delivery of care (perhaps aggregated over time). Researchers then asked whether measures of staffing and outcomes were statistically associated with each other. A clear distinction between direct conclusions from research findings and the opinions of particular authors or interest groups must be made.

It is impossible to specify parameters for staffing that will ensure safety based on current evidence without many qualifiers. The adequacy of staffing (the degree to which staffing covers patient needs) even for the same patients and nurses may change from hour to hour, particularly in acute care settings. Nurse-to-patient ratios and skill mixes in specific settings that are too low for safety still cannot be identified on the basis of the research literature, but decisions must be made on the basis of the judgments by frontline staff and their managers. On a related note, the specific nursing care processes that are more likely to be omitted or rendered less safe under different staffing conditions are not well understood, empirically speaking, and deserve further attention.

A number of other areas identified in the staffing literature are relatively underdeveloped. Most research on staffing has been conducted in acute care settings; however, not all clinical areas within acute care have been equally well studied. A number of observers remarked that for the most part, the state of evidence regarding staffing's impact on specialties outside of adult medical-surgical care is very limited. Data regarding settings for the care of children, childbearing families, and patients with mental health problems are currently very thin.[25] Difficulties in collecting reliable, valid outcomes indicators that are potentially sensitive to nursing care in these other settings is probably at least partly to blame.

The majority of nurses working in hospitals in the United States are, of course, registered nurses. Available evidence suggested that patients in hospitals that use more licensed practical nurses (LPNs) or vocational nurses may see worse outcomes.[30, 40] Indeed, at least one cost-benefit analysis of drawing on findings from one of the largest studies in the field[40] suggested that increasing the proportion of RNs (and decreasing the proportion of practical nurses) in the

composition of hospital staffs may be a more cost-effective measure and could have a bigger impact on outcomes than increasing hours of nursing care per patient day.[41] Likewise, most reports in the literature dealing with unlicensed assistive personnel (UAPs) either failed to find associations with this type of staff or suggested worse outcomes in institutions with high levels of such personnel. There is no direct evidence that it is unsafe to employ LPNs in acute care settings,[42, 43] nor is there empirical support that the use of unlicensed personnel is intrinsically related to poor outcomes. Use of practical nurses and UAPs can be driven by any and all of the factors outlined in Figure 2. Nonetheless, anecdotal evidence suggests that inadequately trained and/or supervised personnel of all kinds at times provide unsafe care; that operational problems having related, but distinct, causes and consequences can lead to substituting other types of workers for RNs and to safety problems; and that the savings associated with using lesser-trained workers sometimes prove to be false economies. The models of care under which LPNs and unlicensed care providers are employed (i.e., the exact roles of non-RN personnel and degree of oversight provided by RNs) has not been considered in research. While RNs have the broadest scope of practice of frontline nursing workers, it is far from established that 100 percent RN staffing is effective in all situations. Future research needs to identify the circumstances under which LPNs and UAPs can be used safely. Until then (and even when it does), local labor market realities, experience, and judgment will need to be used by leaders to establish skill mix and to define the models of care under which RNs, LPNs, and UAPs work.

Early studies have offered early, tantalizing insights regarding a number of variables conceptually close to staffing. These findings include the educational preparation of RN staff in hospitals. Two recent studies[44, 45] found that mortality in surgical and medical patients was lower in hospitals where higher proportions of staff nurses held baccalaureate degrees. The AHRQ-sponsored studies of California hospitals discussed above also suggested that a higher percentage of nurses holding bachelor's and higher degrees was associated with lower fall rates. Additionally, in this latter work, units where higher percentages of RNs held specialty certification had lower proportions of restrained patients. Should these findings be borne out in future studies, there are important potential local and national policy implications. There is a clear need for more research. Similarly, while many feel experience and specialty training have logical associations with quality of care and patient safety, empirical data regarding their impact are very limited at present.

Yet another area where data related to patient outcomes are thin relates to the impact of specific types of work environments on nurse-sensitive outcomes, and in particular the impact of the Magnet hospital model, which has been argued to produce superior patient outcomes (and safer care).[46, 47] Such connections would make intuitive sense, since current Magnet criteria require adherence to many best practices in nursing management, including selection of a well-articulated staffing model driven by data. To our knowledge, there are no studies yet to directly support a connection between safety and specific managerial approaches or to link Magnet status with patient outcomes in the current era of certification. However, early findings with respect to questions around the outcomes of the program are expected in the coming years.

