October 10, 2008

TO THE PARTY ADDRESSED:

I am pleased to enclose a copy of the National Highway Traffic Safety Administration (NHTSA) Final Environmental Impact Statement (FEIS) for new Corporate Average Fuel Economy (CAFE) standards required by the Energy Independence and Security Act of 2007. NHTSA recently proposed standards for model year (MY) 2011-2015 passenger cars and light trucks (Notice of Proposed Rulemaking; 73 *Federal Register* 24,352, May 2, 2008).

The FEIS compares the environmental impacts of the agency's Preferred Alternative and reasonable alternatives, including a "No Action" Alternative, pursuant to the National Environmental Policy Act (NEPA), 42 U.S.C. §§ 4321-4347, and implementing regulations issued by the Council on Environmental Quality (CEQ) and the U.S. Department of Transportation. The FEIS considers direct, indirect, and cumulative impacts and describes these impacts to inform decisionmakers and the public of the environmental impacts of the various alternatives.

Among other potential impacts, NHTSA analyzed the direct and indirect impacts related to fuel and energy use, emissions, including carbon dioxide (CO_2) and its effects on temperature and climate change, air quality, natural resources, and the human environment. NHTSA also considered the cumulative impacts of the proposed standards for MY 2011-2015 passenger cars and light trucks, together with estimated impacts of NHTSA's implementation of the CAFE program through MY 2010 and NHTSA's future CAFE rulemaking for MY 2016-2020, as prescribed by the Energy Policy and Conservation Act (EPCA), as amended by the Energy Independence and Security Act of 2007.

In developing the proposed fuel economy standards and reasonable alternatives, NHTSA considered the four EPCA factors underlying the statutory requirement for "maximum feasible" standards (technological feasibility, economic practicability, the effect of other Government standards on fuel economy, and the need of the Nation to conserve energy) and relevant environmental and safety considerations. NHTSA used a computer model that, for any given model year, applies technologies to a manufacturer's fleet until the manufacturer achieves compliance with the standard under consideration. In light of the EPCA factors, NHTSA assigned monetary values to relevant externalities (both energy security and environmental externalities, including the benefits of reductions in CO_2 emissions).

NHTSA is mailing this EIS to approximately 300 interested parties, including Federal, State, and local agencies, elected officials, environmental and public interest groups, Native American tribes, and other interested individuals.

Chapter 1 of the enclosed FEIS describes the public comment process. Comments on the DEIS and NHTSA's responses to those comments are provided in Chapter 10 of this FEIS. Written comments and the public hearing transcript can be viewed in their entirety in Appendix D of this FEIS. The transcript from the public hearing and written comments submitted to the agency are also a part of the administrative record, and are available on the Federal Docket, which can be found on the web at http://www.regulations.gov, Reference Docket No.: NHTSA-2008-0060.

No sooner than 30 days after the Environmental Protection Agency publishes a Notice of Availability of the FEIS in the *Federal Register*, NHTSA will publish a final CAFE rule and Record of Decision.

The FEIS has been placed in NHTSA's public files and is available for distribution and public inspection at:

DOT Library, W12-300
1200 New Jersey Avenue, SE
West Building
Washington, DC 20590

A limited number of hard copies and CD-ROMs of the DEIS and this FEIS are available from the DOT Library. The DEIS and this FEIS are also available for public viewing on the CAFE Web site at http://www.nhtsa.dot.gov. NHTSA is mailing copies of the FEIS to parties on its CAFE NEPA mailing list, including Federal, State, and local agencies; representatives of Native American tribes, industry, and public-interest groups; and individuals who requested a copy of the DEIS or provided comments during the EIS scoping period or the DEIS public comment period.

Additional information about the project is available from NHTSA's Fuel Economy Division, Office of International Policy, Fuel Economy and Consumer Programs, at 1-202-366-5206 or on the NHTSA CAFE Web site identified above. For assistance, please contact NHTSA through the following Website: https://www.nhtsa.dot.gov/email.cfm or toll free at 1-888-327-4236 (for TTY, contact 1-800-424-9153). The NHTSA CAFE Web site also provides access to the texts of formal NHTSA documents, such as orders, notices, and rulemakings.

Sincerely yours,

David Kelly

David Kelly
Acting Administrator

Enclosure

Summary

S.1 FOREWORD

The National Highway Traffic Safety Administration (NHTSA) prepared this Final Environmental Impact Statement (FEIS) to analyze and disclose the potential environmental impacts of Corporate Average Fuel Economy (CAFE) standards for the total fleet of passenger and non-passenger automobiles (later referred to as cars and light trucks, respectively) and reasonable alternative standards for the NHTSA CAFE Program pursuant to Council on Environmental Quality (CEQ) National Environmental Policy Act (NEPA) implementing regulations, U.S. Department of Transportation (DOT) Order 5610.1C, and NHTSA regulations.[1] This FEIS compares the potential environmental impacts of alternative mpg levels that will be considered by NHTSA for the final rule, including the Preferred Alternative and a No Action Alternative. It also analyzes direct, indirect, and cumulative impacts and analyzes impacts in proportion to their significance. A broad and comprehensive analysis of the alternatives, varied by economic inputs and sensitivities, and likely environmental impacts are included in this FEIS for decisionmakers.

S.2 BACKGROUND

The Energy Policy and Conservation Act of 1975 established a program to regulate automobile fuel economy and provided for the establishment of average fuel economy standards for passenger cars and separate standards for light trucks. As part of that Act, the CAFE Program was established to reduce national energy consumption by increasing the fuel economy of cars and light trucks. The Act directs the Secretary of Transportation to set and implement fuel economy standards for cars and light trucks sold in the United States. NHTSA is delegated responsibility for implementing the Energy Policy and Conservation Act fuel economy requirements assigned to the Secretary of Transportation.

In December 2007, the Energy Independence and Security Act of 2007 amended Energy Policy and Conservation Act CAFE Program requirements and granted DOT additional rulemaking authority. Pursuant to the Energy Independence and Security Act, on April 22, 2008, NHTSA proposed CAFE standards for model year (MY) 2011-2015 passenger cars and light trucks in a Notice of Proposed Rulemaking issued on May 2, 2008.

S.3 PURPOSE AND NEED FOR THE PROPOSED ACTION

The Energy Independence and Security Act sets forth extensive requirements for the rulemaking, and those requirements form the purpose of and need for the standards. The requirements also were the basis for establishing the range of alternatives considered in this FEIS. Specifically, the Energy Policy and Conservation Act requires the Secretary of Transportation to establish average fuel economy standards for each model year at least 18 months before the beginning of that model year and to set them at "the maximum feasible average fuel economy level that the Secretary decides the manufacturers can achieve in that model year." When setting maximum feasible fuel economy standards, the Secretary is required to "consider technological feasibility, economic practicability, the effect of other motor vehicle standards of the Government on fuel economy, and the need of the United States to conserve energy." NHTSA interprets the statutory factors as including environmental issues and permitting the consideration of other relevant societal issues, such as safety. The purpose of this FEIS is to disclose and

[1] NEPA is codified at 42 U.S.C. § 4321-4347. CEQ NEPA implementing regulations are codified at 40 Code of Federal Regulations (CFR) Parts 1500-1508. NHTSA NEPA implementing regulations are codified at 49 CFR Part 520.

analyze the potential environmental impacts of the standards and alternatives for consideration by the NHTSA decisionmaker.

The Energy Independence and Security Act further directs the Secretary, after consultation with the Secretary of Energy and the Administrator of the U.S. Environmental Protection Agency (EPA), to establish separate average fuel economy standards for passenger cars and for light trucks manufactured in each model year beginning with MY 2011 "to achieve a combined fuel economy average for MY 2020 of at least 35 miles per gallon for the total fleet of passenger and non-passenger automobiles manufactured for sale in the United States for that model year." In this FEIS, passenger and non-passenger are also referred to as the car and light truck fleet. In so doing, the Secretary of Transportation is to adopt "annual fuel economy standard increases," but in any single rulemaking, standards may be established for not more than 5 model years. This FEIS covers the initial 5-year rulemaking and also considers the cumulative impacts of reaching the 35-miles-per-gallon (mpg) total fleet requirement during the second 5-year period, MY 2016-2020.

S.4 ALTERNATIVES

NEPA requires an agency to compare the potential environmental impacts of its proposed action and a reasonable range of alternatives. The Energy Policy and Conservation Act fuel economy requirements, including the four factors NHTSA must consider in determining maximum feasible CAFE levels – technological feasibility, economic practicability, the need to conserve energy, and the effect of other standards of the Government on fuel economy – form the purpose of and need for the MY 2011-2015 CAFE standards and, therefore, inform the range of alternatives for consideration in this NEPA analysis. NHTSA recognizes that several alternative CAFE levels are conceivable and that the alternatives represent several points on a continuum of alternatives. The NHTSA decision process must balance the four Energy Policy and Conservation Act factors and be informed by the environmental considerations of NEPA. In developing its reasonable range of alternatives, NHTSA identified alternative stringencies that represent the full spectrum of potential environmental impacts and safety considerations. The Draft Environmental Impact Statement (DEIS) and this FEIS analyze the impacts of six "action" alternatives and the impacts that would be expected if NHTSA imposed no new requirements (the No Action Alternative).

In response to public comments on the DEIS, this FEIS also examines how these alternatives are affected by variations in the economic assumptions input to the computer model NHTSA uses to calculate the costs and benefits of various CAFE standards (the Volpe model). NHTSA calculated and analyzed mpg standards and environmental impacts associated with each alternative under several model input scenarios. The "Reference Case" uses as model inputs the Energy Information Administration's reference case fuel price forecast and a domestic social cost of carbon. The "High Scenario" uses as model inputs the Energy Information Administration's high case for fuel price forecast and a global social cost of carbon. Values for the domestic and social costs of carbon have been updated from the DEIS, as have those for the costs of oil externalities. NHTSA also examined two other input scenarios, Mid-1 and Mid-2 Scenarios, to show how input values between those used in the Reference Case and the High Scenario result in mpg that falls between the mpg associated with the Reference Case and the High Scenario. All input scenarios use a 3-percent discount rate to calculate the current value of carbon emissions reductions. The High Scenario also uses a 3-percent discount rate to calculate the current value of other costs and benefits, while the Reference Case and Mid-1 and Mid-2 Scenarios use a 7-percent discount rate to calculate the current value of costs and benefits other than future carbon reductions.

NHTSA's Preferred Alternative is the Optimized Alternative (Alternative 3), which establishes optimized mpg standards that yield the greatest net benefits of all feasible alternatives. As mpg standards are increased beyond this optimized level, manufacturers would be forced to apply technologies that entail higher incremental costs than benefits, thereby reducing total net benefits.

The most stringent alternative NHTSA analyzed is the Technology Exhaustion Alternative (Alternative 7), which represents the level at which vehicle manufacturers apply all feasible technologies, while recognizing that some must still be installed as part of a vehicle freshening or redesign. Alternative 7 would yield negative net benefits. Another specific alternative NHTSA analyzed was the Total Costs Equal Total Benefits Alternative (Alternative 6), the second most stringent alternative, under which manufacturers would be forced to apply technologies until total costs equal total benefits, yielding zero net benefits. Three other alternatives NHTSA analyzed (Alternatives 2, 4, and 5) illustrate how costs, benefits, and net benefits vary across other possible CAFE standards between the No Action Alternative (Alternative 1) and the Total Costs Equal Total Benefits Alternative (Alternative 6).

As shown in Table S-1, the 50 Percent Above Optimized Alternative would generate a 2015 mpg standard half way between the Optimized and Total Costs Equal Total Benefits Alternatives. The 25 Percent Above Optimized Alternative would generate a 2015 mpg standard halfway between the Optimized and 50 Percent Above Optimized Alternatives, and the 25 Percent Below Optimized Alternative would generate a 2015 standard that falls below the Optimized Alternative by the same absolute amount by which the 25 Percent Above Optimized Alternative exceeds the Optimized Alternative.

Table S-1

Reference Case Alternative CAFE Standards in MY 2015 MPG

	Alt. 1	Alt. 2	Alt. 3	Alt. 4	Alt. 5	Alt. 6	Alt. 7
	No Action	**25% Below Optimized**	**Optimized**	**25% Above Optimized**	**50% Above Optimized**	**Total Costs Equal Total Benefits**	**Technology Exhaustion**
Cars	27.5	33.3	33.4	33.5	33.7	33.9	47.1
Trucks	23.4	25.8	26.0	26.2	26.5	27.0	37.2

The specific mpg standards associated with each alternative in Table S-1 reflect the Reference Case input values for fuel prices, the social cost of carbon, the discount rate, and oil import externalities. Table S-2 lists the Reference Case and High Scenario values for key economic model inputs. Table S-3 shows how the mpg standards associated with each alternative would change with this combination of inputs. Chapter 2 of this FEIS provides a more detailed description of the Input Scenarios used in the analysis**.**

The alternatives in Tables S-1 and S-3 are both defined by the same relationship between costs and benefits calculated by the economic model. The specific mpg standards associated with the alternatives in Tables S-1 and S-3 differ because model input values affect the relationship between costs and benefits. For example, the Optimized Alternative that yields the greatest net benefits is associated with the specific mpg standards of 33.4 for cars and 26.0 for trucks in MY 2015, as shown in Table S-1, based on the Reference Case inputs in Table S-2. For the High Scenario, the Optimized Alternative that yields the greatest net benefits is associated with the specific mpg standards of 37.7 for cars and 29.6 for trucks in MY 2015, as shown in Table S-3.

Table S-2

Reference Case and High Scenario Economic Model Inputs

	Value of Carbon Dioxide (CO_2) (2007 $/ton)	Oil Import Externalities (2007 $/gallon)	*Annual Energy Outlook 2008* a/ Fuel Price	Discount Rate
Reference Case	$2.00 (domestic)	$0.326	$2.41 (reference)	3% CO_2 – 7% Other
High Scenario	$33.00 (global)	$0.116	$3.33 (high)	3% CO_2 – 3% Other

a/ Both the Reference and High *Annual Energy Outlook* fuel price vary by year. Price shown is the average 2011-2030 price for gasoline expressed in 2007 dollars.

Table S-3

High Scenario Alternative CAFE Standards in MY 2015 MPG

	Alt. 1	Alt. 2	Alt. 3	Alt. 4	Alt. 5	Alt. 6	Alt. 7
	No Action	25% Below Optimized	Optimized (Preferred)	25% Above Optimized	50% Above Optimized	Total Costs Equal Total Benefits	Technology Exhaustion
Passenger Cars	27.5	37.2	37.7	38.2	38.8	39.8	47.1
Light Trucks	23.4	28.9	29.6	30.3	31.0	32.3	37.2

An infinite number of mpg standards could theoretically be defined along a continuum from the least to the most stringent levels of CAFE standards. NHTSA selected the specific alternatives analyzed to illustrate cost and benefit characteristics along this continuum. A vast number of model input values also could be used to analyze costs and benefits (along a continuum from low to high values for fuel price, carbon dioxide (CO_2), oil import externalities, and the discount rate), serving as model parameters to these existing alternatives and generating additional mpg levels for analysis.[2] These model parameters are estimated forecasts of future economic circumstances. NHTSA acknowledges that these estimates are subject to uncertainty and debate. Many who commented on the DEIS noted that a combination of different model input values would result in substantially higher mpg standards associated with the Optimized Alternative. In this FEIS, NHTSA addresses uncertainty about model input values by presenting analytical results for the Reference Case and High Scenario model inputs, and for two other scenarios with model inputs that fall between these (the Mid-1 and Mid-2 Scenarios).

The resource sections in Chapters 3 and 4 of this FEIS discuss the analysis of alternatives for the Reference Case model inputs under the heading "Environmental Consequences." The Reference Case discussions are followed by sections entitled "Input Scenarios," which discuss the impacts for the same alternatives under the High Scenario, and for other scenarios that have model inputs and outputs that fall between those of the Reference Case and High Scenario (the Mid-1 and Mid-2 Scenarios). This analytical structure is designed to fully inform decisionmakers and the public about the potential environmental impacts of any combination of economic inputs into the model, across the range of feasible alternatives.

[2] CEQ guidance instructs that "[w]hen there are potentially a very large number of alternatives, only a reasonable number of examples, covering the full spectrum of alternatives, must be analyzed and compared in the EIS." CEQ, *Forty Most Asked Questions Concerning CEQ's National Environmental Policy Act Regulations*, 46 *FR* 18026, 18027, March 23, 1981 (emphasis in original).

S.5 POTENTIAL ENVIRONMENTAL CONSEQUENCES

This FEIS describes potential environmental impacts to a variety of resources. The resource areas that warrant the most detailed analysis are energy resources, air quality, and climate and resources that might be affected by changes in climate. Tables and figures in this section summarize the direct, indirect, and cumulative effects of the CAFE alternatives on energy, air quality, and climate. NHTSA recognizes the national interest in global climate change issues, particularly as related to the Country's use of automobiles and light trucks. "Global climate change" refers to long-term fluctuations in global surface temperatures, precipitation, sea level, cloud cover, ocean temperatures and currents, and other climatic conditions. Scientific research has shown that in the past century, Earth's surface temperature has risen by an average of about 1.3 degrees Fahrenheit (°F) (0.74 degree Celsius[°C]) (IPCC 2007c) and sea levels have risen 6.7 inches (0.17 meter) (IPCC 2007c).

Most scientists now agree that climate change is very likely due to greenhouse gas (GHG) emissions from human activities (IPCC 2007d). Most GHGs are naturally occurring, including CO_2, methane (CH_4), nitrous oxide (N_2O), water vapor, and ozone (O_3). Human activities, such as the combustion of fossil fuel, the production of agricultural commodities, and the harvesting of trees, can contribute to increased concentrations of these gases in the atmosphere.

Levels of atmospheric CO_2 have been rising rapidly. For about 10,000 years prior to the Industrial Revolution, atmospheric CO_2 levels were 280 ppm (plus or minus 20 ppm). Since the Industrial Revolution, CO_2 levels have risen to 367 ppm in 1999 and to 379 ppm in 2005. In addition, other GHGs have been on the increase. Direct atmospheric measurements since 1970 have detected a 150 percent decrease in CH_4 and an 18 percent increase in N_2O (IPCC 2007c).

Contributions to the build-up of GHG in the atmosphere vary greatly from country to country, and depend heavily on the level of industrial and economic activity. Emissions from the United States accounted for approximately 15 to 20 percent of global GHG emissions in the year 2000. With more than one-quarter of these U.S. emissions due to the combustion of petroleum fuels in the transportation sector, CO_2 emissions from the United States transportation sector represent approximately 4 percent of all global GHG emissions. Emissions from passenger cars and light trucks account for about 60 percent of emissions from the U.S. transportation sector.[3]

Throughout this FEIS, NHTSA has relied extensively on findings of the United Nations Intergovernmental Panel on Climate Change (IPCC) and the U.S. Climate Change Science Program (USCCSP). Our discussion relies heavily on the most recent, thoroughly peer-reviewed, and credible assessments of global climate change and its impact on the United States: the IPCC Fourth Assessment Report Working Group I[4] and II[5] Reports,[6] and reports by the USCCSP that include *Scientific Assessments of the Effects of Global Climate Change on the United States* and Synthesis and Assessment Products.[7] This FEIS cites these sources and the studies they review frequently. For these reasons, NHTSA encourages readers to read the Synthesis Report: Summary for Policymakers of the IPCC Fourth

---

[3] Estimation of this number is complicated by the fact that greenhouse gas inventories are taken by EPA, but EPA uses different definitions of passenger cars and light trucks than EPCA.

[7] *See generally* http://www.climatescience.gov/.

Assessment Report before reading this FEIS.[8] This relatively short document summarizes the key findings of the IPCC Fourth Assessment Report.

Because of the link between the transportation sector and GHG emissions, NHTSA recognizes the need to consider the possible impacts on climate and global climate change in the analysis of the effects of these fuel economy standards. NHTSA also recognizes the difficulties and uncertainties involved in such an impact analysis. Accordingly, consistent with CEQ regulations on addressing incomplete or unavailable information in environmental impact analyses, NHTSA has reviewed existing credible scientific evidence which is relevant to this analysis and summarized it in this FEIS. NHTSA has also employed and summarized the results of research models generally accepted in the scientific community.

NHTSA emphasizes that the action of setting fuel economy requirements does not directly regulate emissions from passenger cars and light trucks. NHTSA's authority to promulgate new fuel economy standards is a limited authority and does not allow it to regulate other factors affecting emissions, including society's driving habits. The proposed action before NHTSA is to establish the CAFE standards for MY 2011-2015 passenger cars and light trucks, which has a primary goal of energy conservation. At the same time, the reduction of CO_2 emissions is a substantial by-product of that conservation. Further, the stringency of the fuel economy standards is based on the valuation of both direct (fuel savings) and indirect (*e.g.*, the reduction of CO_2 emissions) benefits. To the extent that the CAFE standards reduce fuel consumption, they play a role in reducing vehicle emissions that would have occurred absent such conservation. Consequently, as discussed in this FEIS, the proposed action will indirectly contribute to reducing impacts on and associated with the ongoing process of global climate change.

Although the alternatives have the potential to substantially decrease GHG emissions, they do not prevent climate change, but only result in reductions in the anticipated increases in CO_2 concentrations, temperature, precipitation, and sea level. They would also to a small degree delay the point at which certain temperature increases and other physical effects stemming from increased GHG emissions would occur. As discussed below, NHTSA presumes that these reductions in climate effects will be reflected in reduced impacts on affected resources.

NHTSA informed the public through notices in the *Federal Register* of its intent to prepare a DEIS for this proposed action. The purpose of these notices was to request from the public its views and comments on the scope of the NEPA analysis, including the impacts and alternatives the DEIS should address, and to inform NHTSA of any available studies that would assist in the impact analysis for global climate-change issues. NHTSA reviewed and considered the public scoping comments and the studies commenters suggested. The predominant request by commenters during the scoping process was that NHTSA focus the DEIS on the standards' possible impacts on both air quality and global climate change.

EPA issued the Notice of Availability of the DEIS on July 3, 2008, which initiated a 45-day public comment period. NHTSA held a public hearing on the DEIS in Washington, DC, on August 4, 2008. The DEIS public comment period ended on August 18, 2008. NHTSA received 66 written comment documents from interested stakeholders. In addition, 44 private citizens and organizations provided oral statements at the public hearing.

[8] IPCC, 2007: Summary for Policymakers. In: *Climate Change 2007: Impacts, Adaptation and Vulnerability. Contribution of Working Group II to the Fourth Assessment Report of the IPCC*, M.L. Parry, O.F. Canziani, J.P. Palutikof, P.J. van der Linden and C.E. Hanson, Eds., Cambridge University Press, Cambridge, UK, 7-22, *available at* http://www.ipcc.ch/pdf/assessment-report/ar4/wg2/ar4-wg2-spm.pdf.

Commenters urged NHTSA to consider standards that would go beyond the Energy Independence and Security Act's minimum requirement to reach 35 mpg by the year 2020. NHTSA has analyzed a full range of alternatives, the most stringent of which exceed the 35 mpg target by 2015. Commenters also noted that environmental impacts could depend on the choice of economic inputs used in the Volpe model. NHTSA has addressed these concerns by analyzing the full range of environmental impacts that result under varying economic inputs for each alternative. Finally, commenters requested that the FEIS discuss the appropriate context of this action in relation to other large-scale actions that reduce GHGs, and NHTSA has included such a discussion in this FEIS.

NHTSA consulted with various federal agencies in the development of this FEIS, including the EPA, the Centers for Disease Control and Prevention, the National Oceanic and Atmospheric Administration, the U.S. Fish and Wildlife Service, the National Park Service, and the U.S. Forest Service.