Evidence Related to Other Settings

There has been intense interest in identifying staffing-outcomes relationships in long-term care settings. RNs are, of course, in the minority among the nursing staff in long-term care, with unlicensed providers providing the bulk of physical care in these facilities. There are many

challenges in using existing documentation and databases to measure outcomes in long-term care facilities,[48] some of which are shared with outcomes measurement in acute care. Long-term care researchers face special issues, specifically with respect to data reliability and measure stability, skewedness of measures, and selection and ascertainment bias (where types of patients at high risk for poor outcomes or who are more closely observed are concentrated in certain nursing homes).[48]

Despite these problems, a critical mass of studies suggests that long-term care facilities with the lowest licensed and unlicensed staffing levels among their peers show disproportionately worse patient outcomes. A study sponsored by the Centers for Medicare and Medicaid Services (CMS) suggested that among short-stay patients, skilled nursing facilities with the lowest staffing levels were 30 percent more likely to fall in the worst 10 percent of facilities for transfers to acute care for acute heart failure, electrolyte imbalances, sepsis, respiratory infection, and urinary tract infection. Facilities with staffing below thresholds of 2.78 hours of aide time and 0.75 hours of RN time had greater probability of having the worst outcome rates for long-stay patients, including pressure ulcers, skin trauma, and weight loss.[49] Similar conclusions were reached in a secondary analysis of data from a pressure ulcers study. In 1,376 residents of 82 long-term care facilities, patients in facilities with more direct RN time (30–40 minutes per patient day and more) had fewer pressure ulcers, acute care hospitalizations, urinary tract infections, and urinary catheters, and less deterioration in ability to perform activities of daily living.[50] In a national sample of nursing homes from 45 States, those that met CMS guidelines for RN and unlicensed hours per patient-day had statistically lower rates of lawsuits after controlling for a multitude of structural, market, and patient factors.[51] Not all studies report such findings. Rantz and colleagues'[52] analysis of outcomes in 92 nursing homes found that staffing levels did not predict facilities' classification as having generally good, mediocre, or poor outcomes and found that on average, costs were somewhat higher in poor-outcome facilities. These researchers suggested that administrative practices other than staffing may play an important role in determining long-term care quality.

Home health is a growing sector in U.S. health care. Staffing models fall somewhere between acute care hospitals and long-term care in terms of the proportions of unlicensed personnel and practical nurses. Allocation of nursing time to patients presumably influences quality and thoroughness of nursing acts and assessments. There may be skill-mix issues as well. However, to date there have been no studies of home health agency staffing models, nurse workloads, or skill mix. OASIS (Outcomes Assessment and Information Set) data gathered by home health providers by mandate from the Medicare program, skillfully analyzed and interpreted, will offer opportunities to examine safety in home care in relation to staffing decisions.[53] Similar statements can be made about nurse staffing in most other ambulatory and community settings as well.

Summary of Current Best Practices

The general conclusion of these studies conducted in various settings is that differences in outcomes are often observed between situations or institutions where staffing is high and those where it is low. A critical mass of data suggests that staffing at the lower end of the continuum may place patients and nurses at heightened risk of poor outcomes. Therefore, it appears hazardous to patients and staff to staff at the lowest levels relative to peer units and health care organizations.

Limitations of cross-sectional observational designs that predominate in this literature have been reviewed extensively in the chapter. Prominent among these is that there is no guarantee that increasing staffing alone improves the process or outcomes of care. Nonetheless, it would appear wise to continue the widespread practice of adjusting staffing levels for setting, specialty, model of care, client needs, special circumstances, and trends in the frequency of outcomes potentially sensitive to nurse staffing.