While the main focus of this FEIS is the quantification of impacts to energy, air quality, and climate, and qualitative analysis of cumulative impacts resulting from climate change, it also addresses other potentially affected resources. NHTSA conducted a qualitative review of the related direct, indirect, and cumulative impacts, positive or negative, of the alternatives on other potentially affected resources (water resources, biological resources, land use, hazardous materials, safety, noise, historic and cultural resources, and environmental justice). Effects of the alternatives on these resources would be too small to address quantitatively. Impacts to biological resources could include reductions in habitat disturbance, decreased impacts from acid rain on water and terrestrial habitats from decreases in petroleum production, and increased agricultural-related disturbances and runoff due to biofuel production. Impacts to land use and development could include increased agricultural land use. Impacts to safety could include downweighting of vehicles and increased vehicle miles traveled, resulting in increased traffic injuries and fatalities. Impacts to hazardous materials could include overall reductions in the generation of air and oil production related wastes, and increases in agricultural wastes due to biofuel production. Impacts to historic and cultural resources could include reductions in acid rain related damage. Noise impacts could include increased noise levels in some areas due to higher vehicle miles traveled. Impacts to environmental justice populations could include increased air toxics in some areas as a result of higher vehicle miles traveled. No impacts are expected to natural areas protected under Section 4(f) of the Department of Transportation Act. In addition, NHTSA has determined a Section 7 review under the Endangered Species Act is not required.

The effects of the alternatives on climate – CO_2 concentrations, temperature, precipitation, and sea-level rise – can translate into impacts on key resources, including freshwater resources, terrestrial ecosystems, coastal ecosystems, land use, human health, and environmental justice. Although the alternatives have the potential to substantially decrease GHG emissions, they do not prevent climate change from occurring. However, the magnitudes of the changes in these climate effects under the alternatives – a few parts per million of CO_2, one or two one-hundredths of a degree Celsius difference in temperature, a small percentage change (0.02 percent to 0.03 percent) in the rate of precipitation increase, and 1 or 2 millimeters of sea-level change – are too small to meaningfully address quantitatively in terms of their impacts on resources. Given the enormous resource values at stake, these distinctions could be important – very small percentages of huge numbers can still yield substantial results – but they are too small for current quantitative techniques to resolve. Consequently, the discussion of resource impacts does not distinguish among the CAFE alternatives, but rather provides a qualitative review of the benefits of reducing GHG emissions and the magnitude of the risks involved in climate change.[9]

[9] *See* 42 U.S.C. § 4332 (requiring federal agencies to "identify and develop methods and procedures … which will insure that presently unquantified environmental amenities and values may be given appropriate consideration"); 40

NHTSA examined the impacts resulting from global climate change due to all global emissions on the U.S. and global scale. Impacts to freshwater resources could include changes in precipitation patterns, decreasing aquifer recharge in some locations, changes in snowpack and time of snowmelt, salt-water intrusion from ocean rise, changes in weather patterns resulting in flooding or drought in certain regions, increased water temperature, and numerous other changes to freshwater systems that disrupt human use and natural aquatic habitats. Impacts to terrestrial ecosystems could include shifts in species range and migration patterns, potential extinctions of sensitive species unable to adapt to changing conditions, increases in the occurrence of forest fires and pest infestation and intensity, and changes in habitat productivity because of increased atmospheric CO_2. Impacts to coastal ecosystems, primarily from predicted sea-level rise, could include the loss of coastal areas due to submersion and erosion, additional impacts from severe weather and storm surges, and increased salinization of estuaries and freshwater aquifers. Impacts to land use could include flooding and severe-weather impacts to coastal, floodplain and island settlements, extreme heat and cold waves, increases in drought in some locations, and weather/sea-level related disruptions of the service, agricultural, and transportation sectors. Impacts to human health could include increased mortality and morbidity due to excessive heat, increases in respiratory conditions due to poor air quality, increases in water and food-borne diseases, changes to the seasonal patterns of vector-borne diseases, and increases in malnutrition. Impacts to environmental justice populations could come from any of the above.

S.5.1 Direct and Indirect Effects

Under NEPA, direct effects “are caused by the action and occur at the same time and place” (40 CFR § 1508.8). CEQ regulations define indirect effects as those that “are caused by the action and are later in time or farther removed in distance but are still reasonably foreseeable. Indirect effects may include … effects on air and water and other natural systems, including ecosystems” (40 CFR § 1508.8). Below is a description of the direct and indirect effects of the CAFE alternatives on energy, air quality, and climate.

S.5.1.1 Energy – Reference Case

Table S-4 shows the impact on annual fuel consumption under the Reference Case for passenger cars and light trucks from 2020 through 2060,[10] a period during which an increasing volume of the fleet will be MY 2011-2015 vehicles. The table shows annual total fuel consumption (both gasoline and diesel) under the No Action Alternative and the six action alternatives for the Reference Case. Fuel consumption under the No Action Alternative is 264.9 billion gallons in 2060. Consumption falls to under 256.3 billion gallons under the Optimized Alternative and would fall to 214.3 billion gallons under the Technology Exhaustion Alternative.

CFR § 1502.23 (requiring an EIS to discuss the relationship between a cost-benefit analysis and any analyses of unquantified environmental impacts, values, and amenities); CEQ, *Considering Cumulative Effects Under the National Environmental Policy Act* (1984), *available at* http://ceq.hss.doe.gov/nepa/ccenepa/ccenepa.htm (recognizing that agencies are sometimes “limited to qualitative evaluations of effects because cause-and-effect relationships are poorly understood” or cannot be quantified).

[10] NHTSA uses 2060 as the end point for the analysis because it is the time at which 98 percent or more of the operating fleet would be made up of MY 2011-2015 or newer vehicles, thus achieving the maximum fuel savings under this rule.

Table S-4

Reference Case Passenger Car and Light Truck Annual Fuel Consumption and Fuel Savings (billion gallons)

Calendar Year	Alternative CAFE Standards for MY 2011-2015						
	Alt. 1	Alt. 2	Alt. 3	Alt. 4	Alt. 5	Alt. 6	Alt. 7
	No Action	25% Below Optimized	Optimized	25% Above Optimized	50% Above Optimized	Total Cost Equal Total Benefit	Technology Exhaustion

S.5.1.2 Energy – Input Scenarios

In response to public comments, and to test how different economic assumptions could affect estimates of fuel consumption, NHTSA examined scenarios that varied cost inputs used in the Volpe model. NHTSA modeled three additional scenarios – High, Mid-1, and Mid-2 – and compared the results to the Reference Case. Table S-5 lists the impact on annual fuel consumption under the High Scenario in the Volpe model for passenger cars and light trucks from 2020 through 2060. The High Scenario uses the economic inputs described in Table S-2. Table S-5 lists annual total fuel consumption for passenger cars and light trucks, both gasoline and diesel, under the No Action Alternative and the six action alternatives. Fuel consumption under the No Action Alternative will reach 230.8 billion gallons by 2060, when the entire fleet is likely to be composed of MY 2011 or newer cars. With the assumption of higher fuel prices, lower consumption is expected across the alternatives. Consumption totals 210.2 billion gallons under the High Scenario Optimized Alternative in 2060, compared to 256.3 billion gallons under the Reference Case Optimized Alternative.

Table S-5

S.5.1.3 Air Quality – Reference Case

Table S-6 summarizes the total national criteria and air toxic pollutant emissions in 2035[11] for the seven alternatives under the Reference Case, left to right in order of increasing fuel economy requirements. At the national level, most emissions analyzed in this FEIS are reduced by the Alternatives under the Reference Case, regardless of analysis year. The No Action Alternative has the highest emissions of all the alternatives for oxides of nitrogen (NO_x), fine particulate matter ($PM_{2.5}$), sulfur oxides (SO_x), volatile organic compounds (VOCs), acetaldehyde, 1,3-butadiene, and diesel particulate matter. Alternative 3 has the highest emissions of all the alternatives for CO and benzene, indicating slight increases over the No Action Alternative. Alternative 7 has the highest emissions of all the alternatives for acrolein and formaldehyde.

S.5.1.4 Air Quality - Input Scenarios

In response to public comments, and to test how different economic assumptions might affect estimates of air quality impacts, NHTSA modeled three additional scenarios – High, Mid-1, and Mid-2 – and compared the results to the Reference Case. Table S-7 summarizes the national criteria and air toxic pollutant emissions in 2035 for the seven alternatives for the High Scenario. For the High Scenario, emissions under each alternative are generally lower than for the Reference Case. At the national level, most emissions are reduced from the No Action Alternative under the High Scenario, but acetaldehyde and formaldehyde demonstrate increases in some localized cases. These localized increases slightly offset the reductions achieved by implementation of Clean Air Act (CAA) requirements, motor vehicle emissions standards, and related programs. All of the alternatives would reduce adverse health outcomes and health costs related to motor vehicle air pollution, and thus would have beneficial health effects that would not need mitigation.

[11] NHTSA uses 2035 as the latest projection year because by 2035 almost all passenger cars and light trucks in operation would meet at least the MY 2011-2015 standards, and the impact of the standards would start to come only from VMT growth rather than further tightening of the standards. NHTSA believes the year 2035 is a practical maximum for impacts of criteria and toxic air pollutants to be considered reasonably foreseeable rather than speculative.

S.5.1.5 Climate – Reference Case GHG Emissions

Table S-8 shows total GHG emissions and emissions reductions from new passenger cars and light trucks from 2010-2100[12] under each of the seven alternatives for the Reference Case. While GHG emissions from this sector will continue to rise over the period (absent other reduction efforts), the effect of the alternatives is to slow this increase by varying amounts. Compared to the No Action Alternative, projections of emissions reductions over the 2010 to 2100 time frame due to other MY 2011-2015 alternative CAFE standards ranged from 5,922 to 28,047 million metric tons of CO_2 ($MMTCO_2$).[13] Over this period, this range of alternatives would reduce global CO_2 emissions (from all sources) by about 0.1 to 0.6 percent (based on global emissions of 4,850,000 $MMTCO_2$).

Table S-8

Reference Case Emissions and Emissions Reductions Due to the MY 2011-2015 CAFE Standards from 2010-2100 ($MMTCO_2$)

Alternative	Emissions	Emissions Reductions Compared to No Action Alternative
1 No Action	221,258	0
2 25 Percent Below Optimized	215,337	5,922

5 50 Percent Above Optimized	213,254	8,004
6 Total Costs Equal Total Benefits	212,345	8,913
7 Technology Exhaustion	193,212	28,047

S.5.1.6 Climate - Reference Case CO_2 Concentration and Global Mean Surface Temperature

This FEIS uses a climate model to estimate the changes in CO_2 concentrations, global mean surface temperature, and changes in sea level for each alternate CAFE standard, and uses increases in global mean surface temperature combined with an approach and coefficients from the IPCC Fourth Assessment Report (IPCC 2007a) to estimate changes in global precipitation. NHTSA used MAGICC (Model for the Assessment of Greenhouse-gas Induced Climate Change) Version 5.3 (Wigley 2003 to 2008) to estimate changes in key direct and indirect effects. The application of MAGICC version 5.3 uses the emissions estimates from the Volpe model, which include CO_2, CH_4, and N_2O from both direct fuel combustion and upstream sources, as well as SO_2, NO_x, CO, and VOCs. NHTSA performed sensitivity analyses to examine the relationship among various CAFE alternatives, climate sensitivities, and scenarios of global emissions paths and the associated direct and indirect effects for each combination. These relationships can be used to infer the effect of the emissions associated with the regulatory alternatives on direct and indirect climate effects.

[12] The global climate change models NHTSA used for this FEIS analysis use 2100 because we believe that, given the present state of the science, 2100 is a practical maximum for impacts of climate change to be considered reasonably foreseeable rather than speculative.
[13] The values here are summed from 2010 through 2100, and therefore are considerably higher than the value of 520 $MMTCO_2$ cited in the Notice of Proposed Rulemaking for the Optimized Alternative. The latter value is the reduction in CO_2 emissions by only MY 2011-2015 passenger cars and light trucks over their lifetimes resulting from the optimized CAFE standards, measured as a reduction from the Notice of Proposed Rulemaking baseline of extending the CAFE standards for MY 2010 to apply to MY 2011-2015.

Table S-9 shows mid-range estimated CO_2 concentrations, increase in global mean surface temperature, and sea-level rise in 2030, 2060, and 2100 under the No Action Alternative and the six action alternatives. There is a fairly narrow band of estimated CO_2 concentrations as of 2100, from 714.6 parts per million under the Technology Exhaustion Alternative to 717.2 parts per million under the No Action Alternative. Because CO_2 concentrations are the key driver of climate effects, this narrow range implies that the differences among alternatives are difficult to distinguish. These estimates include considerable uncertainty due to a number of factors, of which the climate sensitivity is the most important. The IPCC Fourth Assessment Report estimates a range of climate sensitivity from 2.5 to 4.0 °C with a mid point of 3.0 °C which directly relates to the uncertainty in estimated global mean surface temperature.

Table S-9

Reference Case MY 2011-2015 Alternative CAFE Standards Impact on CO_2 Concentration, Global Mean Surface Temperature Increase, and Sea-level Rise in 2100 Using MAGICC (A1B a/)

7 Technology Exhaustion	0.2	1.2	2.6	0.002	0.007	0.013	0.00	0.05	0.11

a/ The A1B scenario is the SRES marker scenario used by the IPCC WGI to represent the SRES A1B (medium) storyline.

For all alternatives, the temperature increase is about 0.87 °C for 2030, 1.94 °C for 2060, and 2.96 °C for 2100. The differences among alternatives are small. For 2100, the reduction in temperature increase in relation to the No Action Alternative ranges from 0.002 °C to 0.013 °C.

S.5.1.7 Climate - Reference Case Global Mean Precipitation

The action alternatives reduce temperature increases slightly in relation to the No Action Alternative, and thus reduce increases in precipitation slightly, as shown in Table S-10. As shown in the table, there is a fairly narrow band of estimated reductions in precipitation increase in the mid-range estimates as of 2090, from 4.49 percent to 4.51 percent, and there is very little difference between the alternatives. Uncertainty in these numbers results from uncertainty in the increase in the global mean surface temperature and uncertainty in the global mean precipitation change.

Table S-10

a/ The A1B scenario is the SRES marker scenario used by IPCC Working Group I to represent the SRES A1B (medium) storyline.

S.5.1.8 Climate - Reference Case Impact on Sea-level Rise

The IPCC Fourth Assessment Report identifies four primary components of sea-level rise: thermal expansion of ocean water; melting of glaciers and ice caps; loss of land-based ice in Antarctica; and loss of land-based ice in Greenland. Ice-sheet discharge is an additional factor that could influence sea level over the long term. The MAGICC model calculates the oceanic thermal expansion component of global mean sea-level rise, using a non-linear temperature- and pressure-dependent expansion coefficient. It also addresses the other three primary components through ice-melt models for small glaciers and the Greenland and Antarctic ice sheets, and excludes non-melt sources, which the IPCC Fourth Assessment Report also excluded.

Table S-9 lists the impact on sea-level rise under the scenarios and shows sea-level rise in 2100 ranging from 37.10 centimeters under the No Action Alternative to 36.99 centimeters under the

Technology Exhaustion Alternative, for a maximum reduction of 0.11 centimeter by 2100 from under the CAFE alternatives for the Reference Case.

S.5.1.9 Climate - Input Scenarios

In response to public comments, and to test how different economic assumptions might affect estimates of emissions reductions and resulting climate effects, NHTSA modeled three additional scenarios – High, Mid-1, and Mid-2 – and compared the results to the Reference Case. Variables that were altered include fuel price, the social cost of carbon, oil import externalities, and the discount rate for other benefits Tables S-11 and S-12 list the results for the High Scenario.

As shown in Table S-11, compared to the Reference Case, total emissions under the High Scenario were lower for all alternatives. The primary reason for this difference is the lower forecast for vehicle miles traveled under the High Scenario. Emissions reductions for all alternatives compared to the No Action Alternative were greater under the High Scenario than under the Reference Case, except for the emissions reduction resulting from the Technology Exhaustion Alternative. There was a greater emissions reduction resulting from the Technology Exhaustion Alternative under the Reference Case than under the High Scenario.

Table S-11

High Scenario Emissions and Emissions Reductions Due to the MY 2011-2015 CAFE Standards from 2010-2100 ($MMTCO_2$)

Alternative	Emissions	Emissions Reductions Compared to No Action Alternative
1 No Action	195,501	0
2 25 Percent Below Optimized	182,890	12,611
3 Optimized	180,591	14,910
4 25 Percent Above Optimized	179,079	16,422
5 50 Percent Above Optimized	177,669	17,832
6 Total Costs Equal Total Benefits	176,736	18,765
7 Technology Exhaustion	170,829	24,672

Table S-12 shows the resulting effects on CO_2 concentration, global mean surface temperature, and sea-level rise. Under the High Scenario, the resulting CO_2 concentration, global mean surface temperature, and sea-level rise were lower than under the Reference Case for all action alternatives except the Technology Exhaustion Alternative. Thus, the differences for the action alternatives compared to the No Action Alternative are greater for the High Scenario than the Reference Case, except for the Technology Exhaustion Alternative.

Table S-12

High Scenario 2011-2015 CAFE Alternatives Impact on CO_2 Concentrations, Global Mean Surface Temperature Increase, and Sea-level Rise in 2100 Using MAGICC (A1B a/)

a/ The A1B scenario is the SRES marker scenario used by IPCC Working Group I to represent the SRES A1B (medium) storyline.

S.5.2 Cumulative Effects

CEQ identifies the impacts that must be addressed and considered by federal agencies in satisfying the requirements of NEPA. These include permanent, temporary, direct, indirect, and cumulative impacts. CEQ regulations implementing the procedural provisions of NEPA define cumulative impacts as "the impact on the environment which results from the incremental impact of the action when added to other past, present, and reasonably foreseeable future actions regardless of what agency or person undertakes such other actions." 40 CFR § 1508.7. Below is a description of the cumulative effects of the CAFE alternatives on energy, air quality, and climate.

S.5.2.1 Energy – Reference Case

The seven alternatives examined for CAFE standards will result in different future levels of fuel use, total energy, and petroleum consumption, which will in turn have an impact on emissions of GHG and criteria air pollutants. Table S-13 presents the cumulative fuel consumption and fuel savings of passenger-car and light-truck fleets from the onset of the new CAFE standards for the Reference Case.

Table S-13

Reference Case Passenger Car and Light Truck Cumulative Annual Fuel Consumption and Cumulative Fuel Savings (billion gallons)

Calendar Year Range	Alternative CAFE Standards for MY 2011-2020

S.5.2.2 Energy - Input Scenarios

To illustrate how different economic assumptions could affect estimates of fuel consumption, NHTSA examined scenarios that varied economic inputs used in the Volpe model. NHTSA modeled three additional scenarios – High, Mid-1, and Mid-2 – and compared the results to the Reference Case. Table S-14 lists the cumulative impact on fuel consumption under the High Scenario in the Volpe model for passenger cars and light trucks from the onset of the new CAFE standards. The High Scenario uses the economic inputs described in Table S-2. The table lists total fuel consumption for passenger cars and light trucks, both gasoline and diesel, under the No Action Alternative and the six action alternatives.

Table S-14

S.5.2.3 Air Quality – Reference Case

Table S-15 summarizes the cumulative national toxic and criteria pollutants in 2035, showing that the Reference Case No Action Alternative has the highest cumulative emissions of all the alternatives for all pollutants except CO, acetaldehyde, acrolein, and formaldehyde. Alternative 3 has the highest emissions of CO and acetaldehyde. Alternative 7 has the highest emissions of all the alternatives for acrolein[14] and formaldehyde.

S.5.2.4 Air Quality - Input Scenarios

In response to public comments, and to test how different economic assumptions could affect air quality by examining scenarios with varied economic inputs used in the Volpe model, NHTSA modeled three additional scenarios – High, Mid-1, and Mid-2 – and compared the results to the Reference Case. Table S-16 summarizes the cumulative national criteria and air toxic pollutant emissions in 2035 for the seven alternatives for the High Scenario. For the High Scenario, emissions under each alternative are generally lower than under the Reference Case. There could be localized increases in criteria and toxic air pollutant emissions in some nonattainment areas as a result of implementation of the CAFE standards under the alternatives. These localized increases slightly offset the reductions being achieved by implementation of CAA standards, motor-vehicle emissions standards, and related programs. All of the alternatives would reduce adverse health outcomes and health costs related to motor-vehicle air pollution, and thus would have beneficial health effects that would not need mitigation.

[14] Data on upstream emissions reductions were not available for acrolein. Thus, the emissions for acrolein reflect only the change in tailpipe emissions.

Table S-15

S.5.2.5 Climate - Reference Case Cumulative GHG Emissions

Table S-17 lists total emissions reductions from MY 2010-2100 new passenger cars and light trucks under each of the seven alternatives for the Reference Case. Projections of emissions reductions over the 2010 to 2100 time frame due to the MY 2011-2020 CAFE standards ranged from 24,321 to 49,157 $MMTCO_2$. Compared to global emissions of 4,850,000 $MMTCO_2$ over this period (projected by the IPCC A1B-medium scenario), the incremental impact of this rulemaking is expected to reduce global CO_2 emissions by about 0.5 to 1.0 percent.

Table S-17

Reference Case MY 2011-2015 Standards and Potential MY 2016-2020 CAFE Standards Cumulative Emissions and Emissions Reductions Due to the Projected for 2010-2100 ($MMTCO_2$)

Alternative	Emissions	Emissions Reductions Compared to No Action Alternative
1 No Action	221,258	0
2 25 Percent Below Optimized	196,937	24,321
3 Optimized	195,816	25,442
4 25 Percent Above Optimized	194,057	27,201
5 50 Percent Above Optimized	192,478	28,780
6 Total Costs Equal Total Benefits	191,073	30,185
7 Technology Exhaustion	172,101	49,157

S.5.2.6 Climate - Reference Case CO_2 Concentration and Global Mean Surface Temperature

The mid-range results of MAGICC model simulations for the No Action Alternative and the six alternatives in terms of CO_2 concentrations and increase in global mean surface temperature in 2030, 2060, and 2100 are presented in Table S-18 and Figures S-1 through S-4. As Figures S-3 and S-4 show, the impact on the growth in CO_2 concentrations and temperature is just a fraction of the total growth in CO_2 concentrations and global mean surface temperature. However, the relative impact of the CAFE alternatives is illustrated by the reduction in growth of both CO_2 concentrations and temperature under the Technology Exhaustion Alternative, which is nearly double that of the 25 Percent Below Optimized Alternative, as shown in Figures S-5 to S-6.

As shown in the table and figures, there is a fairly narrow band of estimated CO_2 concentrations as of 2100, from 712.6 parts per million under the most stringent alternative to 717.2 parts per million under the No Action Alternative. Because CO_2 concentrations are the key driver climate effects, this narrow range implies that the differences among alternatives are difficult to distinguish. The MAGICC model simulations of mean global surface air temperature increases are also shown in Table S-18. For all alternatives, the temperature increase is about 0.87 °C as of 2030, 1.93 to 1.94 °C as of 2060, and 2.94 to 2.96 °C as of 2100. The differences among alternatives are small. As of 2100, the reduction in temperature increase, in relation to the No Action Alternative, ranges from 0.009 °C to 0.02 °C. These estimates include considerable uncertainty due to a number of factors, of which climate sensitivity is the most important. The IPCC Fourth Assessment Report estimates a range of the climate sensitivity from 2.5 to 4.0 °C with a mid-point of 3.0 °C, which directly relates to the uncertainty in the estimated global mean surface temperature.

Table S-18

S.5.2.7 Climate - Reference Case Global Mean Precipitation

The action alternatives reduce temperature increases slightly compared to the No Action Alternative. Thus, the action alternatives also reduce predicted increases in precipitation slightly, as shown in Table S-19. As shown in the table, there is a fairly narrow band of mid-range estimated reductions in precipitation increase as of 2100, from 4.48 percent to 4.51 percent, and there is very little difference between the alternatives. Uncertainty in these numbers results from uncertainty in the increase in global mean surface temperature and uncertainty about the change in global mean precipitation.

S.5.2.8 Climate - Reference Case Impact on Sea-level Rise

The IPCC Fourth Assessment Report identifies four primary components of sea-level rise: thermal expansion of ocean water; melting of glaciers and ice caps; loss of land-based ice in Antarctica; and loss of land-based ice in Greenland. Ice-sheet discharge is an additional factor that could influence sea level over the long term. The MAGICC model calculates the oceanic thermal expansion component of global mean sea-level rise, using a non-linear temperature- and pressure-dependent expansion coefficient. It also addresses the other three primary components through ice-melt models for small glaciers and the Greenland and Antarctic ice sheets, and excludes non-melt sources, which the IPCC Fourth Assessment Report also excluded.

Table S-18 lists the impact on sea-level rise associated with the Reference Case for each alternative and shows sea-level rise in 2100 ranging from 37.10 centimeters under Alternative 1 (No Action) to 36.92 centimeters under the Technology Exhaustion Alternative (Alternative 7), for a maximum reduction of 0.18 centimeters by 2100 from the CAFE alternatives.

a/ The A1B scenario is the SRES marker scenario used by IPCC Working Group I to represent the SRES A1B (medium) storyline.

In summary, the impacts of the MY 2011-2020 CAFE alternatives on global mean surface temperature, sea-level rise, and precipitation are relatively small in the context of the expected changes associated with the emissions trajectories in the Special Report on Emission Scenarios (SRES). This is due primarily to the global and multi-sectoral nature of the climate problem. Emissions of CO_2, the primary gas driving the climate effects, from the United States passenger-car and light-truck fleet represented about 2.5 percent of total global emissions of GHGs in the year 2000.[15] While a substantial source, this is a still small percentage of global emissions, and the relative contribution of CO_2 emissions

[15] CO_2 emissions from passenger cars and light trucks were obtained from EPA's *Inventory of U.S. Greenhouse Gas Emissions and Sinks. 1990–2006*, which can be found at http://www.epa.gov/climatechange/emissions/usinventoryreport.html. Global GHG emissions were obtained from the World Resources Institute's Climate Analysis Indicators Tool (CAIT) Version 5.0. http://cait.wri.org.

from the U.S. passenger car and light truck fleet is expected to decline in the future, due primarily to rapid growth of emissions from developing economies, which are due in part to growth in emissions from the global transportation sector.

S.5.2.9 Cumulative Impacts - Input Scenarios

In response to public comments, and to test how different economic assumptions might affect estimates of cumulative emissions reductions and resulting climate effects, NHTSA modeled three additional scenarios – High, Mid-1, and Mid-2 – and compared the results to the Reference Case. Variables that were altered include fuel price, the social cost of carbon, oil import externalities, and the discount rate for other benefits. Tables S-20 and S-21 lists the results for the High Scenario.

As shown in Table S-20, compared to the Reference Case, total cumulative emissions under the High Scenario were lower for all alternatives. The primary reason for this difference is the lower vehicle miles traveled forecast under the High Scenario. Cumulative emissions reductions for Alternatives 2 through 7 compared to the No Action Alternative were all higher under the High Scenario than under the Reference Case, except the Technology Exhaustion Alternative. Emissions reductions were greater under the Technology Exhaustion Alternative for the Reference Case than for the High Scenario.

Table S-20

High Scenario Alternative CAFE Standards Cumulative Emissions and Emissions Reductions Due to the MY 2011-2015 Standards and Potential MY 2016-2020 Standards for 2010 through 2100 ($MMTCO_2$)

Alternative	Emissions	Emissions Reductions Compared to No Action Alternative
1 No Action	195,501	0
2 25 Percent Below Optimized	160,903	34,598
3 Optimized	157,088	38,413
4 25 Percent Above Optimized	154,618	40,884
5 50 Percent Above Optimized	151,781	43,721
6 Total Costs Equal Total Benefits	150,919	44,583
7 Technology Exhaustion	152,290	43,211

Table S-21 shows the resulting effects on CO_2 concentration, global mean surface temperature, and sea-level rise. Under the High Scenario, the resulting CO_2 concentration, global mean surface temperature, and sea-level rise were lower for all alternatives except the Technology Exhaustion Alternative. Thus, the differences for the action alternatives compared to the No Action Alternative are greater for the High Scenario than the Reference Case, except for the Technology Exhaustion Alternative.

S.5.3 Other Potential Environmental Consequences

While the main focus of this FEIS is on the quantification of impacts to energy, air quality, climate, and qualitative cumulative impacts resulting from climate change, this FEIS also addresses other potentially affected resources. NHTSA conducted a qualitative review of the non-climate change related direct, indirect, and cumulative effects, either positive or negative, of the alternatives on other potentially affected resources. These resource areas included water resources, biological resources, land use, hazardous materials, safety, noise, historic and cultural resources, and environmental justice. Effects of the alternatives on these resources were too small to address quantitatively. Impacts to biological resources could include reductions in habitat disturbance, decreased impacts from acid rain on water and terrestrial habitats from decreases in petroleum production and increased agricultural disturbances and

a/ The A1B scenario is the SRES marker scenario used by the IPCC WGI to represent the SRES A1B (medium) storyline.

runoff due to biofuel production. Impacts to land use and development could include increased agricultural land use. Impacts to safety could include downweighting of vehicles and increased VMT, resulting in increased traffic injuries and fatalities. Impacts to hazardous materials could include overall reductions in the generation of air and oil production related wastes, and increases in agricultural wastes due to biofuel production. Impacts to historic and cultural resources could include reductions in acid rain related damage. Noise impacts could include increased noise levels in some areas due to higher VMT. The non-climate related impact from increased atmospheric CO_2 could, in conjunction with other environmental factors and changes in plant communities, potentially alter growth, abundance, and respiration rates of some soil microbes and impact coral reef and other marine ecosystems from ocean acidification.

Impacts to environmental justice populations could include increased air toxics in some areas as a result of higher VMT. No impacts are expected to resources protected under Section 4(f), and a Section 7 Review under the Endangered Species Act is not required.

S.5.4 Mitigation Measures and Unavoidable Adverse Impacts

Each of the six action alternatives, under any Input Scenario, would result in a decrease in CO_2 emissions and associated climate change impacts, a general decrease in criteria air pollutant emissions and toxic air pollutant emissions, and a decrease in energy consumption as compared to the No Action Alternative. Based on our current understanding of global climate change, certain effects are likely to occur due to the sum total of GHG emissions entering the atmosphere. Any of the alternatives presented here would not prevent these effects. They may diminish the effects of climate change and contribute to global GHG reductions. Under the No Action alternative, CO_2 emissions and energy consumption would continue to increase; thus, any of the alternatives (other than the No Action Alternative) would have a beneficial effect that would not need mitigation.

Increases in national CO emissions could occur under the Optimized Alternative of the Reference Case. While nominally high, these increases are just 0.6 percent of the CO emissions of the No Action Alternative. Furthermore, no violations of the CO standard have been demonstrated since 2002, making any potential increase in these emissions less likely to affect human health even if they were to occur. Localized increases in criteria and toxic air pollutant emissions could occur in some non-attainment areas as a result of implementation of the CAFE standards under the alternatives. These localized increases represent a slight decline in the rate of reductions being achieved by implementation of CAA standards. The Federal Highway Administration has funds dedicated to the reduction of air pollution in nonattainment areas, providing state and local authorities the ability to mitigate for localized increases in levels of criteria and toxic air pollutants in nonattainment areas that might be observed under the standards. Further, EPA has the authority to continue to improve vehicle emissions standards.

WMO	World Meteorological Organization

Glossary

To help readers more fully understand this Final Environmental Impact Statement, NHTSA has provided the following list of definitions for technical and scientific terms, as well as plain English terms used differently in the context of this FEIS.

Term	Definition
25 Percent Above Optimized Alternative (Alternative 4)	Alternative regulatory measure reflecting standards that exceed the Optimized Alternative by 25 percent of the interval between the Optimized Alternative and an alternative based on applying technologies until total costs equal total benefits.
25 Percent Below Optimized Alternative (Alternative 2)	Alternative regulatory measure reflecting standards that fall below the Optimized Alternative by the same absolute amount by which the 25 percent above Optimized Alternative exceeds the Optimized Alternative.
50 Percent Above Optimized Alternative (Alternative 5)	Alternative regulatory measure reflecting standards that exceed the Optimized Alternative by 50 percent of the interval between the Optimized Alternative and an alternative based on applying technologies until total costs equal total benefits.
Adaptation	Initiatives and measures to reduce the vulnerability of natural and human systems against actual or expected climate change effects. Various types of adaptation exist, including anticipatory and reactive, private and public, and autonomous and planned.
Afforestation	Planting of new forests on lands that historically have not contained forests (for at least 50 years).
Anthropogenic	Resulting from or produced by human beings.
Aquaculture	Farming of plants and animals that live in water.
Baseline Alternative	See “No Action Alternative.”
Benthic	Describing habitat or organisms occurring at the bottom of a body of water.
Biosphere	The part of the Earth system comprising all ecosystems and living organisms, in the atmosphere, on land (terrestrial biosphere) or in the oceans (marine biosphere), including dead organic matter, such as litter, soil organic matter, and oceanic detritus.
Carbon sink	Any process, activity, or mechanism that removes a greenhouse gas, an aerosol, or a precursor of a greenhouse gas or aerosol from the atmosphere.
Coral bleaching	The paling in color that results if a coral loses its symbiotic, energy providing, organisms.
Criteria pollutants	Carbon monoxide (CO), airborne lead (Pb), nitrogen dioxide (NO_2), ozone (O_3), sulfur dioxide (SO_2), and fine particulate matter (PM).
Cryosphere	The portion of Earth’s surface that is frozen water, such as snow, permafrost, floating ice, and glaciers.

Term	Definition
Dansgaard-Oeschger events	Very rapid climate changes—up to 7 °C in some 50 years—during the Quaternary geologic period, and especially during the most recent glacial cycle.
Ecosystem	A system of living organisms interacting with each other and their physical environment. The boundaries of what could be called an ecosystem are somewhat arbitrary, depending on the focus of interest or study. Thus, the extent of an ecosystem may range from very small spatial scales to, ultimately, the entire Earth.
El Nińo-Southern Oscillation	The term El Niño was initially used to describe a warm-water current that periodically flows along the coast of Ecuador and Peru, disrupting the local fishery. It has since become identified with a basinwide warming of the tropical Pacific east of the international dateline. This oceanic event is associated with a fluctuation of a global-scale tropical and subtropical surface pressure pattern called the Southern Oscillation. This coupled atmosphere-ocean phenomenon, with preferred time scales of two to about seven years, is collectively known as El Niño-Southern Oscillation, or ENSO. During an ENSO event, the prevailing trade winds weaken, reducing upwelling and altering ocean currents such that the sea surface temperatures warm, further weakening the trade winds.
Emission rates	Rate at which contaminants are discharged from a particular source, usually in weight unit per time period.
Endemic	Restricted to a region.
EPCA factors for setting "maximum feasible" CAFE standards	Technological feasibility, economic practicability, the effect of other motor vehicle standards of the government on fuel economy, and the need of the Nation to conserve energy.
Eutrophication	Enrichment of a water body with plant nutrients.
Evapotranspiration	The combined process of water evaporation from the Earth's surface and transpiration from vegetation.
GREET model	Model developed by Argonne National Laboratory that provides estimates of the energy and carbon contents of fuels as well as energy use in various phases of fuel supply.
High Scenario	Model input scenario that uses the Energy Information Administration's high fuel price forecast of $3.33 per gallon, a global social cost of carbon of $33.00 per ton with a 3 percent discount rate, a 3 percent overall discount rate, and a value of $0.116 per gallon for oil import externalities.
Hydrology	The science dealing with the occurrence, circulation, distribution, and properties of the Earth's water.
Hydrosphere	The component of the climate system comprising liquid surface and subterranean water, such as oceans, seas, rivers, freshwater lakes, and underground water.
Kiloannum	A unit of time equal to 1000 years. Abbreviated symbol is "ka."
Lake stratification	The layering of warmer, less dense water over colder, denser water.

Term	Definition
Lifetime fuel consumption	Total volume of fuel used by a vehicle over its lifetime.
Maximum lifetime of vehicles	The age after which less than 2 percent of the vehicles originally produced during a model year remains in service.
Mid-1 Scenario	An intermediate model input scenario that uses a fuel price forecast of $3.33 per gallon, a global social cost of carbon of $33.00 per ton with 3 percent discount rate, a 7 percent discount rate overall, and a value of $0.116 per gallon for oil import externalities.
Mid 2 Scenario	An intermediate model input scenario that uses a fuel price forecast of $3.33 per gallon, a domestic social cost of carbon of $2.00 per ton with a 3 percent discount rate, a 7 percent overall discount rate, and a value of $0.382 per gallon for oil import externalities.
MOBILE6.2	EPA's motor vehicle emission factor model.
NEPA scoping process	An early and open process for determining the scope of issues to be addressed and for identifying the significant issues related to a proposed action.
No Action Alternative (Alternative 1)	The No Action Alternative assumes that NHTSA would not issue a rule regarding CAFE standards. The No Action Alternative assumes that average fuel economy levels in the absence of CAFE standards beyond 2010 would equal the higher of a manufacturer's product plans or the manufacturer's required level of average fuel economy for MY 2010. The MY 2011 fuel economy in mpg (27.5 mpg and 23.3 mpg for passenger cars and light trucks, respectively) represents the standard the agency believes manufacturers would continue to achieve, assuming that the agency does not issue a rule.
Nonattainment area	Regions where concentrations of criteria pollutants exceed federal standards. Nonattainment areas are required to develop and implement plans to comply with the National Ambient Air Quality Standards within specified time periods.
Ocean acidification	A decrease in the pH of sea water due to the uptake of anthropogenic carbon dioxide.
Optimized Alternative (Alternative 3)	Alternative regulatory measures reflecting the optimized standards.
Optimized standards	Standards set at levels such that the cost of the last technology application (using the Volpe model) equals the benefits of the improvement in fuel economy resulting from that application, thereby maximizing net benefits (benefits minus costs).
Overexploitation of species	Exploitation of species to the point of diminishing returns.
Paleoclimatology	The study of climate change through the physical evidence left on earth of historical global climate change (prior to the widespread availability of records to temperature, precipitation, and other data).
Pathways of fuel supply	Imports to the United States of refined gasoline and other transportation fuels, domestic refining of fuel using imported petroleum as a feedstock, and domestic fuel refining from crude petroleum produced within the United States.

Term	Definition
Permafrost	Ground (soil or rock and included ice and organic material) that remains at or below zero degrees Celsius for at least two consecutive years.
Phenology	The study of natural phenomena in biological systems that recur periodically (development stages, migration) and their relationship to climate and seasonal changes.
Rebound effect	A situation in which improved fuel economy reduces the fuel cost of driving and leads to additional use of passenger cars and light trucks and thus increased emissions of criteria pollutants by passenger cars and light trucks.
Reference Case	Model input scenario that uses the Energy Information Administration's reference case fuel price forecast of $2.41 per gallon, a domestic social cost of carbon of $2.00 per ton with a 3 percent discount rate, a 7 percent overall discount rate, and a value of $0.326 per gallon for oil import externalities.
Reformed CAFE Program	Consists of two basic elements: (1) a process that sets fuel economy targets for different values of vehicle footprint; and (2) a Reformed CAFE standard for each manufacturer, which is equal to the production-weighted harmonic average of the fuel economy targets corresponding to the footprint values of each light truck model it produces.
Saltwater intrusion	Displacement of fresh surface water or groundwater by the advance of saltwater due to its greater density. This process usually occurs in coastal and estuarine areas due to reducing land-based influence (either from reduced runoff and associated groundwater recharge, or from excessive water withdrawals from aquifers) or increasing marine influence (relative sea-level rise).
Silviculture	The management of forest resources.
Survival rate	The proportion of vehicles originally produced during a model year that are expected to remain in service at the age they will have reached during each subsequent year.
Thermohaline circulation	The physical driving mechanism of ocean circulation, resulting from fluxes of heat and freshwater across the sea surface, subsequent interior mixing of heat and salt, and geothermal heat sources.
Total Costs Equal Total Benefits Alternative (Alternative 6)	Alternative reflecting standards based on applying technologies until total costs equal total benefits (zero net benefits).
Technologies	Engine technologies, transmission, vehicle, electrification/accessory and hybrid technologies that influence fuel economy.
Technology Exhaustion Alternative (Alternative 7)	Alternative in which NHTSA applied all feasible technologies by progressively increasing the stringency of the standard in each model year until every manufacturer (among those without a history of paying civil penalties) exhausted technologies estimated to be available during MY 2011-2015.

Term	Definition
Thermohaline circulation	This term refers to the physical driving mechanism of ocean circulation, resulting from fluxes of heat and freshwater across the sea surface, subsequent interior mixing of heat and salt, and geothermal heat sources.
Tipping point	A situation where the climate system reaches a point at which is there is a strong and amplifying positive feedback from only a moderate additional change in a driver, such as CO_2 or temperature increase.
Total vehicle miles	Total number of miles each vehicle will be driven over its lifetime.
Track width	The lateral distance between the centerlines of the base tires at ground, including the camber angle.
Transpiration	Water loss from plant leaves.
Turbidity	A decrease in the clarity of water due to the presence of suspended sediment.
Vehicle footprint	The product of track width times wheelbase divided by 144.
Vehicle miles traveled	Total number of miles driven.
Volpe model	CAFE Compliance and Effects Model developed by the U.S. Department of Transportation's Volpe Center, that, for any given year, applies technologies to the manufacturer's fleet until the manufacturer achieves compliance with the standard under consideration.
Wheelbase	The longitudinal distance between front and rear wheel centerlines.

Chapter 1 Purpose and Need for the Proposed Action

1.1 INTRODUCTION

The Energy Policy and Conservation Act of 1975[1] (EPCA) established a program to regulate automobile fuel economy and provided for the establishment of average fuel economy standards for passenger cars and light trucks. As part of that Act, the Corporate Average Fuel Economy (CAFE) Program was established to reduce national energy consumption by increasing the fuel economy of passenger cars and light trucks. EPCA directs the Secretary of Transportation to set and implement fuel economy standards for passenger cars and light trucks sold in the United States. The National Highway Transportation Safety Administration (NHTSA) is delegated responsibility for implementing EPCA fuel economy requirements assigned to the Secretary of Transportation.[2]

In December 2007, the Energy Independence and Security Act of 2007 (EISA)[3] amended EPCA's CAFE Program requirements, granting the U.S. Department of Transportation (DOT) additional rulemaking authority and responsibilities.[4] Pursuant to EISA, NHTSA recently proposed CAFE standards for model year (MY) 2011-2015 passenger cars and light trucks in a Notice of Proposed Rulemaking[5] (NPRM) (NHTSA 2008b).[6]

Under the National Environmental Policy Act[7] (NEPA), a federal agency must analyze environmental impacts if the agency implements a proposed action, provides funding for an action, or issues a permit for that action. Specifically, NEPA directs that "to the fullest extent possible," federal agencies proposing "major federal actions significantly affecting the quality of the human environment" must prepare "a detailed statement" on the environmental impacts of the proposed action (including alternatives to the proposed action). NHTSA submits this Final Environmental Impact Statement (FEIS) to disclose its evaluation of the potential environmental impacts of adopting CAFE standards for MY 2011-2015.

1.2 NEPA PROCESS

To inform its development of the new CAFE standards required under EPCA, as amended by EISA, NHTSA prepared this FEIS to analyze and disclose the potential environmental impacts of our preferred alternative and other alternative standards pursuant to Council on Environmental Quality (CEQ)

[1] EPCA was enacted for the purpose of serving the Nation's energy demands and promoting conservation methods when feasibly obtainable. EPCA is codified at 49 United States Code (U.S.C.) 32901 *et seq.*
[2] 49 Code of Federal Regulations (CFR) §§ 1.50, 501.2(a)(8). In addition, the U.S. Environmental Protection Agency (EPA) calculates the average fuel economy for each automobile manufacturer that sells vehicles in the United States.
[3] EISA amends and builds on the Energy Policy and Conservation Act by setting out a comprehensive energy strategy for the 21st Century addressing renewable fuels and CAFE standards. EISA is Public Law 110-140, 121 Stat. 1492 (December 19, 2007).
[4] Accordingly, the Secretary of Transportation, DOT, and NHTSA are used interchangeably in this section of the FEIS.
[5] 73 *Federal Register* (*FR*) 24352 (May 2, 2008).
[6] At the same time, NHTSA requested updated product plan information from the automobile manufacturers. *See* Request for Product Plan Information, Passenger Car Average Fuel Economy Standards—Model Years 2008-2020 and Light Truck Average Fuel Economy Standards—Model Years 2008-2020, 73 *FR* 21490, May 2, 2008.
[7] 42 U.S.C. § 4332(2)(C).

NEPA implementing regulations, DOT Order 5610.1C, and NHTSA regulations.[8] This FEIS compares the potential environmental impacts among alternatives, including a no action alternative. It also analyzes direct, indirect, and cumulative impacts and discusses impacts in proportion to their significance.

1.3 PURPOSE AND NEED

NEPA requires that a proposed action's alternatives be developed based on the action's purpose and need. The purpose and need statement explains why the action is needed and the action's intended purpose, and serves as the basis for developing the range of alternatives to be considered in the NEPA analysis. In accordance with EPCA, as amended by EISA, the purpose of the rulemaking action is to establish MY 2011-2015 CAFE standards at "the maximum feasible average fuel economy level that the Secretary of Transportation decides the manufacturers can achieve in that model year." When setting "maximum feasible" fuel economy standards, the Secretary is required to "consider technological feasibility, economic practicability, the effect of other motor vehicle standards of the Government on fuel economy, and the need of the United States to conserve energy."[9] NHTSA interprets these statutory factors to include environmental and safety concerns.[10]

As explained in the NPRM:

- "Technological feasibility" means whether a particular method of improving fuel economy can be available for commercial application in the model year for which a standard is being established.
- "Economic practicability" means whether a standard is one within the financial capability of the industry, but not so stringent as to lead to adverse economic consequences, such as significant job losses or unreasonable elimination of consumer choice.
- "The effect of other motor vehicle standards of the Government on fuel economy" means the unavoidable adverse effects on fuel economy of compliance with emission, safety, noise, or damageability standards.
- "The need of the United States to conserve energy" means the consumer cost, national balance of payments, environmental, and foreign policy implications of the Nation's need for large quantities of petroleum, especially imported petroleum.

EPCA, as amended by EISA, requires that the CAFE standards for passenger cars and light trucks must increase ratably to at least the levels necessary to meet 35 mpg requirements for MY 2020. EPCA further directs the Secretary, after consultation with the Secretary of Energy and the Administrator of the Environmental Protection Agency (EPA), to establish separate average fuel economy standards for passenger cars and for light trucks manufactured in each model year beginning with MY 2011, "to achieve a combined fuel economy average for model year 2020 of at least 35 miles per gallon for the total fleet of passenger and non-passenger automobiles manufactured for sale in the United States for that model year."[11] In so doing, the Secretary of Transportation is to adopt "annual fuel economy standard

[8] NEPA is codified at 42 U.S.C. §§ 4321-4347. CEQ NEPA implementing regulations are codified at 40 CFR Parts 1500-1508, and NHTSA's NEPA implementing regulations are codified at 49 CFR Part 520.

[9] 49 U.S.C. §§ 32902(a), 32902(f).