Evidence-Based Practice Implications

A key implication arising from this review is that as much as possible, investigators should align their studies with emerging taxonomies and specifications of measures promulgated by authoritative sources (e.g., the Joint Commission). Continued proliferation of measures is slowing progress in this field. Standardized measurement will advance meta-analytic efforts and facilitate aggregation of data across studies. As hospitals and health systems are inundated with data-reporting demands, wise investigators will leverage ongoing measurement efforts by selecting core measures and common metrics already collected by hospitals. There is value for researchers to forge strategic partnerships with professional sponsors of public and private data repositories. Agencies and researchers alike will be served well by study designs that use already de-identified data and make minimal use of protected health information, particularly since the Health Insurance Portability and Accountability Act took effect in 2004.

Likewise, both researchers and clinical administrators must fully harness the potential of new health information systems to capture clinical data. High-quality data on clinical performance will drive both scientific understanding and organizations' strategic quests for excellence. Some authors suggested that competing on the analytics is a characteristic of high-performing organizations.[54]

Leaders at all levels in the health care system must decide how to apply the findings of this literature. It is impossible to read and discuss this area of research without considering whether regulation of nurse staffing is a valid application of the findings, especially in the current climate in health care. As mentioned earlier, there are no evidence-based minimum staffing ratios,[27, 55] although clinicians and managers set operating ratios every day, largely on the basis of their experience and, to a lesser extent, from extrapolations of researchers' findings. As in all aspects of health care management, empirical evidence needs to be interpreted in the context of local data and experience. Although unsatisfying to proponents and opponents of regulation, it bears mentioning that a like or dislike of minimum ratios is often based on one's values and opinions about the capacity and inclination of health care leaders to make responsible staffing decisions autonomously.

Even absent any specific legal mandates to do so, benchmarking staffing and outcomes against peers and attempting to avoid extremes of low staffing and high adverse events, keeping in mind important contextual factors when making comparisons, is undoubtedly the best administrative practice. Keeping in mind that there are many factors affecting the outcomes of care (see Figure 2), a range of efforts needs to be undertaken to increase the quality of clinical practice or reliability, defined by the Institute for Healthcare Improvement as "the number of actions that achieve the intended result divided by the number of actions taken during a target time period."[56]

Executives and managers make a host of decisions beyond those involving staffing that affect the clinical effectiveness of nursing staff. Thought leaders in the arena of patient safety practices

have identified a number of organizational strategies that may constitute better practice in managing the impact of nurse staffing on patient care quality and safety. For example, efforts to optimize clinical, throughput flow and reduce practice variability may reduce threats to staff and patients due to system and personnel overload.[57] Managing supply and demand in health care settings by smoothing peaks and valleys of patient flow,[58] as well as staffing levels, may be effective in modulating workflow extremes that cause staff distress and might pose risks to patients. Implementing systems that enable staff to standardize high-volume common practices (such as patient education, discharge planning, and risk assessments) may be expected to increase efficiency, while enabling staff to customize these highly effective interventions to the unique characteristics of the patient/family. Engaging staff in self-governance related to patient flow has also been cited as a promising best practice. Considered key to safe staffing, professional judgment as the gold standard establishes the threshold for safe patient care in a given clinical setting,[59] as nurses use a systematic decision matrix to determine if the staff on a particular unit can accept responsibility for additional patients. Informed by understanding of scientific conclusions linking staffing and patient outcomes in comparable settings, the self-governing and administrative teams of the future may use internally generated data to support decisions related to staffing adequacy and effectiveness.[60] Through systematic microsystem (unit) assessment, combined with concurrent measurement tracing structure, processes, and outcomes of care, it is possible to calibrate the expertise and dose of the nurse and individualize interventions to the unique characteristics and needs of the patient, optimizing patient care.[61]

As clinicians and administrators in clinical settings gain greater access to real-time data that enable them to explore links between structure, process, and outcomes, increasingly sophisticated tools such as virtual dashboards are promising.[18] Despite a tradition in nursing that has emphasized scientific inquiry as a fundamental source of evidence for practice, there is growing awareness that data that emerge from practice and practitioners (particularly when collected using systematic methods and with high-quality measures) may be a vital source of material for research in this and other areas of policy-relevant inquiry.[62]