[10] *See, e.g.*, *Competitive Enterprise Inst. v. NHTSA*, 956 F.2d 321, 322 (D.C. Cir. 1992) (citing *Competitive Enterprise Inst. v. NHTSA*, 901 F.2d 107, 120 n.11 (D.C. Cir. 1990)), and 73 *FR* 24,352, 24,364, May 2, 2008.

[11] 49 U.S.C. §§ 32902(b)(1), 32902(b)(2)(A).

increases."[12] The standards for passenger cars and light trucks must be "based on one or more vehicle attributes related to fuel economy." In any single rulemaking, standards may be established for not more than 5 model years.[13] EPCA also mandates a minimum standard for domestically manufactured passenger cars.[14]

1.3.1 Notice of Intent and Scoping

In March 2008, NHTSA issued a Notice of Intent (NOI) to prepare an EIS for the MY 2011-2015 CAFE standards. The NOI described the statutory requirements for the standards, provided initial information about the NEPA process, and initiated scoping[15] by requesting public input on the scope of the environmental analysis to be conducted.[16] Two important purposes of scoping are identifying the substantial environmental issues that merit in-depth analysis in the EIS, and identifying and eliminating from detailed analysis the environmental issues that are not substantial and therefore require only a brief discussion in the EIS.[17] Scoping should "deemphasize insignificant issues, narrowing the scope of the environmental impact statement process accordingly."[18]

Consistent with NEPA and its implementing regulations, on April 10 and 11, 2008, NHTSA mailed the NOI to:

- 78 contacts at federal agencies having jurisdiction by law or special expertise with respect to the environmental impacts involved, or authorized to develop and enforce environmental standards, including other modes within DOT;
- the Governors of every state and U.S. territory;
- 23 organizations representing state and local governments;
- 14 Native American tribal organizations and academic centers that had issued reports on climate change and tribal communities; and
- 92 contacts at other stakeholder organizations that NHTSA reasonably expected to be interested in the NEPA analysis for the MY 2011-2015 CAFE standards, including auto industry organizations, environmental organizations, and other organizations that had expressed interest in prior CAFE rules.

NHTSA used its letters transmitting the NOI to develop a mailing list for future notices about the NEPA process for the CAFE standards. For instance, NHTSA asked each Governor to, "share [the] letter and the enclosed [NOI] with the appropriate environmental agencies and other offices within your administration and with interested local jurisdictions or local government organizations within your State." NHTSA further requested that each Governor ask their representative to provide contact information for the state's lead office on the CAFE EIS by returning a mailing list form to NHTSA or by

[12] 49 U.S.C. § 32902(b)(2)(C).
[13] 49 U.S.C. §§ 32902(b)(3)(A), 32902(b)(3)(B).
[14] 49 U.S.C. § 32902(b)(4).
[15] Scoping, as defined under NEPA, is an early and open process for determining the scope of issues to be addressed in an EIS and for identifying the significant issues related to a proposed action. 40 CFR § 1501.7.
[16] *See* Notice of Intent to Prepare an Environmental Impact Statement for New Corporate Average Fuel Economy Standards, 73 *FR* 16615, March 28, 2008.
[17] 40 CFR §§ 1500.4(g), 1501.7(a).
[18] 40 CFR § 1500.4(g).

sending NHTSA an e-mail containing the information requested on the form. NHTSA asked federal agency contacts to share the NOI with other interested parties within their organizations. NHTSA asked contacts at other stakeholder organizations to let NHTSA know whether they wished to remain on the agency's NEPA mailing list for the CAFE EIS by returning a mailing list form or sending NHTSA an e-mail containing the information requested on the form. NHTSA indicated that organizations that did not return the form would be removed from the NEPA mailing list.

1.3.1.1 Supplemental Notice of Public Scoping

In April 2008, NHTSA issued a supplemental notice of public scoping providing additional information about:

- participating in the scoping process;
- the proposed standards; and
- the alternatives NHTSA expected to consider in its NEPA analysis.[19]

NHTSA outlined its plans for its NEPA analysis for the MY 2011-2015 CAFE standards, explaining that it would:

> …consider the direct, indirect and cumulative environmental impacts of the proposed standards and those of reasonable alternatives. Among other potential impacts, NHTSA will consider direct and indirect impacts related to fuel and energy use, emissions, including Carbon Dioxide (CO_2) and their effects on temperature and climate change, air quality, natural resources, and the human environment. NHTSA also will consider the cumulative impacts of the proposed standards for MY 2011-2015 automobiles together with estimated impacts of NHTSA's implementation of the CAFE program through MY 2010 and NHTSA's future CAFE rulemaking for MY 2016-2020, as prescribed by EPCA, as amended by EISA…[20]

NHTSA also acknowledged that it "anticipate[d] considerable uncertainty in estimating and comparing the potential environmental impacts of the proposed standards and the alternatives relating to climate change in particular."[21]

In preparing the supplemental scoping notice, NHTSA consulted with CEQ and EPA. In that notice, NHTSA again invited all stakeholders to submit written comments on the appropriate scope of NHTSA's NEPA analysis for CAFE standards for MY 2011-2015 passenger cars and light trucks. To help identify and narrow the issues for analysis in the EIS, NHTSA specifically requested comments, peer-reviewed scientific studies, and other information addressing the potential impacts of the standards and reasonable alternatives relating to climate change.[22]

Following its publication in the *Federal Register* on April 28, 2008, NHTSA sent copies of the supplemental scoping notice directly to:

- 46 Governors from whom NHTSA had not received a lead State NEPA contact in response to the agency's initial letters;

---

[19] Supplemental Notice of Public Scoping for an Environmental Impact Statement for New Corporate Average Fuel Economy Standards, 73 *FR* 22913, April 28, 2008.
[20] *Id.* at 22916.
[21] *Id.* at 22916.
[22] *Id.* at 22917.

- 24 state and local government NEPA contacts that had responded to the agency's initial letters;
- 11 administrators or other officials at other DOT agencies and offices;
- 62 NEPA contacts at other federal agencies; and
- 42 other stakeholders that asked to remain or be included on NHTSA's NEPA mailing list.

During the first week of May 2008, NHTSA mailed the supplemental scoping notice to Governors and stakeholders who had indicated a preference for receiving NHTSA's NEPA communications by U.S. mail. NHTSA e-mailed the supplemental scoping notice to all other stakeholders on May 6 and 7, 2008.

During the first week of May, NHTSA also mailed copies of the NOI and the supplemental scoping notice to more than 580 federally recognized Native American tribes, inviting them to submit written comments on the scope of NHTSA's NEPA analysis for the CAFE standards. In letters transmitting the two notices, NHTSA asked contacts at each tribe to let NHTSA know whether they wished to remain on the agency's NEPA mailing list for the CAFE EIS by returning a mailing list form or sending NHTSA an e-mail containing the information requested on the form. NHTSA indicated that tribes that did not return the form would be removed from the NEPA mailing list.

NHTSA's letters transmitting the NOI also explained our plans for communicating primarily by e-mail throughout the EIS process unless stakeholders indicated a preference for communications by U.S. mail. Representative copies of NHTSA's letters transmitting the NOI and the supplemental scoping notice to the stakeholders described above are available in the docket for this FEIS, Docket No. NHTSA-2008-0060, at http://www.regulations.gov.

In June 2008, NHTSA contacted various federal and state agencies and held meetings in person or by telephone to discuss the potential effects of the actions to be taken under EPCA and EISA. These agencies included Office of Protected Resources, National Oceanic and Atmospheric Administration (NOAA); Endangered Species Program, U.S. Fish and Wildlife Service; Cultural Resources, National Park Service; Advisory Council on Historic Preservation; Forest Health Monitoring Program and Forest Legacy Program, U.S. Forest Service; Division of Emergency and Environmental Health Services, Centers for Disease Control and Prevention (CDC); NEPA Compliance and Health Effects, Benefits, and Toxics Center, EPA; NEPA Oversight, CEQ; and Historical and Cultural Programs, Maryland Historical Trust. Comments received from these agencies were incorporated into the Draft Environmental Impact Statement (DEIS).

1.3.2 Summary of Scoping Comments and NHTSA's Responses

NHTSA received 1,748 comment letters in response to its two scoping notices. All but 11 of these letters were a form letter similar in content and sent by individuals. The non-form letters were provided by federal and state agencies, automobile trade associations, environmental advocacy groups, and two individuals.

Several commenters addressed the issues on which NHTSA specifically sought comment in its supplemental scoping notice and helped the agency identify and narrow the environmental issues for analysis. Other commenters questioned NHTSA's decision to prepare an EIS instead of an environmental assessment (EA). Still other commenters raised issues that are more properly addressed outside the NEPA process in other rulemaking documents. For example, some commenters raised economic and social issues, and courts have generally held that such issues are appropriate for consideration under NEPA only if they directly interrelate to the effects on the physical environment.[23] Other commenters made suggestions about the process to follow or the factors to be considered in setting CAFE standards – issues that are germane to the NPRM and other supporting documents.

Note that Sections 1.3.2.1 through 1.3.2.6 restate our responses to scoping comments. Specifically, they respond to those comments that spoke to the scope of NHTSA's NEPA analysis for the MY 2011-2015 CAFE standards. For this reason, the responses often are stated in terms of references or discussions appearing in the DEIS or refer specifically to the DEIS.

1.3.2.1 Federal Agencies

Federal agencies that provided scoping comments included EPA (Docket No. NHTSA-2008-0060-0016) and the Department of Health and Human Services, CDC (Docket No. NHTSA-2008-0060-0010 and NHTSA-2008-0060-0140). After receiving scoping comments from EPA and CDC, NHTSA conducted a telephone conference with CDC on June 12, 2008, and met with EPA officials at the EPA Washington, DC, headquarters on June 17, 2008, to discuss each agency's respective scoping comments. NHTSA also consulted with NOAA, the U.S. Fish and Wildlife Service, the U.S. National Park Service, and the U.S. Forest Service.

EPA indicated that some of the factors that affect air quality, such as meteorology and atmospheric processes, will not be taken into account when evaluating environmental impacts and that this limitation should be acknowledged. NHTSA agrees with EPA's suggestion, and this limitation is acknowledged in Chapters 3 and 4.

In addition to the regulatory scenarios that NHTSA developed using the Volpe model, EPA suggested that NHTSA evaluate reasonable alternative scenarios by using other combinations of inputs, including fuel prices, manufacturer compliance costs, economic discount rates, the projected benefits of greenhouse gas (GHG) emission reductions (including assumptions about the social cost of carbon (SCC) emissions), and the likely manufacturer and consumer response to the footprint curve embedded in the proposed rule. The NHTSA benefit-cost analysis did include several sensitivity analyses to examine the impact of different model input assumptions, such as the values of economic and environmental externalities and the price of gasoline. NHTSA presented the results of the sensitivity analyses in the Preliminary Regulatory Impact Analysis (PRIA), and discussed them in Chapter 3 of the DEIS (NHTSA 2008a).

EPA also stated that NHTSA should consider the impacts of each alternative on air toxics emissions. NHTSA conducted these suggested analyses; *see* Chapters 3 and 4.

EPA additionally recommended that the projected impacts of the EPCA program components that provide alternative means for manufacturers to demonstrate compliance with CAFE standards be analyzed, because EPA believes that these components of the program can be expected to lower compliance costs and reduce projected fuel savings. As explained in Chapters 3 and 4, although NHTSA expects that manufacturers' use of CAFE-related flexibilities will lead to higher fuel consumption and emissions than presented in this analysis, NHTSA does not currently have a reasonable basis to develop specific quantitative estimates of such effects. NHTSA will reevaluate the potential to do so after

[23] *See, e.g.*, *Ashley Creek Phosphate Co. v. Norton*, 420 F.3d 934, 944 (9th Cir. 2005); *Hammond v. Norton*, 370 F. Supp. 2d 226, 243 (D.D.C. 2005).

reviewing the updated product plans it has requested of vehicle manufacturers and related comments in response to the NPRM.

The Department of Health and Human Services, CDC, suggested that NHTSA relate projected changes in fleet emissions, fuel consumption, and fleet design to human health outcomes. It indicated that the levels of automobile emissions such as ozone-forming emissions, nitrogen oxides, and hydrocarbons, are affected by the CAFE standards and in turn directly affect human health. Consequently, CDC requested that potential health effects be analyzed for all of the alternatives, including an economic analysis of the associated health costs. It also suggested that transportation-related emissions contribute to climate change with resulting environmental impacts that directly affect human health worldwide, so NHTSA should also evaluate the health impacts of climate change.

NHTSA's analysis of alternative CAFE standards incorporates the economic value of reduced damages to human health that would result from the reductions in emissions of criteria air pollutants and GHGs estimated to result from each alternative. These reductions in damages to human health are valued using estimates of damage costs per unit of emissions of each pollutant that specifically reflect the chemical composition and geographic distribution of emissions generated by motor-vehicle use and by production and distribution of transportation fuels. These estimates were developed by EPA for use in its analysis of benefits from regulations that would reduce emissions from motor vehicle use and from the production and distribution of transportation fuels. Human health is further discussed in Chapters 3 and 4.

The CDC suggested that crash-related injuries be considered, including effects on other transportation-system users, because it believes that changing CAFE standards would affect fleet design and have the potential to increase or decrease crash-related injuries. It added that decreasing vehicle fleet disparities in size and weight can decrease crash-related injuries to those driving lighter-weight vehicles. In addition, two commenters requested consideration of lightweight vehicle materials as a fuel-saving technology. As discussed in the NPRM, NHTSA's analysis does include the potential to improve fuel economy through greater utilization of lightweight materials on heavier vehicles for which doing so would be unlikely to compromise highway safety. Further, NHTSA expects that basing CAFE standards on vehicle footprint would discourage manufacturers from reducing vehicle size. Therefore, although it does not have a reliable basis to estimate changes in crash frequency or severity, NHTSA expects that attribute-based standards would tend to improve, rather than degrade, highway safety.

Finally, the CDC recommended that NHTSA's analysis of potential health impacts be conducted in collaboration with public health officials. NHTSA discussed the CDC scoping comments with CDC officials on June 12, 2008. NHTSA appreciates the suggestion and the effort CDC took to submit scoping comments. After a thorough discussion, NHTSA believes it reached a high degree of understanding and assured CDC that health impacts would be included in various ways in the DEIS. NHTSA is confident that the consultants retained to assist in the analysis and development of the DEIS, along with its own staff, have the requisite knowledge and skills to effectively incorporate health issues into the document.

1.3.2.2 States

NHTSA received a number of comments representing the interests of states, including comments from the New York State Department of Transportation (Docket No. NHTSA-2008-0060-0012), the Washington State Department of Transportation (Docket No. NHTSA-2008-0060-0177), and the Minnesota Pollution Control Agency (Docket No. NHTSA-2008-0060-0011). NHTSA received a single, combined comment letter from the Attorneys General of the States of California, Connecticut, New Jersey, New Mexico, Oregon, and Rhode Island, the Commonwealth of Pennsylvania Department of

Environmental Protection, and the New York City Corporation Counsel (Docket No. NHTSA-2008-0060-0007.1).

The New York and Washington DOTs suggested that NHTSA consider the serious impacts of climate change and the consequent need for accelerated national fuel economy standards to be implemented both sooner than the year 2020 and to cover a greater number of vehicle types. They encouraged NHTSA to work with states and vehicle manufacturers to meet the common goals of economic stability and reduced transportation-related GHG emissions in an expedited way, including promoting the production of fuel-efficient vehicles and vehicles capable of using alternative fuels and advanced biofuels, and thereby advance the development of hybrid-electric, battery-electric, cleaner-diesel, and fuel-cell technologies. NHTSA appreciates the New York and Washington DOTs' interest in the development of new CAFE standards. As in other CAFE rulemakings, NHTSA will give careful consideration to comments from states, vehicle manufacturers, and other stakeholders. We also note that we engage regularly with other countries on matters related to vehicle research and regulation.

In response to the first comment regarding accelerated CAFE standards, as proposed in the NPRM and the DEIS, NHTSA is considering the environmental impacts of several alternatives covering a range of stringency for MY 2011-2015. The CAFE level required under the standards identified in the NPRM increases at an average annual rate of 4.5 percent – a rate fast enough to, if extended through 2020, exceed the 35 mile-per-gallon (mpg) requirement established in the EISA. The NPRM and the DEIS also include more stringent CAFE alternatives than those that would be established by the proposed standards. The proposed standards result in the maximum difference between benefits and costs, or net benefits. Each of the alternatives that would establish higher CAFE standards would result in larger fuel savings and emission reductions than those resulting from the proposed standards. But they would also result in lower net benefits than the proposed standards due to higher costs to society and could, therefore, fail to meet one or more of the statutory criteria applicable under EPCA.

The New York State DOT asked how Alternative 7, Technology Exhaustion, compares to the other alternatives under study. Alternative comparisons can be found in Section 2.5.

The Minnesota Pollution Control Agency suggested that the EIS discuss the incremental change in emissions for each alternative over the projected lifetime of the model year vehicles affected, the respective changes in atmospheric concentrations of GHGs in terms of CO_2 equivalents, and the direct and indirect impacts of these changes in concentrations. The comment further included the recommendation that changes in concentrations be incorporated into the range of emission scenarios prepared by the Intergovernmental Panel on Climate Change (IPCC), including other reasonably foreseeable U.S. emissions changes. This analysis is presented in Chapters 3 and 4.

The Minnesota Pollution Control Agency also recommended the use of the published marginal cost estimates found in the economics literature for the next emitted ton of CO_2 to provide a basis for assessing the cumulative environmental impacts of releases as monetized damages that might contribute to a larger global problem. Detailed estimates of economic benefits and costs of establishing alternative CAFE standards are presented in the PRIA (NHTSA 2008a). As that document explains, consistent with its treatment of pollutants such as nitrogen oxides, NHTSA's analysis applies an estimate representing damage costs, not marginal avoidance costs. As Chapter VIII of the PRIA describes, these estimates utilize the value recommended in a survey of nearly 100 published estimates of the social cost of carbon as a basis for assessing the monetized benefits of the reductions in CO_2 emissions projected to result from alternative CAFE standards.

The joint letter from the Attorneys General of California and several other states stated that the EIS must do more than simply present raw data on tons of GHGs emitted from the relevant sources. The letter stated that the EIS must also educate the public about the scientific consensus on climate change and explain how the contribution made by the emissions from the standard, coupled with emissions from other foreseeable sources, would affect global warming (*i.e.*, cumulative emissions should be modeled to determine a potential change in temperature, and this change should be compared to climate scenarios outlined by the IPCC).

This NEPA document informs the public about the scientific consensus on climate change and explains how the incremental contribution made by the emissions from the standards, coupled with emissions from other foreseeable sources, would affect global warming. *See* Sections 3.4 and 4.4.

In another comment, the Attorneys General suggested that for each alternative, NHTSA report not only the emissions that would result if each manufacturer meets the standard, but the emissions that would result if a series of other reasonably foreseeable events occur. NHTSA should report a range of emissions based on how the standard might operate in the real world. EPA made a similar comment, and NHTSA's response is included above under the EPA comments.

The Attorneys General also referenced what they state to be significant new studies and research on the health-related effects, both direct and indirect, of global warming, and requested that NHTSA take these into account. NHTSA reviewed those studies and research and incorporated them as appropriate in Chapters 3 and 4.

The Attorneys General also requested that NHTSA describe and discuss the potential "tipping points" associated with global warming "that could create unstoppable, large-scale, disastrous impacts for the planet." The term tipping point refers to a situation in which the climate system reaches a point at which there is a strong and amplifying positive feedback from only a moderate additional change in driver, such as CO_2 or temperature increase. These tipping points could result in abrupt climate change, defined in Committee on Abrupt Climate Change (2002) (as cited in Meehl *et al.* 2007) to "occur when the climate system is forced to cross some threshold, triggering a transition to a new state at a rate determined by the climate system itself and faster than the cause."

While climate models do take positive (and negative, *i.e.*, dampening) feedback mechanisms into account, the magnitude of their effect and the threshold at which a tipping point is reached might not be well understood in some cases. In fact, MacCracken *et al.* (2008) notes that existing climate models may not include some critical feedback loops, and Hansen *et al.* (2007) states that the predominance of positive feedbacks in the climate system has the potential to cause large, rapid fluctuations in climate change effects. Therefore, it is important to discuss these mechanisms and the possibility of reaching points that could bring about abrupt climate change. The existence of these mechanisms and other evidence has led some climate scientists including Hansen *et al.* (2007) to conclude that a CO_2 level exceeding about 450 parts per million (ppm) is "dangerous."[24] Overall, however, the IPCC concludes that these abrupt changes are unlikely to occur this century…" (Meehl *et al.* 2007). Whether these tipping points exist and the levels at which they occur are still a matter of scientific investigation.

Where information in the analysis included in the DEIS is incomplete or unavailable, NHTSA has relied on CEQ's regulations regarding incomplete or unavailable information (*see* 40 CFR § 1502.22(b)). In this case, the DEIS acknowledges that information on tipping points or abrupt climate change is incomplete, and the state of the science does not allow for a characterization of how the CAFE alternatives influence these risks, other than to say that the greater the emission reductions, the lower the risk of abrupt climate change.

[24] Defined as more than 1 degree Centigrade (°C) above the level in 2000.

1.3.2.3 Automobile Trade Associations

Automobile trade associations that provided scoping comments on the proposal included the National Automobile Dealers Association (NADA) (Docket No. NHTSA-2008-0060-0013) and the Alliance of Automobile Manufacturers (AAM) (Docket No. NHTSA-2008-0060-DRAFT-0033.1[1]). They noted that NHTSA is not responsible for GHG emissions, because vehicle usage is a voluntary choice, and that the scope of NHTSA's environmental analysis should be restricted to impacts that can clearly be attributed to the standards, with other factors, including fuel prices, manufacturer competition, and consumer preferences, held constant. EPA's comment on the same topic noted that fuel price was an important input into the setting of the standards which could have an effect on the environmental benefits estimated.

As indicated in its response to EPA, NHTSA agrees that fuel price can have an impact on the environmental benefits and, thus, should be considered. Reformed CAFE, and the process used to set the standards ensure that consumer preferences are maintained. The first step in setting standards involves collecting confidential manufacturers' product plan data. Vehicle manufacturers operate in a competitive environment. As profit-maximizing firms, they make product plans to reflect their forecast of what consumers want to buy. In the standard-setting process, NHTSA adds technologies at the individual vehicle-specific level to improve fleet-wide fuel economy. In order to preserve consumer preferences as predicted by vehicle manufacturers, the number and attributes of the vehicles, including their performance, are not altered. Reformed CAFE allows manufacturers to compete by producing a mix of vehicles they think consumers want to buy. No longer do manufacturers have to average out large vehicles with small ones to meet CAFE standards.

NADA also asked that all assumptions regarding the impacts on the rate of vehicle fleet turnover be provided, and that NHTSA forecast the introduction of vehicles meeting the standards into the fleet.

NHTSA's approach to analyzing the rate of vehicle fleet turnover is set forth in the NPRM. *See* 73 *FR* 24352, 24406-24407 (May 2, 2008).

Additionally, NADA requested that NHTSA consider any unique environmental impacts associated with the manufacturing and maintenance of vehicles affected by the proposed action, including alternative fuel vehicles. *See* Section 3.5 for an explanation of these issues.

The AAM stated that it disputes NHTSA's definition of the No Action Alternative as the alternative of maintaining CAFE standards at MY 2010 levels, because it believes that the baseline for comparison of the alternatives under NEPA should be set based on the scope of legal authority NHTSA has under EISA. The AAM recommended that NHTSA redefine the No Action Alternative to be consistent with the minimum CAFE standard increases needed to achieve a combined fuel economy level of 35 mpg by MY 2020. The AAM stated that such redefinition of the No Action Alternative would change NHTSA's calculation of the magnitude of the environmental impacts of the rulemaking, and might also change the agency's assessment of the significance of those effects. Accordingly, the AAM stated that it might be more appropriate for NHTSA to prepare a less elaborate EA, rather than a more-searching EIS.[25]

NEPA requires that NHTSA examine a no action alternative that reflects the state of the environment if the action were not taken. Even though NHTSA is required under EISA to set new fuel economy standards, we must analyze a scenario in which NHTSA does not take this action, which serves

[25] *Id.* at 18-22.

as a baseline against which to compare the other alternatives (*see* Section 1.3.2.6 concerning NHTSA's decision to prepare an EIS).

Another issue raised by the AAM was the extent of NHTSA's analysis of global effects associated with CO_2 emissions. The AAM stated that it agrees with NHTSA's statement in the May 2008 NPRM that "the appropriate value to be placed on changes [in] climate damages caused by carbon emissions should be ones that reflect the change in damages to the United States alone."[26] The AAM interpreted this statement in the NPRM as a proposal by NHTSA "to limit analysis undertaken in connection with the rulemaking to effects within the United States' own borders."[27] The AAM stated that this conclusion should carry over to the NEPA analysis, and that it believes NHTSA should scale back the estimated harms in any studies of the global effects associated with carbon emissions.

NHTSA agrees in part regarding the estimates employed for SCC, as discussed in the NPRM. NHTSA disagrees, however, with the AAM's characterization of NHTSA's statement in the NPRM as being a proposal to limit the agency's environmental impact analysis under NEPA. Potential environmental impacts are global in this instance, and the analysis must look beyond the borders of the United States. The section of the NPRM preamble quoted by the AAM discussed valuation of SCC as an input into the Volpe model. NHTSA has an obligation under NEPA to "recognize the worldwide and long-range character of environmental problems."[28]

NHTSA has considered the AAM's comment on the issue of the global effects of the agency's action. In the NPRM, NHTSA also requested "comment on its tentative conclusions for the value of the SCC emissions, the use of a domestic versus global value for the economic benefit of reducing CO_2 emissions, the rate at which the value of the SCC grows over time, the desirability of and procedures for incorporating benefits from reducing emissions of GHGs other than CO_2, and any other aspects of developing a reliable SCC value for purposes of establishing CAFE standards." *Id.* at 24414-24415.

Furthermore, an appropriate discussion of global climate change does not make sense if NHTSA limits analysis to the effects within the United States, because this environmental problem is inherently global in nature. Climate science focuses on accumulations of carbon emissions in the global atmosphere because the atmospheric concentration of GHGs is basically uniform across the globe (IPCC 1997). That is, carbon emissions from one nation disperse into the global atmosphere and have impacts in other nations, and conversely, benefits from emissions reductions in one nation are felt in all nations for the same reason. That said, NHTSA considers the AAM's comment as a suggestion to focus on environmental impacts within the United States, and agrees that this type of national rulemaking warrants specific discussion of regional U.S. impacts and how global climate change specifically affects the United States. Accordingly, NHTSA devoted a substantial section of the DEIS to such discussion.

The AAM argued in its comments that "the principal cumulative effects on which NHTSA's NEPA analysis should focus are those associated with the additive effects over the last decade or more of CAFE standards on the light-truck side, combined with those for this proposed rulemaking, which increases CAFE standards for both passenger cars and trucks." The AAM was primarily disputing the Ninth Circuit's decision in *Center for Biological Diversity v. NHTSA*, 508 F.3d 508, 550 (9th Cir. 2007),

[26] *See* 73 *FR* 24352, 24414.
[27] Alliance Comments, *supra* at 29.
[28] 42 U.S.C. § 4332(f). *See also* CEQ, *Council on Environmental Quality Guidance on NEPA Analyses for Transboundary Impacts* (July 1, 1997), at 3, *available at* http://ceq.hss.doe.gov/nepa/regs/transguide.html (last visited June 16, 2008) (stating that "agencies must include analysis of reasonably foreseeable transboundary effects of proposed actions in their [NEPA] analysis of proposed actions in the United States.").

in which the Court concluded that "by allowing particular fuel economy levels … NHTSA's regulations are the proximate cause of [tailpipe GHG] emissions."

In response to the AAM's comment, NHTSA notes that the CEQ regulations define "cumulative impacts" as "the impacts on the environment which result from the incremental impact of the action when added to other past, present, and reasonably foreseeable future actions regardless of what agency (Federal or non-Federal) or person undertakes such other actions. Cumulative impacts can result from individually minor but collectively significant actions taking place over a period of time." 40 CFR § 1508.7.

In the DEIS, NHTSA addresses the cumulative impacts (through 2100) of MY 2011-2015 standards, NHTSA's implementation of the CAFE Program through MY 2010, and "assumed" CAFE standards for MY 2016-2020. NHTSA has reviewed the available research and literature and has estimated the cumulative impacts on energy, air quality, and climate change. Our analysis considers both physical effects and resource impacts due to the cumulative impacts on climate change. Physical effects include changes in temperature, precipitation, and sea-level rise. Resource impacts include cumulative weather-based impacts on freshwater and terrestrial ecosystems and on human health and land-use patterns, and non-weather impacts. Our cumulative impacts analysis accounts for uncertainty and is consistent with CEQ regulations.

To this end, while this NEPA analysis considers some of the issues suggested by the AAM, including an analysis of the cumulative emissions impacts resulting from the CAFE Program since its inception (*see* Chapter 3) and an analysis of the standards and cumulative air quality impacts (in terms of criteria pollutant emissions, for example) on human health and the environment, NHTSA believes that the cumulative impacts analysis suggested by the AAM comments might be too narrow for our purposes.

1.3.2.4 Environmental Advocacy Groups

The Environmental Defense Fund (Docket No. NHTSA-2008-0060-0015) commented on the scope of NHTSA's NEPA analysis in conjunction with the Northern Health Impact Resource Group, Physicians for Social Responsibility, American Public Health Association, and the Johnson County Health Department. The commenters suggested a framework and methodology for analyzing the potential health impacts of climate change related to the CAFE standards and suggested that NHTSA request technical assistance from agencies with special expertise in this area. They suggested that the health benefits of the reduction of the emissions of pollutants regulated under the Clean Air Act, including criteria pollutants, and generated at every stage of the fuel cycle (*i.e.*, fuel production, refining, transport, storage, and combustion in vehicle engines) be quantified using traditional risk assessment. The commenters asserted that proper quantification of the economic benefits of reducing these adverse health impacts might justify adoption of more stringent fuel economy standards.

The commenters also suggested that NHTSA consider the policy alternatives under consideration as conforming to (as one example) no action, moderate action, and stringent action pathways. These pathways might be comparable to the different emissions scenarios employed by the IPCC, and they are also consistent with NHTSA's proposed categorization of alternative policy options. Assessment of health impacts could then be conducted for the degree of reductions in national or global GHG emissions associated with the relative stringency of each pathway, to provide decisionmakers with some useful insight into the health consequences of the various degrees of stringency associated with specific CAFE alternatives. Estimates of changes in incidence or prevalence of climate-sensitive health outcomes could be performed at 5-year intervals into the future, and inflation-adjusted costs associated with those health outcomes could also be calculated as a means of valuing the incremental contribution of the alternatives.

NHTSA has listed the alternatives in order of increasing stringency, as indicated by the mpg estimates associated with each. NHTSA has presented a full range of alternatives, from no action through a full consideration and exhaustion of the technological approaches NHTSA believes are currently available to increase CAFE (without regard to cost) consistent with the commenters' concerns. Further, the analysis included in the DEIS employs three IPCC scenarios to estimate the changes in CO_2 concentrations and temperature that are due to the alternatives. These scenarios (A2, A1B, and B1) represent a high, moderate, and low estimate of what future emissions levels might be. There is a great deal of uncertainty associated with estimating emissions levels in the year 2100, and the IPCC treats these scenarios (along with the other four scenarios) as equally probable. Given this uncertainty in the emission scenarios and in the analysis generally, it is not productive to estimate final impacts on human health or on other environmental areas because the range of error would obscure any reported differences in the alternatives. For these reasons, human health and environmental outcomes resulting from the CAFE alternatives are qualitatively assessed, and NHTSA's analysis includes a sense of the direction of the impacts and the relative magnitude by alternative, which will inform NHTSA's decisions on the standards.[29] Attempts to quantify impacts, including estimating health outcomes, would provide an unrealistic sense of precision that would not, in NHTSA's opinion, provide useful information for the decisionmaker or the public.

In the DEIS, NHTSA has analyzed both the criteria pollutants and mobile source air toxics (MSATs) by estimating the emissions levels of each generated under the CAFE alternatives. Upstream emissions[30] are included to the extent possible. (Upstream emissions of acrolein are not available.) Transportation conformity[31] does not apply because neither the Federal Highway Administration (FHWA) nor the Federal Transit Administration (FTA) is taking the action. General conformity[32] provides an explicit exception for rulemaking activities. Consequently, there is no requirement to analyze concentrations for the criteria pollutants. *See* the discussion of conformity in Chapter 3 for more information.

NHTSA's approach regarding MSATs follows that of the FHWA guidance on MSATs analysis issued in February 2006 and the approach generally followed by the Federal Aviation Administration. The FHWA stated that uncertainties associated with the exposure and health risk assessments, in addition to the fact that uncertainties are inherent in the emissions modeling process, raised concerns about the utility of studying MSATs beyond an emissions burden analysis. In addition, the NHTSA analysis demonstrates an overall reduction at the national level of both MSATs and criteria air pollutants, which should reduce health risk, making any further level of analysis of marginal benefit.

[29] *See* 42 U.S.C. § 4332(2)(B) (directing agencies to "insure that presently unquantified environmental amenities and values may be given appropriate consideration in decisionmaking along with economic and technical considerations"); *see* also 40 CFR § 1502.22.

[30] Emissions associated with extraction, refining, storage, and distribution of the fuel.

[31] The Transportation Conformity Rules (40 CFR 51 Subpart T), which apply to transportation plans, programs, and projects funded under title 23 U.S.C. or the Federal Transit Act. Highway and transit infrastructure projects funded by the Federal Highway Administration or the Federal Transit Administration usually are subject to transportation conformity.

[32] The General Conformity Rules (40 CFR 51 Subpart W), which apply to all other federal actions not covered under transportation conformity. The General Conformity Rules established emissions thresholds, or *de minimis* levels, for use in evaluating the conformity of a project. If the net emission increases due to the project are less than these thresholds, then the project is presumed to conform and no further conformity evaluation is required. If the emission increases exceed any of these thresholds, then a conformity determination is required. The conformity determination could entail air quality modeling studies, consultation with EPA and state air quality agencies, and commitments to revise the State Implementation Plan or to implement measures to mitigate air quality impacts.

Health costs are already included in the modeling process by which NHTSA analyzes alternatives for the CAFE standard. Using a process that maximizes net benefits, NHTSA assesses the societal costs and benefits associated with each of the alternatives. Included in the societal costs are damages to health.

Finally, NHTSA received scoping comments from CDC and EPA and has consulted with each agency. NHTSA has also retained a nationally recognized consulting firm to assist with the analysis. NHTSA believes that we have or have retained the requisite expertise and knowledge to address the health and environmental impacts as required under NEPA.

1.3.2.5 Individuals

Scoping comments from individuals included approximately 1,737 letters that were similar in form and content. These letters recommended that NHTSA base the new standards on what the commenters considered more realistic gas prices and encourage the domestic automobile manufacturers to speed up the production of more fuel-efficient automobiles.

NHTSA's analysis of alternative CAFE standards relies on fuel price forecasts reported in the U.S. Energy Information Administration's (EIA's) *Annual Energy Outlook*, an official U.S. Federal Government forecast that is widely relied upon by federal agencies in their analysis of proposed regulations. The alternative CAFE standards analyzed in the NPRM and the PRIA were developed and evaluated using fuel price forecasts from EIA's *Annual Energy Outlook 2008 Revised Early Release*, and NHTSA will consider any subsequent revisions in the final edition of *Annual Energy Outlook 2008* in preparing the Final Rule and Final Regulatory Impact Analysis (FRIA). Extensive tests of the effect of higher fuel prices on the stringency of the optimized CAFE standards, as well as upon the resulting fuel savings, reductions in CO_2 emissions, and total economic benefits are reported in Tables IX-5a and IX-5b of the PRIA. As to the timeline for production of more fuel-efficient vehicles, the standards NHTSA proposed increase at a rate that, if sustained through 2020, would exceed the 35 mpg minimum average requirement specified by EISA.

Comments from private individuals included a letter from Susan and Yuli Chew (the Chews) (Docket No. NHTSA-2008-0060-0014) suggesting that the fuel price assumptions used by NHTSA are out of date. This comment is similar to the comments of other individuals and is addressed above.

The Chews also suggested that the assumptions of the buyer's payback calculation are flawed. This comment appears to refer to the 4.7- and 4.2-year payback periods for the passenger-car and light-truck CAFE standards reported in PRIA Table IX-10, p. IX-14. These payback periods are calculated from the increases in fuel economy, annual fuel savings, and value per gallon of fuel saved at forecast retail fuel prices for the standards. They are thus empirical estimates of the actual time required for buyers of new vehicles to recoup the higher purchase prices of those vehicles in the form of fuel cost savings, rather than assumptions about buyers' time horizons for valuing fuel savings.

The Chews also questioned the "carry-forward" and "carry-back" credits. While NHTSA cannot precisely estimate the potential environmental impacts of discounting credits, NHTSA believes its analysis of how the various compliance flexibilities might affect the potential environmental impacts of the standards spans the likely range of impacts that would be associated with discounting credits. The requirements covering the use of credits for alternatively fueled vehicles are explained in the EPCA. NHTSA does not have discretion to discount credits in future years. The point, however, will become moot as these credits are being phased out under the EISA, as noted by the commenter. They will no longer be allowed at all for MY 2020 vehicles.

The Chews suggested that the effect of ethanol is not properly discussed in terms of air quality and natural and human resources and that the benefit of alternative-fuel vehicles has been magnified, as only small portions of Midwest states have any E85[33] infrastructure in place.

In setting CAFE standards, NHTSA sets the fuel economy targets manufacturers are required to meet but does not specify the technologies required to meet those targets. Companies are provided credits under the Alternative Motor Fuels Act, but Congress is phasing out those credits. Even if the manufacturers employ the production of vehicles that can run on 85 percent ethanol in their strategies to meet the new targets, the existence of these vehicles does not necessarily change the production of ethanol, because consumers would have to choose to fill their vehicles with E85 fuel, and also have it available at their fueling stations.

NHTSA believes that the extent to which ethanol will actually be used as a transportation fuel will primarily be determined by its availability at retail fueling stations and its retail price in relation to that of gasoline. Because the availability of ethanol and its price in relation to that of gasoline are unlikely to be affected substantially by the stringency of CAFE standards, the use of ethanol is similarly unlikely to differ substantially among the alternative CAFE standards considered for MY 2011-2015. Thus, while the volume of ethanol that is produced, distributed, and consumed could substantially affect total emissions from the production and use of transportation fuels, this effect is not likely to differ substantially among alternative CAFE standards. As a consequence, the extent of ethanol use is unlikely to affect the changes in total emissions from production and use of transportation fuels resulting from alternative CAFE standards, or the environmental impacts associated with those changes in emissions.

The Chews also stated that the benefits are almost twice as much as the costs for MY 2011-2015, so the target should be adjusted to be more aggressive than planned. Regarding these benefits, NHTSA's NPRM reflects the best information available to NHTSA when the analysis was performed, and the standards reflect those benefits. NHTSA has requested comment on its estimate of benefits and costs, and on its analytical methods. After reviewing these comments, which are due on July 1, 2008, NHTSA will revisit its analysis in preparing the final rule.

The Chews suggested that the phasing out of the fuel economy incentives by dual-fuel vehicles (*e.g.*, E85) is welcomed and overdue. Dual-fuel vehicles are designed to run on gasoline or an alternative fuel. By law, manufacturers of these vehicles can lower their CAFE requirements by a certain amount within the limits specified in statute. To assess the environmental impacts of in-use operation of dual-fuel vehicles, data detailing the operation of the vehicle using the alternative fuel would be necessary. Unfortunately, such data depend on each individual's use of the dual-fuel vehicle, and are not available.

1.3.2.6 Other Comments

There were several comments submitted that go beyond the scoping process under NEPA or address regulatory issues within the NPRM or the PRIA.

The AAM (Docket No. NHTSA-2008-0060-DRAFT-0033.1[1]) submitted comments suggesting that an EIS is not warranted, and that an EA would be adequate.

NHTSA's rationale for preparing an EIS is explained in its NOI to prepare an EIS.[34]

[33] Automobile fuel that is 85 percent denatured ethanol and 15 percent gasoline.
[34] 73 *FR* 16615, 16616 (March 28, 2008).

The AAM also stated its belief that because the setting of CAFE standards under EPCA involves consideration of environmental factors, the "functional equivalence doctrine" applies to NHTSA's mandate for setting CAFE standards.[35] The AAM maintains that the functional equivalence doctrine is applied by courts to eliminate the need for an agency to perform NEPA analysis where the agency's Congressional mandate already involves specific procedures for considering the environment that offer the functional equivalent of an EIS.[36] According to the AAM, courts have ruled that EPA regulation under the Clean Air Act is the functional equivalent of NEPA analysis, making separate application of NEPA by EPA unnecessary.

In those instances where courts have found an agency exempt from NEPA requirements via the functional equivalence doctrine, the doctrine has been narrowly drawn. For example, the D.C. Circuit has repeatedly described the functional equivalence doctrine as a narrow exemption that is applicable "when the agency's organic legislation mandates procedures for considering the environment that are 'functional equivalents' of the NEPA process."[37] Other circuit courts have adopted even more narrow interpretations of the functional equivalence doctrine, construing it to mean that one process requires the same steps as another.[38] Although NHTSA considers environmental impacts when setting CAFE standards, EPCA does not require explicit consideration of environmental impacts; rather, the analysis is one that the agency has conducted in the context of evaluating the Nation's need to conserve energy.[39] EPCA does not require a level of environmental analysis commensurate with the requirements of NEPA. Moreover, courts have long held that NEPA applies except in limited circumstances.[40] Consequently, NHTSA declines to adopt the AAM's suggestion, and has prepared a DEIS to consider the environmental impacts of the standards in the context of NHTSA's CAFE Program. The DEIS will aid the agency in completing a robust analysis of the environmental impacts of the rulemaking for MY 2011-2015 CAFE standards.

The AAM also suggested that NHTSA consider an alternative tied to the "least capable manufacturer" approach that was applied prior to the advent of Reformed CAFE. NHTSA does not adopt this approach for the following reasons. NHTSA's earlier "Unreformed CAFE" standards specified a "one size fits all" (uniform) level of CAFE that applied to each manufacturer and that was set with particular regard to the lowest projected level of CAFE among the manufacturers that have a substantial

[39] *See Center for Biological Diversity v. NHTSA*, 508 F.3d 508, 547 (9th Cir. 2007) (describing as complementary EPCA's goal of energy conservation and NEPA's goal of helping public officials make decisions that are based on an understanding of environmental consequences); *Massachusetts v. EPA*, 127 S. Ct. 1438, 1462 (2007) (categorizing EPCA's requirement to set CAFE standards as "DOT's mandate to promote energy efficiency" and distinguishing this mandate as "wholly independent" of the Clean Air Act's command that EPA protect the public's health and welfare); *see* also *Center for Auto Safety v. NHTSA*, 793 F.2d 1322, 1324-1325 n.12 (D.C. Cir. 1986) (listing the four statutory factors NHTSA is to consider when determining "maximum feasible" fuel economy, and noting approvingly that NHTSA interpreted the "need of the Nation to conserve energy" factor as requiring consideration of, among other issues, the "environmental … implications of our need for large quantities of petroleum").
[40] *See Pacific Legal Foundation v. Andrus*, 657 F.2d 829, 833 (6th Cir. 1981); *Calvert Cliffs' Coordinating Committee, Inc. v. U.S. Atomic Energy Commission*, 449 F.2d 1109, 1114-1115 (D.C. Cir. 1971).

share of the market. The manufacturer with the lowest projected CAFE level is typically known as the "least capable" manufacturer. However, NHTSA's 2006 CAFE standards for light trucks adopted a different "Reformed CAFE" approach. (71 *FR* 17566 [April 6, 2006]). EISA recently codified that approach, requiring that all CAFE standards be based on one or more vehicle attributes. (49 U.S.C. § 32902(b)(3)(A); *see* 73 *FR* 24352, 24354-24355 [May 2, 2008] [discussing NHTSA's proposal to base CAFE standards on the attribute of vehicle size, as defined by vehicle footprint].)

As NHTSA explained when proposing Reformed CAFE standards for MY 2008-2011 light trucks, "[u]nder Reformed CAFE, it is unnecessary to set standards with particular regard to the capabilities of a single manufacturer in order to ensure that the standards are technologically feasible and economically practicable for all manufacturers with a substantial share of the market. This is true both fleet wide and within any individual category of vehicles." *See* 70 *FR* 51414, 51432 (August 30, 2005). Specifically:

> There is no need under Reformed CAFE to set the standards with particular regard to the capabilities of the "least capable" manufacturer. Indeed, it would often be difficult to identify which manufacturer should be deemed the "least capable" manufacturer under Reformed CAFE. The "least capable" manufacturer approach was simply a way of implementing the guidance in the conference report [part of EPCA's legislative history][41] in the specific context of Unreformed CAFE….
>
> …The very structure of Reformed CAFE standards makes it unnecessary to continue to use that particular approach in order to be responsive to guidance in the conference report. Instead of specifying a common level of CAFE, a Reformed CAFE standard specifies a variable level of CAFE that varies based on the production mix of each manufacturer. By basing the level required for an individual manufacturer on that manufacturer's own mix, a Reformed CAFE standard in effect recognizes and accommodates differences in production mix between full- and part-line manufacturers, and between manufacturers that concentrate on small vehicles and those that concentrate on large ones.
>
> There is an additional reason for ceasing to use the "least capable" manufacturer approach. There would be relatively limited added fuel savings under Reformed CAFE if we continued to use the "least capable" manufacturer approach even though there ceased to be a need to use it….

(70 *FR* 51433).

In addition, the AAM's suggested approach would not result in the increases in fuel economy mandated by EISA – namely, 35 mpg by MY 2020.

In light of the fact that Congress recently codified the Reformed CAFE approach for both passenger cars and light trucks, and for all of the reasons stated above, NHTSA does not consider in detail an alternative tied to the historic "least capable manufacturer" approach.

Other comments, described below, suggested that NHTSA's NEPA analysis consider certain economic or social issues that are beyond the scope of NEPA.

[41] *See* 70 *FR* 51414, 51425-51426 (August 30, 2005) (discussing the conference report).

The AAM suggested that appropriate cumulative effects should include "The economic disbenefits and counterproductive/unintended consequences of CAFE standard increases," specifically including, "at a minimum, … the cumulative effects in this regard stemming from employment losses and associated health effects, for both this current proposed rule and the 2006 light truck rule. The same is true as to cumulative safety disbenefits and cumulative environmental disbenefits in terms of increased criteria pollutant emissions traceable to the fleet turnover and rebound effects."

The AAM also suggested that NHTSA consider what it characterized as additional categories of "environmental" effects in the DEIS, including the quality of life of unemployed automotive industry workers and fleet turnover.

The CDC suggested that "health and well-being"-related impacts of decreasing dependency on motor vehicle fuel, such as mental health benefits, reduced stress, and increased economic stability be evaluated in the DEIS. NHTSA discussed this comment with CDC on June 12, 2008. In particular, NHTSA and CDC discussed the potential for human health impacts in two areas – namely, the potential for social instability resulting from energy concerns and for changes in family expenditures related to energy. Further, in the discussion with CDC, the difficulty in addressing such issues was acknowledged. NHTSA agreed to examine the source provided by CDC concerning health issues related to petroleum scarcity (*see* Chapter 3).