Research Implications

There are a great many questions in this field that are still unanswered. There is a clear need to investigate processes of care that are specific to nursing that are associated with safer patient care as well as safer, more efficient interdisciplinary team functioning. Data issues (a lack of measures and of data sources) are a major barrier to work on care delivery. In a discussion of nursing workload measurement tools, the International Council of Nurses noted that "existing tools are unable to capture more than 40 percent of nursing work"[63] (p. 16). Future research must tackle the black box of nursing practice by acknowledging the complexity of nursing assessment, planning, intervention, and evaluation. Addressing variance in the quality of patient care performed by nurses is key to interpreting inconsistencies in the nurse staffing literature and perhaps at the heart of efforts to improve patient care outcomes. Ultimately, it is a priority for future research to explicate links between structure, process, and outcome in nursing practice and patient care.[64]

As indicated before, study of models of care using non-RN staff in acute care, of the impacts of high levels of staffing on health-promoting nursing interventions and nurse-sensitive outcomes, and of staffing and outcomes in understudied specialties in acute care and in nonacute care settings is vital. Ultimately, research in this area is on a track to assist in establishing

evidence-based management[54] that complements the profession's ongoing efforts in evidence-based practice.

Conclusion

From a research tradition in which nurse staffing factors were primarily background variables, the study of nurse staffing and patient outcomes has emerged as a legitimate and strategically crucial field of inquiry. However, despite significant growth in the number and sophistication of studies responding to public policy and provider demand for these findings, results have been inconsistent. This chapter highlights the methodologic challenges inherent in this area of inquiry and explicates how the diversity in measures and units of analyses confound literature synthesis. In the face of myriad pressures to adopt a position for or against mandated nurse-to-patient ratios, the state of the young science does not permit precision in prescribing safe ratios. In fact, it may be concluded that further research is crucial to tease out the nuances in the staffing-outcomes equation. It is essential to advancing the field that future studies replicate, extend, and refine the current body of knowledge, making explicit how characteristics of the workforce, now barely considered (for example, years of experience or professional certification), in addition to the "dose" of the nurse, are linked to processes of care that ultimately result in clinical outcomes (both desirable and adverse). Until then, selected better practices have been noted, with the potential to contribute to pragmatic efforts to improve patient care quality and safety in hospitals.

Search Strategy

The literature on nurse staffing and patient safety is rapidly evolving, very heterogeneous in terms of measures and methods, and equivocal in terms of many of its conclusions regarding specific measures. Our aim was to describe broad trends in this literature, and to this end, we based our work on four systematic, integrated reviews that contained detailed search criteria and clearly-articulated inclusion criteria and provided detailed syntheses of findings. Three of these four reviews were drawn from AHRQ publications, the most recent of which[30] included articles we had identified in our own searches of PubMed® and CINAHL® databases since 2002 and 2003 using the terms "nurse staffing," "safety," and "outcomes."

Evidence Table. Major Integrative Reviews of the Staffing-Outcomes Literature

Study	Methods	Outcomes Associated With Staffing	Outcomes for Which Data Considered Limited or Mixed
Seago 2001[25]	16 studies dealing with staffing-safety outcomes relationships, 1990–2000 Grading of design and outcome measures	NPR: Length of stay Nosocomial infections (UTI, postoperative infections, pneumonia) Pressure ulcers	NPR: Mortality Unplanned readmissions Failure to rescue Skill mix: Negative patient outcomes
Hickam 2003[38]	26 studies examining nurse workload/staffing ratios and safety outcomes, 1980–2002 (22 published 1996 or later) Grading of design appropriateness and execution	Workload and skill mix: Nonfatal adverse events Workload: Medication errors	Mortality Recognition of errors Probability that errors will affect outcomes
Lang 2004[27]	43 studies examining effects of nurse staffing on patient, nurse, and hospital outcomes, 1980-2003, excluding studies of ICUs and long-term care facilities General comments on methods limitations for all studies; grading of effect sizes	Patient outcomes: Failure to rescue Mortality Shock in medical patients; gastrointestinal hemorrhage Nurse outcomes: Nurse needlestick injuries Burnout Institutional outcomes: Documentation quality Extended length of stay	Patient outcomes: Pneumonia UTIs Falls Nosocomial infections Medication errors Pressure ulcers Patient satisfaction Morbidity Adverse drug events Intravenous errors Cardiac arrests Patient injuries Nurse outcomes: Nurse job satisfaction Absenteeism Institutional outcomes: Assaults on psychiatric units Hospital financial outcomes