Courts have generally held that economic and social issues need only be considered if they directly interrelate to the effects on the physical environment.[42] Because these issues raised by the AAM and CDC do not stem from effects on the physical environment, they are not addressed in this document.

The Attorneys General suggested the additional alternative of downweighting for all vehicles, not just vehicles weighing more than 5,000 pounds, and stated that there is strong evidence that downweighting of vehicles does not make them less safe. As discussed above, other comments also raised the downweighting alternative and related concerns. Chapter 2 explains NHTSA's rationale for choosing alternatives, and explains why NHTSA believes that the safety risks with downweighting preclude its selection as a reasonable alternative.

The Attorneys General also requested that NHTSA expand its analysis of reduced vehicle weight as a means of improving fuel economy. As mentioned above and discussed in the NPRM, NHTSA's analysis does include the potential to improve fuel economy through greater utilization of light-weight materials on heavier vehicles for which doing so would be unlikely to compromise highway safety.

Other comments refer to issues NHTSA expects to address in the final rule. These include comments from states concerning new technologies, comments from the AAM concerning the proper construction of the term, "ratably," and comments from individuals.

1.3.3 Summary of Public Comments on the DEIS

On June 26, 2008, NHTSA submitted to EPA a DEIS that disclosed and analyzed the potential environmental impacts of new CAFE standards and reasonable alternative standards in the context of NHTSA's CAFE Program pursuant to CEQ NEPA implementing regulations, DOT Order 5610.1C, and NHTSA regulations. On July 2, 2008, NHTSA published a *Federal Register* Notice of Availability announcing the availability of the DEIS. NHTSA's Notice of Availability also made public the date and location of a public hearing, and invited the public to participate at the hearing on August 4, 2008, in

[42] *See, e.g., Ashley Creek Phosphate Co. v. Norton*, 420 F.3d 934, 944 (9th Cir. 2005); *Hammond v. Norton*, 370 F. Supp.2d 226, 243 (D.D.C. 2005).

Washington, DC. On July 3, 2008, EPA issued its Notice of Availability for the DEIS, triggering the 45-day public comment period. In accordance with CEQ implementing regulations, the public was invited to submit written comments on the DEIS until August 18, 2008.

NHTSA mailed approximately 200 copies of the DEIS to interested parties, including federal, state, and local agencies; elected officials; environmental and public interest groups; Native American tribes; and other interested individuals, as listed in Chapter 9 of the DEIS.

A total of 44 commenters spoke at the hearing. In addition, NHTSA received 66 written comment documents from interested stakeholders, including EPA, the CDC, state and local agencies, elected officials, automobile trade associations, organizations, and private citizens. The transcript from the public hearing and written comments submitted during the public-comment period are part of the administrative record, and are available on the Federal Docket Web site at http://www.regulations.gov, Reference Docket No. NHTSA-2008-0060. Chapter 10 of this FEIS contains public comments on the DEIS and NHTSA's responses to those comments. Appendix D of this FEIS provides a copy of each written comment document and the public hearing transcript in their entirety.

Commenters raised a wide variety of issues regarding the DEIS. For example, some commenters were concerned about how NHTSA's alternatives relate to EPCA's requirement to establish the "maximum feasible average fuel economy." Other commenters had questions about how NHTSA had fulfilled its statutory requirements under NEPA, specifically in regard to public involvement and the timing of the EIS and CAFE rulemaking. A few commenters questioned the need for the agency to produce an EIS, citing the Government's (at the time) pending en banc petition for review of the Ninth Circuit Court of Appeals decision (*Center for Biological Diversity v. NHTSA*, 508 F.3d 508 [9th Cir. 2008], vacated and withdrawn, 2008 WL 3822966 [9th Cir. 2008] [denying the government's petition as moot]), while one commenter suggested that NHTSA should prepare an EA instead of an EIS.

NHTSA received a number of comments on various aspects of the Volpe model, many expressing concern about the economic assumptions that were input to the model. The most common of these input-related comments included concerns regarding the values assigned to fuel price, social cost of carbon, discount rate, and rebound effect; the technologies and vehicle attributes considered by the model and their associated costs; assumptions about the types of vehicles on the road in the future (particularly the market penetration of hybrids); and the use of auto manufacturers' product plans. Commenters also suggested that the Volpe model consider the military and national security costs associated with ensuring oil supplies, consider a different method to account for consumer demand and behavior directly, and use related changes to U.S. vehicle fleet turnover.

NHTSA received comments on the alternatives in the DEIS. Commenters questioned NHTSA's definition of the No Action Alternative (Alternative 1), specifically regarding the projected baseline mpg and other factors considered, or not considered, in its definition. Commenters also questioned how the Optimized Alternative (Alternative 3) represents an optimization of cost and benefits. Some commenters recommended that NHTSA select alternatives below Optimized, while others recommended that NHTSA use the requirement of "ratable" to derive standards that ratably increase to 35 mpg. Multiple commenters recommended that NHTSA select alternatives above Optimized, including the Total Costs Equal Total Benefits Alternative (Alternative 6). Several commenters argued for adoption of the Technology Exhaustion Alternative (Alternative 7), while others did not believe this alternative represented a true exhaustion of technological options. Some commenters stated that NHTSA did not consider a reasonable range of alternatives. In addition, there were comments regarding the alternatives' relationship to the "maximum feasible fuel economy standard." Some commenters requested that NHTSA consider new alternatives, such as alternatives that might not be within NHTSA's jurisdiction or that more aggressively raised the fuel economy standards so as to reach or exceed 35 mpg by 2015.

NHTSA received comments concerning the methodology for analyzing air quality impacts and associated health costs. Commenters noted that the DEIS did not include full-scale photochemical air quality modeling and, therefore, did not characterize the ambient air quality impacts or health outcomes associated with each alternative. Commenters also expressed concern that the dollar-per-ton values used to reflect the monetized health-related benefits associated with criteria pollutant emission reductions omitted a number of unquantified health and environmental effects.

Many commenters referenced suggestions made by the scientific community that CO_2 emissions should be reduced 80 percent by 2050 to mitigate the worst effects of climate change. Commenters suggested that this goal be used as a reference point from which to measure greenhouse gas reductions achieved through the different alternatives presented in the DEIS. Commenters stated that this contextual comparison would be more appropriate than comparing the alternatives based on their contribution to the reduction in global temperature and sea-level rise.

Other commenters suggested updated methodologies that could be employed in the FEIS. For example, some commenters recommended re-running the analysis using the revised version (5.3) of MAGICC (Model for the Assessment of Greenhouse-gas Induced Climate Change). Commenters also recommended running MAGICC using a range of climate sensitivities to reflect the 2.0 to 4.5 °C range projected in the IPCC report. Many commenters questioned the accuracy of the “scaling approach” implemented in the DEIS, which assumed a linear relationship between emission levels and climate responses. Commenters further stated that the DEIS did not fully address the issue of tipping points.

A few commenters also stated that the proposed rulemaking would substantially impact endangered species and that a proper analysis of these impacts was absent from the comparison of the impacts of each alternative in the DEIS.

In addition to comments on the DEIS, NHTSA received a number of comments regarding the rulemaking. Some of these comments dealt with the issue of federal preemption of state laws, arguing that NHTSA’s rulemaking should not preempt state regulation of GHG emissions from automobiles. Other comments on the rulemaking objected to NHTSA’s vehicle footprint approach, either suggesting a more inclusive consideration of vehicle attributes, such as towing capacity, or questioning the use of a size-based system that has the built-in risk of manufacturers upsizing vehicles to achieve lower fuel economy targets.

In Chapter 10 of this FEIS, NHTSA sets forth excerpts of the comments on the DEIS, followed by NHTSA’s responses to those comments. Written comments and the public hearing transcript can be viewed in their entirety in Appendix D of this FEIS.

1.3.4 Submission of the Final EIS and Next Steps

NHTSA is mailing this FEIS to the agencies, individuals, and organizations on the distribution list provided in Chapter 9, and submitted it to EPA for formal issuance of a Notice of Availability. No sooner than 30 days after EPA publishes a Notice of Availability of the FEIS in the *Federal Register*, NHTSA will publish a final CAFE rule and Record of Decision. The Record of Decision will state and explain NHTSA’s decision and describe NHTSA’s consideration of applicable environmental laws and policies.

Chapter 2 Proposed Action and Alternatives

2.1 INTRODUCTION

The National Environmental Policy Act[1] (NEPA) requires an agency to compare the environmental impacts of its proposed action and alternatives. An agency must rigorously explore and objectively evaluate all reasonable alternatives, including a No Action Alternative. For alternatives an agency eliminates from detailed study, the agency must "briefly discuss the reasons for their having been eliminated."[2] The purpose of and need for the agency's action provides the foundation for determining the range of reasonable alternatives to be considered in its NEPA analysis.[3]

In developing the new Corporate Average Fuel Economy (CAFE) standards and possible alternatives, the National Highway Traffic Safety Administration (NHTSA) considered the four Energy Policy and Conservation Act (EPCA) factors that guide the agency's determination of "maximum feasible" standards:

- Technological feasibility
- Economic practicability
- The effect of other standards of the Government on fuel economy
- The need of the Nation to conserve energy[4]

In addition, NHTSA also considered relevant environmental and safety factors. For instance, NHTSA has placed monetary values on environmental externalities, including the benefits of reductions in carbon dioxide (CO_2) emissions. The NEPA analysis presented in NHTSA's Draft Environmental Impact Statement (DEIS) and this Final Environmental Impact Statement (FEIS) is informing the agency's action in setting final CAFE standards. During the standard-setting process, NHTSA consults with the U.S. Environmental Protection Agency (EPA) and the Department of Energy (DOE) regarding a variety of matters as required by EPCA.

2.2 STANDARDS-SETTING AND BENEFIT-COST ANALYSIS

To inform the balancing of the EPCA factors relevant to standard setting, NHTSA examined various levels of stringencies (mpg levels) to conduct a benefit-cost analysis for each level. A benefit-cost analysis weighs the expected benefits against the expected costs of specific alternatives on a societal basis, relative to a "no action" baseline. Costs of any specific CAFE alternative include the aggregate costs to increase the utilization of fuel-saving technologies, where such costs are expressed on a retail price equivalent basis. The benefits of any specific alternative include fuel savings over the operational life of new vehicles with increased fuel economy and the social benefits of reducing petroleum consumption and environmental externalities.

For each alternative under all scenarios, NHTSA calculated the costs and the benefits. This information replaces the benefit-cost information discussed in the DEIS which relied on the PRIA. The tables are entitled "FEIS Benefit-Cost Information, October 2, 2008," and are shown in Appendix C.

---

[1] 42 United States Code (U.S.C.) § 4332(2)(C). NEPA is codified at 42 U.S.C. §§ 4321 *et seq.*
[2] 40 Code of Federal Regulations (CFR) §§ 1502.14(a), (d).
[3] 40 CFR § 1502.13. *Vermont Yankee Nuclear Power Corp. v. Natural Resources Defense Council*, 435 U.S. 519, 551 (1978); *City of Alexandria v. Slater*, 198 F.3d 862, 867-69 (DC Cir. 1999), cert. denied sub nom. 531 U.S. 820 (2000).
[4] 49 U.S.C. § 32902(f).

NHTSA has a long-standing practice of analyzing regulatory options based on the best available information regarding (1) the future vehicle market, (2) the technologies expected to be available during the relevant model years, and (3) the key economic factors, such as future fuel prices. Among these categories, all information except NHTSA's forecast of the future vehicle market is made available to the public. The forecast of the future vehicle market is based substantially on confidential product planning information manufacturers submit to the agency, as individual manufacturers are better able than any other entity to anticipate what mix of products they are likely to sell in the future.

2.2.1 Volpe Model

Until 2002, when NHTSA began work on CAFE standards for light trucks sold during model years 2005-2007, the agency used tools such as spreadsheets to analyze regulatory options. For that rulemaking and ensuing rulemakings, the agency has supplemented such tools with a modeling system developed specifically to assist NHTSA with applying technologies to thousands of vehicles and developing estimates of the costs and benefits of potential CAFE standards. The CAFE Compliance and Effects Modeling System, developed by DOT's Volpe National Transportation Systems Center and commonly referred to as "the Volpe model," enables the agency to efficiently, systematically, and reproducibly evaluate many more regulatory options, including attribute-based CAFE standards required by EISA, than was previously possible, and to do so much more quickly. The model assumes that manufacturers apply the most cost-effective technologies first, yielding the greatest net benefits. As more stringent fuel economy standards are evaluated, the model recognizes that manufacturers must apply less cost-effective technologies. The model then compares the discounted present value of costs and benefits for any specific CAFE standard.

Model documentation, publicly available in the rulemaking docket, explains how the model is installed, how the model inputs and outputs are structured, and how the model is used. The model can be used on any Windows-based personal computer with Microsoft Office 2003 and the Microsoft .NET framework installed (the latter available without charge from Microsoft). The executable version of the model, with all of its codes and accompanying demonstration files, is available upon request, and has been provided to manufacturers, consulting firms, academic institutions, nongovernmental organizations, research institutes, foreign government officials, and other organizations. The current version of the model was developed using Microsoft Development Environment 2003, and every line of computer code (primarily in C#.NET) has been made available to individuals who have requested the code. Many of these individuals have run the model using market forecast data that they estimated on their own.[5]

The Volpe model requires the following types of input information: (1) a forecast of the future vehicle market, (2) estimates of the availability, applicability, and incremental effectiveness and cost of fuel-saving technologies, (3) estimates of vehicle survival and mileage accumulation patterns, the rebound effect, future fuel prices, the "social cost of carbon," and many other economic factors, (4) fuel characteristics and vehicular emissions rates, and (5) coefficients defining the shape and level of CAFE curves to be examined. The model makes no *a priori* assumptions regarding inputs such as fuel prices and available technology, and does not dictate the form or stringency of the CAFE standards to be examined. The agency makes those selections and, in the case of technology assumptions, has determined that confidential product plans are a vital source of information.

Using inputs selected by the agency based on the best available information and data, NHTSA projects a set of technologies each manufacturer could apply in attempting to comply with the various levels of potential CAFE standards to be examined. The model then estimates the costs associated with

[5] Resources for the Future (RFF) has run the model and is working under contract with EPA to expand its capability.

this additional technology utilization, as well as accompanying changes in travel demand, fuel consumption, fuel outlays, emissions, and economic externalities related to petroleum consumption and other factors.

Recognizing the uncertainty inherent in many of the underlying estimates in the model, NHTSA has used the Volpe model to conduct both sensitivity analyses, by changing one factor at a time, and a probabilistic uncertainty analysis (a Monte Carlo analysis that allows simultaneous variation in these factors) to examine how key measures (*e.g.*, mpg levels of the standard, total costs, and total benefits) vary in response to change in these factors. This type of analysis is used to estimate the uncertainty of the costs and benefits of a given set of CAFE standards.

The model can also be used to fit coefficients defining an attribute-based standard, and to estimate the stringency that either (a) maximizes net benefits to society, (b) achieves a specified stringency at which total costs equal total benefits, (c) imposes a specified average required CAFE level, or (d) results in a specified total incremental cost, *etc*. The agency uses this information from the Volpe model as a tool to assist in setting standards.

Although NHTSA has used the Volpe model as a tool to inform its consideration of potential CAFE standards, the Volpe model, alone, does not determine the CAFE standards NHTSA will propose or promulgate as final regulations. NHTSA considers the results of analyses conducted using the Volpe model and external analyses, including assessments of greenhouse gases and air pollution emissions, and technologies that may be available in the long term. NHTSA also considers whether the standards could expedite the introduction of new technologies into the market, and the extent to which changes in vehicle prices and fuel economy might affect vehicle production and sales. Using all of this information, the agency considers the governing statutory factors, along with environmental issues and other relevant societal issues, such as safety, and promulgates the maximum feasible standards based on its best judgment on how to balance these factors.

2.2.2 Input Scenarios

As noted in the public comments, there is a vast number of model input values that could be used to calculate costs and benefits of the alternatives, including, but not limited to, future fuel prices, the value of carbon dioxide emissions reductions (referred to as the social cost of carbon or SCC), the discount rate, and oil import externalities.[6,7] These model parameters are estimated forecasts of future economic conditions. These estimates are subject to uncertainty and debate, and as several commenters noted, the CAFE standards and resulting environmental impacts could depend on the choice of the economic assumptions utilized by the Volpe model. These commenters urged NHTSA to examine impacts under different input scenarios.

The sensitivity analysis reported in the Preliminary Regulatory Impact Analysis (PRIA) revealed changes in required fuel economy levels due to variations in the value of CO_2, oil import externalities, the rebound effect (the estimated increase in driving due to higher fuel economy standards), and higher fuel prices. In the DEIS, NHTSA addressed these concerns in Section 3.4.4.2, "Sensitivity Analysis."

[6] For further discussion of what constitutes "oil import externalities," *see* page 24410 of the Notice of Proposed Rulemaking, Average Fuel Economy Standards (NHTSA 2008b).
[7] Council on Environmental Quality (CEQ 1981) guidance instructs that "[w]hen there are potentially a very large number of alternatives, only a reasonable number of examples, covering the full spectrum of alternatives, must be analyzed and compared in the EIS" (emphasis in original).

In this FEIS, NHTSA further addresses these concerns by presenting analytical results for the alternatives under four model input scenarios: Reference Case, High Scenario, Mid-1 Scenario, and Mid-2 Scenario. The Reference Case uses the Energy Information Administration's (EIA's) reference case fuel price forecast ($2.41 per gallon) and a domestic SCC. The High Scenario uses the EIA high fuel price forecast ($3.33 per gallon) and a global SCC. The Reference Case value for oil import externalities ($0.326 per gallon) is higher than the High Scenario input value ($0.116 per gallon) due to higher fuel price and SCC values in the High Scenario. *See* Section 10.2.2.10 for a description of the components of the oil externality values. In analyzing the benefits of future CO_2 emissions reductions, the Reference Case, High Scenario, Mid-1 Scenario, and Mid-2 Scenario all employ a 3-percent discount rate. For non-CO_2 impacts, the High Scenario uses a 3-percent discount rate, while the Reference Case and Mid-1 and Mid-2 Scenarios use a 7-percent discount rate. *See* Table 2.3-1 for a list of the different input values used in the scenarios. Sections 3.4 and 4.4 describe in detail the environmental impacts of the Reference Case and High Scenario alternatives, and briefly discuss the impacts of the Mid-1 and Mid-2 Scenarios. Appendix B shows the full analysis results for the Mid-1 and Mid-2 Scenarios.

Table 2.2-1

Economic Model Input Scenarios

	Value of CO_2 (2007$/ton)	**Oil Import Externalities (2007$/gallon)**	**AEO 2008 a/ Fuel Price**	**Discount Rate**
Reference Case	$2.00 (Domestic)	$0.326	$2.41 (Reference)	3% CO_2 – 7% Other
Mid-2 Scenario	$2.00 (Domestic)	$0.382	$3.33 (High)	3% CO_2 – 7% Other
Mid-1 Scenario	$33.00 (Global)	$0.116	$3.33 (High)	3% CO_2 – 7% Other
High Scenario	$33.00 (Global)	$0.116	$3.33 (High)	3% CO_2 – 3% Other

a/ Both the Reference and High *Annual Energy Outlook* fuel price vary by year. Price shown is the average 2011-2030 price for gasoline expressed in 2007 dollars.

The analysis of costs and benefits employed in the Volpe model reflects NHTSA's current assessment of a broad range of technologies that can be applied to passenger cars and light trucks. NHTSA consulted with EPA to develop a list of fuel-saving technologies cost and effectiveness numbers for the NPRM and DEIS. EPA published the results of this collaboration in a report (EPA 2008h). A copy of the report and other studies used in the technology update was placed in the rulemaking docket.

2.2.3 Technology Assumptions

NHTSA specifically sought comment on the estimates, which it had developed jointly with EPA, of the availability, applicability, cost, and effectiveness of fuel-saving technologies, and the order in which the technologies were applied. *See* 73 *FR* 24352, 24367. While NHTSA asked manufacturers to submit such information in the request for product plans, the agency also conducted its own independent analysis of the all the comments and data – including comments and information from entities outside the automobile manufacturing community – received through the rulemaking process. This involved hiring an international engineering consulting firm that specializes in automotive engineering, and that was used by the EPA in developing its recent advance notice of proposed rulemaking to regulate greenhouse gas emissions under the Clean Air Act (CAA).[8]

[8] 73 *FR* 44354 (July 30, 2008).

NHTSA and its consultants undertook a thorough review of the NPRM technology assumptions and all comments received on those assumptions, based on both old and new public and confidential manufacturer information. NHTSA and its consultants reviewed and compared comments on the availability and applicability of technologies, and the logical progression between them. The agency also reviewed and compared the methodologies used for determining the costs and effectiveness of the technologies as well as the specific estimates provided. Relying on the expertise of its consultants and taking into consideration all the information available, NHTSA revised its estimates of the availability and applicability of many technologies, and revised its estimate of the order in which the technologies are applied. In addition, the agency and its consultant generally agreed with commenters who said that in several cases, the technology related costs used in the NPRM and DEIS were underestimated and benefits were overestimated. The agency also agreed with commenters that both sets of estimates were not well differentiated by vehicle class and that the technology decision trees needed to be expanded and refined. NHTSA used the revised technology and effectiveness estimates in analyzing all of the alternatives and scenarios presented in this FEIS. The agency believes that the representation of technologies—that is, estimates of the availability, applicability, cost, and effectiveness of fuel-saving technologies, and the order in which the technologies are applied—used in this action is the best available.

The technologies considered by the model are briefly described below, under the five broad categories of engine, transmission, vehicle, electrification/accessory, and hybrid technologies.

Types of engine technologies that were considered under the benefit-cost analysis include the following:

- *Low-friction lubricants* – reduce fuel consumption, and more advanced engine oils are now available with improved performance and better lubrication.

- *Reduction of engine friction losses* – can be achieved through low-tension piston rings, roller cam followers, improved material coatings, more optimal thermal management, piston surface treatments, and other improvements in the design of engine components and subsystems that improve engine operation and fuel economy, and reduce friction and emissions.

- *Conversion to dual overhead cam with dual cam phasing* – as applied to overhead valves designed to increase the air flow with more than two valves per cylinder and thermal efficiencies by reducing pumping losses.

- *Cylinder deactivation* – does not inject fuel into some cylinders during light-load operation, such as coasting, and when cruise control is activated. Active cylinders combust at almost double the load required if all cylinders are operating, with pumping losses substantially reduced so long as the engine is operated in this mode.

- *Variable valve timing* – alters the timing or phase of the intake valve, exhaust valve, or both, primarily to reduce pumping losses, increase specific power, and control residual gases.

- *Discrete variable valve lift* – reduces fuel consumption by improved air flow and thermal efficiency by pumping loss reduction. Accomplished by hydraulically controlled switching between two or more cam profile lobe heights.

- *Continuous variable valve lift* – is an electromechanically controlled system in which cam period and phasing is changed as lift height is controlled. This yields a wide range of performance optimization and combustion efficiency, including enabling the engine to be valve throttled.

- *Stoichiometric gasoline direct-injection technology* – injects fuel at high pressure directly into the combustion chamber to improve cooling of the air/fuel charge within the cylinder, which allows for higher compression ratios and increased thermodynamic efficiency.

- *Combustion restart* – can be used in conjunction with gasoline direct-injection systems to enable idle-off or start-stop functionality. Similar to other start-stop technologies, additional enablers, such as electric power steering, accessory drive components, and auxiliary oil pump, might be required.

- *Turbocharging and downsizing* – increases the available airflow and specific power level, allowing a reduced engine size while maintaining or improving performance. This reduces pumping losses at lighter loads in comparison to a larger engine, while reducing net friction losses.