Study	Methods	Outcomes Associated With Staffing	Outcomes for Which Data Considered Limited or Mixed
Kane 2007[30]	94 studies examining associations of nurse-to-patient and hours per patient-day on patient outcomes in hospital practice from the United States and Canada, 1987-2005 Formal meta-analysis (calculation of pooled effect sizes across studies and subpopulations) incorporating evaluation of methodological quality	RN NPR: Hospital-related mortality Failure to rescue+ Medical complications Unplanned extubation* Pulmonary failure*+ Hospital-acquired pneumonia* Bloodstream infections+ Cardiopulmonary resuscitation*+ Extended length of stay * Evidence of a stronger effect or more consistent evidence in ICUs + Evidence of a stronger effect or more consistent evidence in surgical patients HPPD (all staff types) Mortality Shock Upper gastrointestinal bleeding Nosocomial infection Extended length of stay	RN HPPD: Limited support LPN and UAP NPR and HPPD: Trend toward association of worse outcomes with higher use/levels

NPR: Nurse-to-patient ratios
ICU: Intensive care unit
RN: Registered nurse
LPN: Licensed practical nurse
UAP: Unlicensed assistive personnel
HPPD: Hours of care per patient-day
UTI: Urinary tract infection

Chapter 26. Work Stress and Burnout Among Nurses: Role of the Work Environment and Working Conditions

Bonnie M. Jennings

Background

Stress has been categorized as an antecedent or stimulus, as a consequence or response, and as an interaction. It has been studied from many different frameworks (or perspectives?). For example, Selye[1] proposed a physiological assessment that supports considering the association between stress and illness. Conversely, Lazarus[2] (p. 19) advocated a psychological view in which stress is "a particular relationship between the person and the environment that is appraised by the person as taxing or exceeding his or her resources and endangering his or her well-being."

Stress is not inherently deleterious, however. Each individual's cognitive appraisal, their perceptions and interpretations, gives meaning to events and determines whether events are viewed as threatening or positive.[2] Personality traits also influence the stress equation because what may be overtaxing to one person may be exhilarating to another.[3]

Nevertheless, stress has been regarded as an occupational hazard since the mid-1950s.[4] In fact, occupational stress has been cited as a significant health problem.[5–7] Work stress in nursing was first assessed in 1960 when Menzies[8] identified four sources of anxiety among nurses: patient care, decisionmaking, taking responsibility, and change. The nurse's role has long been regarded as stress-filled based upon the physical labor, human suffering, work hours, staffing, and interpersonal relationships that are central to the work nurses do. Since the mid-1980s, however, nurses' work stress may be escalating due to the increasing use of technology, continuing rises in health care costs,[9] and turbulence within the work environment.[10]

In 1974, Freudenberger[11] coined the term "burnout" to describe workers' reactions to the chronic stress common in occupations involving numerous direct interactions with people. Burnout is typically conceptualized as a syndrome characterized by emotional exhaustion, depersonalization, and reduced personal accomplishment.[12] Work life, however, is not independent from family life; these domains may even be in conflict.[13, 14] Stress may result from the combined responsibilities of work, marriage, and children.[15–17] The effects of both work and nonwork stress among nurses have been studied infrequently.[18] And yet, nonwork stress may be particularly salient to nursing, a predominantly female profession. Women continue to juggle multiple roles, including those roles related to the home and family, for which the women may have sole or major responsibility.

Nevertheless, work stress and burnout remain significant concerns in nursing, affecting both individuals and organizations. For the individual nurse, regardless of whether stress is perceived positively or negatively, the neuroendocrine response yields physiologic reactions that may ultimately contribute to illness.[1] In the health care organization, work stress may contribute to absenteeism and turnover, both of which detract from the quality of care.[9] Hospitals in particular are facing a workforce crisis. The demand for acute care services is increasing concurrently with changing career expectations among potential health care workers and growing dissatisfaction among existing hospital staff.[19] By turning toxic work environments into healthy workplaces, researchers and nurse leaders believe that improvements can be realized in recruitment and

retention of nurses, job satisfaction for all health care staff, and patient outcomes—particularly those related patient safety.[20]

Research Evidence