- *Exhaust-gas recirculation boost* – increases the exhaust-gas recirculation used in the combustion process to increase thermal efficiency and reduce pumping losses. Might require additional enablers, such as intake manifold pressure monitoring.

- *Diesel engines* – have several characteristics that give superior fuel efficiency, including reduced pumping losses due to lack of (or greatly reduced) throttling, and a combustion cycle that operates at a higher compression ratio, with a very lean air/fuel mixture, than an equivalent-displacement gasoline engine. Might require additional enablers, such as NO_x trap catalyst after-treatment or selective catalytic reduction NO_x after-treatment.

Types of transmission technologies considered under the benefit-cost analysis include:

- *Improved automatic transmission controls and externals* – optimizes shift schedule to maximize fuel efficiency under wide ranging conditions, and minimizes losses associated with torque converter slip through lock-up or modulation.

- *Six-, seven-, and eight-speed automatic transmissions* – influence the width of gear ratio spacing and transmission ratio optimization available under different operating conditions, thereby offering greater engine optimization and higher fuel economy.

- *Dual clutch or automated shift manual transmissions* – are similar to conventional transmissions, but the vehicle controls shifting and launch functions. A dual-clutch automated shift manual transmission uses separate clutches for even-numbered and odd-numbered gears, so the next expected gear is pre-selected, which allows for faster and smoother shifting.

- *Continuously variable transmission* – commonly uses V-shaped pulleys connected by a metal belt rather than gears to provide ratios for operation. Unlike manual and automatic transmissions with fixed transmission ratios, continuously variable transmissions can provide fully variable transmission ratios with an infinite number of gears, enabling finer optimization of the transmission ratio under different operating conditions so that the powertrain can operate at its optimum efficiency.

- *Manual 6-speed transmission* – like automatic transmissions, increases the number of available ratios in a manual transmission to improve fuel economy by allowing the driver to select a ratio that optimizes engine operation at a given speed.

Types of vehicle technologies considered under the benefit-cost analysis include:

- *Low-rolling-resistance tires* – have characteristics that reduce frictional losses associated with the energy dissipated in the deformation of the tires under load, therefore improving fuel economy.

- *Low-drag brakes* – reduce the sliding friction of disc brake pads on rotors when the brakes are not engaged because the brake shoes are pulled away from the rotating drum.

- *Front or secondary axle disconnect for four-wheel drive systems* – provides a torque distribution disconnect between front and rear axles when torque is not required to the non-driving axle. This results in the reduction of associated parasitic energy losses, therefore improving fuel economy.

- *Aerodynamic drag reduction* – is achieved by changing vehicle shape or frontal area, including skirts, air dams, underbody covers, and more aerodynamic side view mirrors.

- *Material substitution* – encompasses a variety of techniques that include application of lighter-weight materials, higher-strength materials, component redesign, and size matching of components.

Types of electrification/accessory technologies considered under the benefit-cost analysis include:

- *Electric power steering* – is an electrically-powered, decoupled steering system that has advantages over traditional hydraulic power steering because it draws power only when required by the operator to steer the vehicle, which is only a small percentage of vehicle operating time.

- *Improved accessories* – the technology associated with an intelligent cooling system. This ignores other electrical accessories (electrical lubrication and electrical air conditioning), which might be present in full hybrid applications.

- *Higher-voltage, Improved alternator* – provides a mechanical-to-electrical power conversion for the numerous electrical load requirements of a vehicle. Traditionally, alternators are optimized for cost. Increased conversion efficiency alternators cost more, but result in less fuel required to power the electrical loads, thus improving vehicle fuel economy.

- *12-volt micro-hybrid* – commonly implemented as a 12-volt belt-driven integrated starter-generator, this is the most basic hybrid system that facilitates idle-stop capability. Along with other enablers, this system replaces a common alternator with an enhanced power starter-alternator, both belt driven, and a unique accessory drive system.

- *Integrated starter generator* – is similar to the 12-volt micro-hybrid in function and design, except that it uses a 110- to 144-volt battery that contains greater battery capacity and maintains a smaller electric machine than other hybrid electric vehicle designs. Along with other enablers, this system replaces a common alternator with an enhanced power starter-alternator, either accessory belt driven or crank mounted, with a generator for recovering energy while slowing down.

Types of hybrid technologies considered under the benefit-cost analysis include:

- *2-mode hybrid* – is a full hybrid system that uses an adaptation of a conventional stepped-ratio automatic transmission by replacing some of the transmission clutches with two electric motors that control the ratio of engine speed to vehicle speed, while clutches allow the motors to be bypassed, which improves both the transmission torque capacity for heavy-duty applications and fuel economy at highway speeds.

- *Power-split hybrids* – is a full hybrid system that replaces the vehicle's transmission with a single planetary gear and a motor/generator. This motor/generator uses its engine torque to either charge the battery or supply additional power to the drive motor. A second, more powerful motor/generator, is permanently connected to the vehicle's final drive and always turns with the wheels. The planetary gear splits the engine's torque between the first motor/generator and the drive motor to either charge the battery or supply power to the wheels.

- *Plug-in hybrid electric vehicles* – are vehicles with the means to charge the battery packs from an outside source of electricity (usually the electric grid). These vehicles have larger battery packs with more energy storage and a greater capability to be discharged and have a control system that allows the battery pack to be substantially depleted under electric-only operation.

2.2.4 FEIS Analytical Improvements

A number of changes occurred from the NPRM and DEIS that provide analytical improvements in this FEIS. These changes explain why the CAFE levels, fuel savings, and CO_2 emissions that are attributable to each alternative and scenario in this FEIS differ from those presented in the NPRM and DEIS.

As discussed in the NPRM and the DEIS, the agency requested new product plans from manufacturers for analyzing alternative standards for the final rule. The product plans submitted in May 2007 did not take into consideration the passage of EISA and the minimum 35 mpg combined fleet requirement by 2020. In addition, during that time, the fuel prices rose substantially. The new product plans reflect those new realities in the following ways:

- Companies provided product plans that implemented some of the cost effective technologies that the agency had projected in the NPRM. This increased the baseline against which the fuel saving from the standards is measured. Some of the savings and CO_2 emission reductions attributed in the NPRM to the rulemaking action must now be attributed to improved product plans.

- The size of the overall fleet has declined from the time of the NPRM to the final rule resulting in less vehicle miles traveled.

In the NPRM, the two-wheel drive vehicles were classified in the same way they were classified by their manufacturers in their May 2007 product plans. For the purposes of this analysis and the final rule, however, they were reclassified in accordance with the discussion in the NPRM of the proper classification of those vehicles. This resulted in the shifting of slightly over one million two-wheel drive vehicles from the truck fleet to the car fleet, which lowers average car mpg due to the inclusion of vehicles previously categorized as trucks, and lowers truck mpg because the truck category now has a larger proportion of heavier trucks. Following our careful consideration of the public comments on that discussion, we reaffirm the reasoning and conclusions of that discussion.

As discussed in Section 2.2.3, NHTSA also revised the technology assumptions proposed in the NPRM based on comments and new information received during the comment period and used those assumptions for analyzing alternatives and scenarios for the FEIS and final rule. In several cases, the costs in the NPRM and DEIS were underestimated and benefits overestimated, and in most cases, these estimates were not well differentiated by vehicle class. The agency also revised its phase-in schedule of the technologies to account for lead time.

The agency, working with other agencies of the U.S. government, also updated its estimates of the domestic and global values of the SCC as well as estimates for other externalities based on comments and updated information received during the comment period. Specifically, this FEIS uses a domestic SCC of $2, which is lower than the DEIS/NPRM SCC of $7.00, but a higher global SCC at $33 as compared to $14 used in the NPRM and DEIS. These are discussed in greater detail in Chapter 10 Responses to Public Comments.

2.3 ALTERNATIVES

EPCA, as amended by EISA, requires attribute-based fuel economy standards for passenger cars and light trucks. NHTSA first employed this Reformed CAFE approach in establishing standards for MY 2008-2011 light trucks.[9] In May 2008, NHTSA proposed separate standards for MY 2011-2015 passenger cars and light trucks, again using this approach.[10] The alterations reflect the agency's best assessment based on the comments received and analyzed. Under the standards, fuel economy targets are established for vehicles of different sizes. Each manufacturer's required level of CAFE is based on its distribution of vehicles among those sizes and the fuel economy target required for each size. Size is defined by vehicle footprint.[11] The fuel economy target for each footprint reflects the technological and economic capabilities of the industry. These targets are the same for all manufacturers, regardless of the differences in their overall fleet mix. Compliance is determined by comparing a manufacturer's harmonically averaged fleet fuel economy levels in a model year with an average required fuel economy level calculated using the manufacturer's actual production levels and the targets for each footprint of the vehicles that it produces.

A large number of alternatives can be defined along a continuum from the least to the most stringent levels of CAFE. The specific alternatives NHTSA examined, described below, were selected to illustrate estimated costs and benefits. The fuel economy levels associated with the alternatives encompass a reasonable range to evaluate the potential environmental impacts of the CAFE standards and alternatives under NEPA, in view of EPCA requirements.

[9] *See* Average Fuel Economy Standards for Light Trucks, Model Years 2008-2011, 71 *FR* 17566, 17587-17625, April 6, 2006 (describing that approach).
[10] The proposed standards include light truck standards for one model year (MY 2011) that were previously covered by a 2006 final rule, Average Fuel Economy Standards for Light Trucks, Model Years 2008-2011, 71 *FR* 17566, April 6, 2006.
[11] A vehicle's footprint is generally defined as "the product of track width [the lateral distance between the centerlines of the base tires at ground, including the camber angle] … times wheelbase [the longitudinal distance between front and rear wheel centerlines] … divided by 144 …." 49 CFR § 523.2.

At one end of this range is the No Action Alternative (Alternative 1), which assumes that NHTSA would not issue a rule regarding CAFE standards. The No Action Alternative also assumes that average fuel economy levels in the absence of CAFE standards beyond 2010 would equal the higher of a manufacturer's product plans or the manufacturer's required level of average fuel economy for MY 2010. Costs and benefits of other alternatives are calculated relative to the baseline of the No Action Alternative. The No Action Alternative, by definition, would yield no incremental costs or benefits (and it would not satisfy the EPCA requirement to set standards such that the combined fleet achieves a combined average fuel economy of at least 35 mpg for MY 2020).

At the other end of the range of possible alternatives is the Technology Exhaustion Alternative (Alternative 7). This alternative would require every manufacturer to apply the maximum technology expected to be available over the period necessary to meet the statutory goals of EPCA, as amended by the EISA, without consideration of the accompanying costs. By definition, this alternative would apply all known technologies by make and model in the manufacturers' product plans while recognizing constraints associated with vehicle manufacturing and design cycles. It produces a CAFE standard that requires the use of technologies where costs exceed benefits. (*See* the NPRM for additional details on how the agency arrives at a CAFE standard, after application of the Volpe model).

NHTSA has examined five alternatives that fall between the extremes of the No Action Alternative and the Technology Exhaustion Alternative as defined below. Table 2.3-1 shows the estimated fuel economy levels for each alternative under the Reference Case.

Table 2.3-1

Reference Case Alternative CAFE Standards
MY 2015 Required MPG

	Alt. 1	Alt. 2	Alt. 3	Alt. 4	Alt. 5	Alt. 6	Alt. 7
	No Action	**25% Below Optimized**	**Optimized**	**25% Above Optimized**	**50% Above Optimized**	**Total Costs Equal Total Benefits**	**Technology Exhaustion**
Passenger Cars	27.5	33.3	33.4	33.5	33.7	33.9	47.1
Light Trucks	23.4	25.8	26.0	26.2	26.5	27.0	37.2

Analyzing the environmental impacts of these alternatives provides information on the full spectrum of CAFE choices reasonably available to the decisionmaker. Although NEPA requires – and this FEIS analyzes – a full spectrum of alternatives, EPCA contains additional requirements and factors that NHTSA must apply in setting "maximum feasible" CAFE standards: (1) technological feasibility, (2) economic practicability, (3) the effect of other motor vehicle standards of the government on fuel economy, and (4) the need of the Nation to conserve energy.

Table 2.2-1 shows model input values for the SCC, the value of oil import externalities, fuel prices, and the discount rate for the Reference Case, High Scenario, and two intermediate scenarios – Mid-1 and Mid-2. Tables 2.3-2 and 2.3-3 show how the specific mpg standards associated with each of the seven alternatives vary across the Reference Case and the three Input Scenarios for cars and for light trucks, respectively. Table 2.3-4 shows the combined fuel economy standards for cars and light trucks for the seven alternatives for the Reference Case and the three Input Scenarios. These are the combined average fuel economy levels that would occur if each manufacturer exactly met its obligations under these standards.[12]

Table 2.3-2

MY 2015 Required MPG for Passenger Cars by Alternative and Model Input Scenario

	Alt. 1	Alt. 2	Alt. 3	Alt. 4	Alt. 5	Alt. 6	Alt. 7
Input Scenario	**No Action**	**25% Below Optimized**	**Optimized**	**25% Above Optimized**	**50% Above Optimized**	**Total Costs Equal Total Benefits**	**Technology Exhaustion**
Reference Case	27.5	33.3	33.4	33.5	33.7	33.9	47.1
Mid-2 Scenario	27.5	36.7	37.1	37.5	37.9	38.7	47.1
Mid-1 Scenario	27.5	36.7	37.2	37.8	38.3	39.3	47.1
High Scenario	27.5	37.2	37.7	38.2	38.8	39.8	47.1

Table 2.3-3

MY 2015 Required MPG for Light Trucks by Alternative and Model Input Scenario

	Alt. 1	Alt. 2	Alt. 3	Alt. 4	Alt. 5	Alt. 6	Alt. 7
Input Scenario	**No Action**	**25% Below Optimized**	**Optimized**	**25% Above Optimized**	**50% Above Optimized**	**Total Costs Equal Total Benefits**	**Technology Exhaustion**
Reference Case	23.4	25.8	26.0	26.2	26.5	27.0	37.2
Mid-2 Scenario	23.4	26.2	27.1	27.9	28.8	30.6	37.2
Mid-1 Scenario	23.4	29.3	29.6	29.9	30.2	30.8	37.2
High Scenario	23.4	28.9	29.6	30.3	31.0	32.3	37.2

Table 2.3-4

MY 2015 Required MPG for Passenger Cars and Light Trucks by Alternative and Model Input Scenario

	Alt. 1	Alt. 2	Alt. 3	Alt. 4	Alt. 5	Alt. 6	Alt. 7
Input Scenario	**No Action**	**25% Below Optimized**	**Optimized**	**25% Above Optimized**	**50% Above Optimized**	**Total Costs Equal Total Benefits**	**Technology Exhaustion**
Reference Case	25.5	29.4	29.6	29.8	30.0	30.4	42.0
Mid-2 Scenario	25.5	31.1	31.8	32.5	33.2	34.6	42.0
Mid-1 Scenario	25.5	32.9	33.3	33.8	34.2	35.0	42.0
High Scenario	25.5	32.9	33.6	34.2	34.8	36.0	42.0

Tables 2.3-2 through 2.3-4 show that the estimated fuel economies under the No Action and Technology Exhaustion Alternatives are the same for the Reference Case and the three Input Scenarios. Therefore, environmental impacts for the Reference Case and the three Input Scenarios fall between the impacts of the No Action Alternative and the Technology Exhaustion Alternative.

[12] NHTSA notes that the precise level of CAFE that each manufacturer will be required to meet will be determined after the manufacturers submit final production and fleet mix figures at the end of each model year in question.

2.3.1 Preferred Alternative

The agency's Preferred Alternative is the Optimized Alternative, the level at which marginal costs equal marginal benefits. For any set of economic assumption model inputs, the Optimized Alternative yields the greatest net benefits. As fuel economy standards are increased beyond this level, manufacturers would need to apply technologies that entail higher incremental costs than benefits, thereby reducing net benefits. This alternative is described in more detail in Section 2.3.4. Table 2.2-1 lists the inputs (social cost of carbon, oil import externalities, fuel price, and discount rate) for the Reference Case and the Mid-1, Mid-2, and High Scenarios. The required fuel economy levels (combined for cars and light trucks) for the Optimized Alternative can be found in Table 2.3-4.

2.3.2 Alternative 1: No Action

The No Action Alternative assumes that NHTSA would not issue a rule regarding CAFE standards. The No Action Alternative assumes that average fuel economy levels in the absence of CAFE standards beyond 2010 would equal the higher of a manufacturer's product plans or the manufacturer's required level of average fuel economy for MY 2010. The MY 2011 fuel economy in mpg (27.5 mpg and 23.3 mpg for passenger cars and light trucks, respectively) represents the standard the agency believes manufacturers would continue to achieve, assuming that the agency does not issue a rule.[13] The No Action Alternative will yield different levels of impacts under the Reference Case and the Input Scenarios, as the Input Scenarios include the high values for fuel price. Relatively higher fuel prices serve to dampen future VMT growth and result in less fuel consumption and greenhouse gases. The air quality emissions analysis would also be different because it relies on VMT estimates and the amount of fuel produced.

NEPA requires agencies to consider a No Action Alternative in their NEPA analyses (*see* 40 CFR § 1502.14(b)), although the recent amendments to EPCA direct NHTSA to set new CAFE standards and do not permit the agency to take no action on fuel economy. In the NPRM, NHTSA refers to the No Action Alternative as the no increase or baseline alternative.

2.3.3 Alternative 2: 25 Percent Below Optimized

This alternative reflects standards that are more stringent than the No Action Alternative but less stringent than the Optimized Alternative (Alternative 3). Alternative 2 is less stringent than the Optimized Alternative by 25 percent of the difference in fuel economy between the Optimized Alternative and Alternative 6 (Total Costs Equal Total Benefits). This alternative falls below the Optimized Alternative by the same absolute amount by which the 25 Percent Above Optimized Alternative exceeds the Optimized Alternative.

As shown for passenger cars, the average required fuel economy in mpg for the industry in MY 2015 would range from 33.3 mpg for the Reference Case to 37.2 for the High Scenario. For light trucks, the average required fuel economy in mpg for the industry in MY 2015 would range from 25.8 mpg for the Reference Case to 28.9 for the High Scenario. The combined industry-wide average fuel economy for all passenger cars and light trucks would range from 29.4 mpg for the Reference Case to 32.9 for the High Scenario.

[13] *See* 40 CFR §§ 1502.2(e) and 1502.14(d).

2.3.4 Alternative 3: Optimized

The Optimized Alternative, which applies technologies until marginal benefits equal marginal costs and net benefits are maximized, is NHTSA's Preferred Alternative. For any set of economic assumption model inputs, the Optimized Alternative yields the greatest net benefits. As fuel economy standards are increased beyond this level, manufacturers would need to apply technologies that entail higher incremental costs than benefits, thereby reducing net benefits.

As shown for passenger cars, the average required fuel economy for the industry in MY 2015 would range from 33.4 mpg for the Reference Case to 37.7 for the High Scenario. For light trucks, the average required fuel economy for the industry in MY 2015 would range from 26.0 mpg for the Reference Case to 29.6 for the High Scenario. In MY 2015, the combined industry-wide average fuel economy for all passenger cars and light trucks would range from 29.6 mpg for the Reference Case to 33.6 for the High Scenario.

2.3.5 Alternative 4: 25 Percent Above Optimized

This alternative reflects standards that increase the fuel economy levels of the Optimized Alternative by 25 percent of the difference between the Optimized and the Total Costs Equal Total Benefits Alternative fuel economy levels.

As shown for passenger cars, the average required fuel economy in mpg for the industry in MY 2015 would range from 33.5 mpg for the Reference Case to 38.2 for the High Scenario. For light trucks, the average required fuel economy for the industry in MY 2015 would range from 26.2 mpg for the Reference Case to 30.3 for the High Scenario. In MY 2015, the combined industry-wide average fuel economy for all passenger cars and light trucks would range from 29.8 mpg for the Reference Case to 34.2 for the High Scenario.

2.3.6 Alternative 5: 50 Percent Above Optimized

This alternative reflects standards that increase the fuel economy levels to the Optimized Alternative level by 50 percent of the difference between the Optimized and the Total Costs Equal Total Benefits Alternative fuel economy levels.

As shown for passenger cars, the average required fuel economy for the industry in MY 2015 would range from 33.7 mpg for the Reference Case to 38.8 for the High Scenario. For light trucks, the average required fuel economy or the industry in MY 2015 would range from 26.5 mpg for the Reference Case to 31.0 for the High Scenario. In MY 2015, the combined industry-wide average fuel economy for all passenger cars and light trucks would range from 30.0 mpg for the Reference Case to 34.8 for the High Scenario.

2.3.7 Alternative 6: Total Costs Equal Total Benefits

This alternative reflects standards based on applying technologies until total costs equal total benefits. It results in zero net benefits because the benefits to society are completely offset by the costs. This is known as the Total Costs Equal Total Benefits Alternative.

As shown for passenger cars, the average required fuel economy for the industry in MY 2015 would range from 33.9 mpg for the Reference Case to 39.8 for the High Scenario. For light trucks, the average required fuel economy for the industry in MY 2015 would range from 27.0 mpg for the Reference Case to 32.3 for the High Scenario. In MY 2015, the combined industry-wide average fuel economy for all passenger cars and light trucks would range from 30.4 mpg for the Reference Case to 36.0 for the High Scenario.

2.3.8 Alternative 7: Technology Exhaustion

NHTSA developed the Technology Exhaustion Alternative by progressively increasing the stringency of the standard in each model year until every manufacturer (among those without a history of paying civil penalties) exhausted technologies estimated to be available during MY 2011-2015. Except for phase-in constraints, this analysis was performed using the same technology-related estimates (*e.g.*, incremental costs, incremental fuel savings, availability, applicability, and dependency on vehicle freshening and redesign) as used for other alternatives, such as those that maximize net benefits and those that produce total benefits approximately equal to total costs. For the Technology Exhaustion Alternative, NHTSA removed phase-in constraints in order to develop an estimate of the effects of fuel economy increases that might be achieved if manufacturers could apply as much technology as theoretically possible, while recognizing that some technologies must still be installed as part of a vehicle freshening or redesign.

In each year, NHTSA increased the stringency until the first manufacturer exhausted available technologies; beyond this stringency, NHTSA estimated that the manufacturer would be unable to comply (NHTSA is precluded from considering manufacturers' ability to use CAFE credits) and would be forced to pay civil penalties. NHTSA then increased the stringency until the next manufacturer was unable to comply, and continued to increase the stringency of the standard until every manufacturer was unable to apply enough technology to comply.

For passenger cars, the average required fuel economy for the industry would be 47.1 mpg in MY 2015 and 37.2 mpg for light trucks in MY 2015. The combined industry-wide average fuel economy for all passenger cars and light trucks would be 42.0 mpg in MY 2015.

2.4 ALTERNATIVES CONSIDERED BUT NOT ANALYZED IN DETAIL

As a result of the scoping and DEIS comment process, several suggestions were made to NHTSA regarding alternatives that should be included in this DEIS and examined in detail. NHTSA considered these alternatives and discusses them below along with the reasons why we believe these referenced alternatives do not warrant further analysis in this FEIS.

- **Downweighting Vehicles.** NHTSA was requested by commenters to consider as an alternative in the FEIS the potential for increased fuel economy by replacing heavy materials in passenger cars with lighter materials; a practice known as downweighting. As discussed in Chapter 1 and the NPRM, NHTSA's analysis does include the potential to improve fuel economy through greater utilization of lightweight materials on heavier vehicles, for which doing so would be unlikely to compromise highway safety. This request relates to specific technology choices (which CAFE standards do not require) rather than regulatory alternatives. Consequently, this comment does not warrant analysis of an additional alternative within the FEIS.

- **Least Capable Manufacturer Approach.** NHTSA's earlier Unreformed CAFE standards specified a "one size fits all" (uniform) level of CAFE that applied to each manufacturer and that was set with particular regard to the lowest projected level of CAFE among the manufacturers that have a substantial share of the market. The major manufacturer with the lowest projected CAFE level is typically known as the "least capable" manufacturer. However, NHTSA's 2006 CAFE standards for light trucks adopted a different Reformed

CAFE approach (71 *FR* 17566, April 6, 2006). EISA recently codified that approach, requiring that all CAFE standards be based on one or more vehicle attributes (49 U.S.C. § 32902(b)(3)(A); 73 *FR* 24352, 24354-24355, May 2, 2008) (discussing NHTSA's proposal to base CAFE standards on the attribute of vehicle size, as defined by vehicle footprint).

As NHTSA explained when proposing Reformed CAFE standards for MY 2008-2011 light trucks, "[u]nder Reformed CAFE, it is unnecessary to set standards with particular regard to the capabilities of a single manufacturer in order to ensure that the standards are technologically feasible and economically practicable for all manufacturers with a substantial share of the market. This is true both fleet-wide and within any individual category of vehicles" (70 *FR* 51414, 51432, August 30, 2005). Specifically:

> There is no need under Reformed CAFE to set the standards with particular regard to the capabilities of the "least capable" manufacturer. Indeed, it would often be difficult to identify which manufacturer should be deemed the "least capable" manufacturer under Reformed CAFE. The "least capable" manufacturer approach was simply a way of implementing the guidance in the conference report (part of EPCA's legislative history)[14] in the specific context of Unreformed CAFE….
>
> …The very structure of Reformed CAFE standards makes it unnecessary to continue to use that particular approach in order to be responsive to guidance in the conference report. Instead of specifying a common level of CAFE, a Reformed CAFE standard specifies a variable level of CAFE that changes based on the production mix of each manufacturer. By basing the level required for an individual manufacturer on that manufacturer's own mix, a Reformed CAFE standard in effect recognizes and accommodates differences in production mix between full- and part-line manufacturers, and between manufacturers that concentrate on small vehicles and those that concentrate on large ones.
>
> There is an additional reason for ceasing to use the "least capable" manufacturer approach. There would be relatively limited added fuel savings under Reformed CAFE if we continued to use the "least capable" manufacturer approach even though there ceased to be a need to use it…." (70 *FR* 51433, August 30, 2005).

In addition, the commenter's suggested approach would not result in the increases in fuel economy mandated by EISA – namely, 35 mpg by MY 2020. In light of the fact that Congress recently codified the Reformed CAFE approach for both passenger cars and light trucks, and for all of the reasons stated above, NHTSA declines to consider in detail an alternative tied to the historic "least capable manufacturer" approach as the commenter suggested.

2.5 COMPARISON OF ALTERNATIVES

The CEQ NEPA regulations (40 CFR Part 1500.2(e)) direct federal agencies to use the NEPA process to identify and assess the reasonable alternatives to proposed actions that would avoid or minimize adverse effects of these actions upon the quality of the human environment. CEQ regulations (40 CFR 1502.14) state:

[14] *See* 70 *FR* 51414, 51425-51426, August 30, 2005 (discussing the conference report).

> Based on the information and analysis presented in the sections on the Affected Environment (Sec. 1502.15) and the Environmental Consequences (Sec. 1502.16), it [an EIS] should present the environmental impacts of the proposal and the alternatives in comparative form, thus sharply defining the issues and providing a clear basis for choice among options by the decisionmaker and the public.

This section summarizes the direct, indirect, and cumulative effects of the CAFE alternatives on energy, air quality, and climate. No quantifiable, alternative-specific effects were identified for the other resources discussed in Chapters 3 and 4. Refer to the text in Chapter 4 for qualitative discussions of the potential direct and indirect effects of the alternatives on these other resources. Reductions in fuel consumption are demonstrated for all the alternatives in Section 3.2 and 4.2. Emissions of criteria pollutants and mobile source air toxics generally show reductions although carbon monoxide emissions increase slightly under some of the alternatives. *See* Section 3.3 and 4.3. Although the alternatives have the potential to substantially decrease GHG emissions, they do not prevent climate change from occurring, but only result in reductions of less than 1 percent in the anticipated increases in CO_2 concentrations, temperature, precipitation, and sea level. As discussed below, NHTSA's presumption is that these reductions in climate effects will be reflected in reduced impacts on affected resources. The resources addressed in Chapter 4 of the FEIS include freshwater resources, terrestrial ecosystems, coastal ecosystems, land use, and human heath. However, the magnitudes of the changes in these climate effects that the alternatives produce – a few parts per million (ppm) of CO_2, one-hundredth of a degree Celsius (°C) difference in temperature, a small percentage change in the rate of precipitation increase, and 1 or 2 millimeters (mm) of sea level – are too small to address quantitatively in terms of their impacts on resources. Given the enormous resource values at stake, these distinctions may be important – very small percentages of huge numbers can still yield measurable results – but they are too small for current quantitative techniques to resolve. Consequently, the discussion of resource impacts does not distinguish among the CAFE alternatives, but rather provides a qualitative review of the benefits of reducing GHG emissions and the magnitude of the risks involved in climate change. Thus, there are no differences in resource impacts to report in this comparison of the alternatives.

To illustrate how different economic assumptions could affect estimates of fuel consumption, emissions reductions, and resulting health and climate effects, NHTSA examined four model input scenarios: Reference Case, High Scenario, Mid-1 Scenario, and Mid-2 Scenario. Table 2.2-1 shows the key input assumptions for these four scenarios. This section examines direct and indirect effects and cumulative effects on energy, air quality, and climate, across alternatives for the Reference Case and the High Scenario. Specific methodologies are discussed in Chapters 3 and 4, and corresponding results for the Mid-1 and Mid-2 Scenarios are presented in Appendix B.

2.5.1 Direct and Indirect Effects

2.5.1.1 Energy

President George W. Bush signed the EISA on December 17, 2007. In his signing statement, he reiterated his 2007 State of the Union goal to reduce car and light truck fuel consumption by 20 percent over 10 years. Consistent with the President's goals, EISA requires an industry-wide combined average fuel economy through vehicle and fuel standards of at least 35 miles per gallon by 2020, saving billions of gallons of fuel and also fulfilling a U.S. promise to reduce national greenhouse gas emissions.

Under NEPA, direct effects "are caused by the action and occur at the same time and place" (40 CFR 1508.8). CEQ regulations define indirect effects as those that "are caused by the action and are later in time or father removed in distance but are still reasonably foreseeable. Indirect effects may include …

effects on air and water and other natural systems, including ecosystems" (40 CFR 1508.8). Below is a description of the direct and indirect effects of the CAFE alternatives on energy, air quality, and climate.

2.5.1.1.1 Reference Case

Table 2.5-1 shows the impact on fuel consumption for passenger cars and light trucks from 2020 through 2060, a period in which an increasing volume of the fleet will be MY 2011-2015 passenger cars. The table shows total fuel consumption (both gasoline and diesel) under the No Action Alternative and the six other alternatives. Fuel consumption under the No Action Alternative is 264.9 billion gallons in 2060. Consumption falls to 256.3 billion gallons under the Optimized Alternative (Alternative 3) and falls to 214.3 billion gallons under the Technology Exhaustion Alternative (Alternative 7).

Table 2.5-1

Reference Case Passenger Car and Light Truck Annual Fuel Consumption and Fuel Savings (billion gallons)

	Alternative CAFE Standards for Model Years 2011-2015						
	Alt. 1	Alt. 2	Alt. 3	Alt. 4	Alt. 5	Alt. 6	Alt. 7
Calendar Year	No Action	25% Below Optimized	Optimized	25% Above Optimized	50% Above Optimized	Total Cost Equal Total Benefit	Technology Exhaustion
Passenger Cars and Light Trucks Annual Fuel Consumption (billion gallons)							
2020	151.8	149.4	149.2	148.7	148.4	147.8	134.9
2030	172.4	167.7	167.2	166.5	165.8	164.9	141.8
2040	198.5	192.8	192.1	191.3	190.4	189.3	161.1
2050	229.7	222.9	222.2	221.2	220.1	218.7	185.9
2060	264.9	257.1	256.3	255.1	253.8	252.3	214.3
Passenger Cars and Light Trucks Annual Fuel Savings from No Action (billion gallons)							
2020	--	2.4	2.6	3.1	3.4	3.9	16.9
2030	--	4.7	5.2	5.8	6.6	7.5	30.5
2040	--	5.8	6.4	7.2	8.2	9.2	37.4
2050	--	6.8	7.4	8.5	9.5	10.8	43.8
2060	--	7.8	8.6	9.7	11.0	12.5	50.5

2.5.1.1.2 High Scenario

Table 2.5-2 lists the impact on fuel consumption under the High Scenario in the Volpe model for passenger cars and light trucks from 2020 through 2060. The High Scenario uses the economic inputs presented in Table 2.2-1. The table lists total fuel consumption for passenger cars and light trucks, both gasoline and diesel, under the No Action Alternative and the six alternative CAFE standards. The No Action Alternative in the High Scenario reflects a higher fuel price input than in the Reference Case, resulting in lower fuel consumption with no regulatory action by 2060, when the entire fleet is likely to be composed of MY 2011 or later cars, fuel consumption reaches 230.8 billion gallons. With the assumption of higher fuel prices, lower consumption is also expected across the alternatives. Consumption totals 210.2 billion gallons under the Optimized Alternative in 2060, as opposed to 256.3 billion gallons under the Optimized Alternative in the Reference Case.

Table 2.5-2

High Scenario Passenger Car and Light Truck Annual Fuel Consumption and Fuel Savings (billion gallons)

	Alternative CAFE Standards for Model Years 2011-2015						
	Alt. 1	**Alt. 2**	**Alt. 3**	**Alt. 4**	**Alt. 5**	**Alt. 6**	**Alt. 7**

Passenger Cars and Light Trucks Annual Fuel Consumption (billion gallons)							
2020	139.1	133.4	132.4	131.4	130.5	129.6	123.7
2030	155.4	144.4	142.6	140.8	139.5	138.2	127.8
2040	177.2	163.7	161.6	159.5	157.7	156.3	143.8
2050	202.6	187.0	184.6	182.1	180.1	178.5	164.0
2060	230.8	213.0	210.2	207.4	205.1	203.1	186.7
Passenger Cars and Light Trucks Annual Fuel Savings from No Action (billion gallons)							
2020	--	5.6	6.7	7.8	8.6	9.4	15.5
2030	--	11.0	12.8	14.6	15.9	17.2	27.5
2040	--	13.5	15.6	17.8	19.4	20.9	33.4
2050	--	15.5	18.0	20.6	22.5	24.2	38.6
2060	--	17.8	20.6	23.4	25.6	27.6	44.1

2.5.1.2 Air Quality

2.5.1.2.1 Reference Case

Table 2.5-3 summarizes the total national criteria and air toxic pollutant emissions in 2035[15] for the seven alternatives under the Reference Case, left to right in order of increasing fuel economy requirements. Under the Reference Case, the No Action Alternative has the highest emissions of all the alternatives for NO_x, $PM_{2.5}$, SO_x, VOCs, acetaldehyde, 1,3-butadiene, and diesel particulate matter. Alternative 3 has the highest emissions of all the alternatives for CO_2 and benzene. Alternative 7 has the highest emissions of all the alternatives for acrolein and formaldehyde.

Localized increases in criteria and toxic air pollutant emissions could occur in some nonattainment areas as a result of implementation of the CAFE standards under the action alternatives. These localized increases represent a slight decline in the rate of reductions being achieved by implementation of Clean Air Act standards. All of the action alternatives would reduce adverse health outcomes and health costs related to motor vehicle air pollution, and thus would have beneficial health effects that would not need mitigation.

2.5.1.2.2 High Scenario

Table 2.5-4 summarizes the national criteria and air toxic pollutant emissions in 2035 for the seven alternatives for the High Scenario. For the High Scenario, emissions with the action alternatives are generally lower than under the Reference Case.

[15] NHTSA uses 2035 as the latest projection year because by 2035 almost all passenger cars and light trucks in operation would meet at least the MY 2011-2015 standards and the impact of the standards would start to come only from VMT growth rather than further tightening of the standards. NHTSA believes the year 2035 is a practical maximum for impacts of criteria and toxic air pollutants to be considered reasonably foreseeable rather than speculative.

Table 2.5-3

Reference Case Alternative CAFE Standards Nationwide Criteria Pollutant Emissions and Toxic Air Pollutant Emissions from Passenger Cars and Light Trucks (tons/year) (Calendar Year 2035)

	Alt. 1	Alt. 2	Alt. 3	Alt. 4	Alt. 5	Alt. 6	Alt. 7
	No Action	25% Below Optimized	Optimized	25% Above Optimized	50% Above Optimized	Total Costs Equal Total Benefits	Technology Exhaustion
Criteria Pollutant Emissions (tons/year) for Passenger Cars and Light Trucks (Calendar Year 2035)							
Carbon monoxide (CO)	19,745,847	19,809,449	19,866,650	19,460,737	19,411,428	19,219,623	11,050,380

Acetaldehyde	8,209	8,206	8,208	8,198	8,197	8,165	7,733
Acrolein	351	354	353	367	369	378	720
Benzene	47,515	47,428	47,517	46,703	46,570	46,154	29,324
1,3-butadiene	3,885	3,834	3,834	3,818	3,815	3,781	3,231
Diesel particulate matter (DPM)	119,499	116,161	115,786	115,400	114,858	114,592	104,644
Formaldehyde	13,035	12,949	12,915	13,122	13,142	13,169	16,745

Table 2.5-4

High Scenario Alternative CAFE Standards Nationwide Criteria Pollutant Emissions and Toxic Air Pollutant Emissions from Passenger Cars and Light Trucks (tons/year) (Calendar Year 2035)

	Alt. 1	Alt. 2	Alt. 3	Alt. 4	Alt. 5	Alt. 6	Alt. 7
	No Action	25% Below Optimized	Optimized	25% Above Optimized	50% Above Optimized	Total Costs Equal Total Benefits	Technology Exhaustion
Criteria Pollutant Emissions (tons/year) for Passenger Cars and Light Trucks (Calendar Year 2035)							
Carbon monoxide (CO)	17,713,991	16,946,492	17,052,955	16,475,978	16,127,830	15,629,753	9,913,291
Nitrogen oxides (NO_x)	1,228,251	1,181,455	1,180,414	1,159,073	1,146,599	1,129,532	949,127
Particulate matter ($PM_{2.5}$)	89,447	86,654	86,251	86,389	85,756	85,318	81,727
Sulfur oxides (SO_x)	238,442	221,475	219,361	215,533	212,881	209,978	182,153
Volatile organic compounds (VOCs)	1,709,979	1,620,442	1,621,526	1,572,211	1,546,659	1,507,558	1,081,653

Table 2.5-4 (cont'd)

High Scenario Alternative CAFE Standards Nationwide Criteria Pollutant Emissions and Toxic Air Pollutant Emissions from Passenger Cars and Light Trucks (tons/year) (Calendar Year 2035)

	Alt. 1	Alt. 2	Alt. 3	Alt. 4	Alt. 5	Alt. 6	Alt. 7
	No Action	25% Below Optimized	Optimized	25% Above Optimized	50% Above Optimized	Total Costs Equal Total Benefits	Technology Exhaustion
Toxic Air Pollutant Emissions (tons/year) for Passenger Cars and Light Trucks (Calendar Year 2035)							
Acetaldehyde	7,364	7,318	7,326	7,244	7,239	7,211	6,938
Acrolein	315	356	353	379	393	412	646
Benzene	42,626	40,639	40,753	39,588	38,860	37,822	26,306
1,3-butadiene	3,885	3,815	3,821	3,790	3,754	3,709	3,231
Diesel particulate matter (DPM)	107,203	99,856	98,495	98,385	97,499	96,932	93,876
Formaldehyde	11,694	11,933	11,878	12,000	12,178	12,394	15,022

Localized increases in criteria and toxic air pollutant emissions could occur in some nonattainment areas as a result of implementation of the CAFE standards under the action alternatives. These localized increases represent a slight decline in the rate of reductions being achieved by implementation of Clean Air Act standards. All of the action alternatives would reduce adverse health outcomes and health costs related to motor vehicle air pollution, and thus would have beneficial health effects that would not need mitigation.

2.5.1.3 Climate

2.5.1.3.1 Reference Case

GHG Emissions

Table 2.5-5 shows total emissions and emissions reductions from new passenger cars and light trucks from 2010-2100 for each of the seven alternatives for the Reference Case. Compared to the No Action Alternative, projections of emissions reductions over the 2010 to 2100 timeframe due to other MY 2011-2015 CAFE standard alternatives ranged from 5,922 to 28,047 million metric tons of carbon dioxide ($MMTCO_2$).[16] Over this period, this range of alternatives would reduce global CO_2 emissions by about 0.1 to 0.6 percent (based on global emissions of 4,850,000 $MMTCO_2$).

Climate: CO_2 Concentration and Global Mean Surface Temperature

Table 2.5-6 shows estimated CO_2 concentrations, increase in global mean surface temperature, and sea-level rise in 2030, 2060, and 2100 for the No Action Alternative and the six action alternative CAFE levels for the Reference Case. There is a fairly narrow band of estimated CO_2 concentrations as of 2100, from 714.6 ppm for Technology Exhaustion to 717.2 ppm for the No Action Alternative. As CO_2 concentrations are the key driver of all the other climate effects, this narrow range implies that the differences among alternatives are difficult to distinguish.

[16] The values here are summed from 2010 through 2100, and are thus considerably higher than the value of 520 $MMTCO_2$ that is cited in the NPRM for the "Optimized" alternative. The latter value is the reduction in CO_2 emissions by only MY 2011-15 cars and light trucks over their lifetimes resulting from the optimized CAFE standards, measured as a reduction from the NPRM baseline of extending the CAFE standards for MY 2010 to apply to 2011-15.

Table 2.5-5

Reference Case Emissions and Emissions Reductions Due to the MY 2011-2015 CAFE Standards from 2010-2100 ($MMTCO_2$)

Alternative	Emissions ($MMTCO_2$)	Emissions Reductions Compared to No Action Alternative ($MMTCO_2$)
1 No Action	221,258	0
2 25 Percent Below Optimized	215,337	5,922
3 Optimized	214,643	6,616
4 25 Percent Above Optimized	214,144	7,114
5 50 Percent Above Optimized	213,254	8,004

a/ The A1B scenario is the SRES marker scenario used by the IPCC WGI to represent the SRES A1B (medium) storyline.

Climate: Global Mean Rainfall and Global Mean Surface Temperature

The CAFE alternatives reduce temperature increases slightly with respect to the No Action Alternative, and thus reduce increases in precipitation slightly, as shown in Table 2.5-7. As shown in the table and figures, there is a fairly narrow band of estimated precipitation increase reductions as of 2090, from 4.50 percent to 4.51 percent, and there is very little difference among the alternatives for the Reference Case.

Table 2.5-7

Reference Case MY 2011-2015 CAFE Alternatives: Impact on Reductions in Global Mean Precipitation based on A1B a/ SRES Scenario Using Increases in Global Mean Surface Temperature Simulated by MAGICC for 2020, 2055, and 2090 b/

6 Total Costs Equal Total Benefits	0.00	0.00	0.00
7 Technology Exhaustion	0.00	0.01	0.02

a/ The A1B scenario is the SRES marker scenario used by the IPCC WGI to represent the SRES A1B (medium) storyline.

b/ The difference in the years displayed for the temperature and precipitation table is due to choosing a midpoint from ranges developed by the IPCC. *See* Table 3.4-6.

Climate: Impact on Sea-level Rise

Table 2.5-6 lists the impact on sea-level rise under the alternatives and shows sea-level rise in 2100 ranging from 37.1 centimeters (cm) under the No Action Alternative to 36.99 centimeters under the Technology Exhaustion Alternative, for a maximum reduction of 0.11 centimeter by 2100 from the CAFE alternatives for the Reference Case.

2.5.1.3.2 High Scenario

Comparing High Scenario Table 2.5-8 with Reference Case Table 2.5-5 shows that total emissions under the High Scenario were lower for all alternatives. Correspondingly, emissions reductions compared to the No Action Alternative were higher for all alternatives under the High Scenario. The primary reason for this difference is the higher mpg and lower VMT forecasted under the High Scenario.

Table 2.5-8

High Scenario Emissions and Emissions Reductions Due to the MY 2011-2015 CAFE Standards from 2010-2100 ($MMTCO_2$)

	Alternative	Emissions ($MMTCO_2$)	Emissions Reductions Compared to No Action Alternative ($MMTCO_2$)
1	No Action	195,501	0
2	25 Percent Below Optimized	182,890	12,611
3	Optimized	180,591	14,910
4	25 Percent Above Optimized	179,079	16,422
5	50 Percent Above Optimized	177,669	17,832
6	Total Costs Equal Total Benefits	176,736	18,765
7	Technology Exhaustion	170,829	24,672

Table 2.5-9 shows the resulting effects on CO_2 concentration, global mean surface temperature, and sea-level rise. Under the High Scenario, the resulting CO_2 concentration, global mean surface temperature, and sea-level rise were lower for all alternatives except the Technology Exhaustion Alternative (which were the same for both scenarios). Thus, the differences for the action alternatives compared to the No Action Alternative are greater for the High Scenario than the Reference Case.

2.5.2 Cumulative Effects

The CEQ identifies the impacts that must be addressed and considered by federal agencies in satisfying the requirements of NEPA. This includes permanent, temporary, indirect and cumulative impacts. CEQ regulations implementing the procedural provisions of NEPA define cumulative impacts as “the impact on the environment which results from the incremental impact of the action when added to other past, present, and reasonably foreseeable future actions regardless of what agency or person undertakes such other actions” (40 CFR 1508.7). The following sections describe the cumulative effects of the CAFE alternatives on energy, air quality, and climate.

2.5.2.1 Energy

2.5.2.1.1 Reference Case

Table 2.5-10 shows the cumulative fuel consumption of the fleet of passenger cars and light trucks under Alternative 1 (No Action) and the six alternative CAFE standards for the Reference Case. By 2060, when the entire fleet is likely to comprise MY 2011 or later cars, cumulative fuel consumption (from 2010) reaches 9.7 trillion gallons under the No Action Alternative. Cumulative consumption declines across the alternatives, from 8.8 trillion gallons under the Optimized Alternative (Alternative 3) to 7.4 trillion gallons under the Technology Exhaustion Alternative (Alternative 7), which represent cumulative savings of 2.3 trillion gallons relative to the Reference Case No Action Alternative.

Table 2.5-9

High Scenario 2011-2015 CAFE Alternatives Impact on CO_2 Concentration, Global Mean Surface Temperature Increase, and Sea-level Rise in 2100 Using the MAGICC Model (A1B a/)

Totals by Alternative	CO_2 Concentration (ppm)			Global Mean Surface Temperature Increase (°C)			Sea-level Rise (cm)

2010-2060	--	933.1	975.7	1,049.8	1,114.6	1,181.6	2,331.7

2.5.2.1.2 High Scenario

In response to public comments, and to test how different economic assumptions could affect estimates of fuel consumption, NHTSA ran a series of scenarios (called the High, Mid-1 and Mid-2 Scenarios) using various economic input assumptions and compared the results to the Reference Case. Results from the High Scenario are presented in Table 2.5-11. The High Scenario assumes higher fuel prices than are assumed in the Reference Case, which results in lower fuel consumption across all of the CAFE alternatives examined. This is true even for the No Action Alternative (Alternative 1), because higher fuel prices in the High Scenario would reduce fuel consumption (relative to the Reference Case) even in the absence of any change in CAFE standards.

Table 2.5-11

High Scenario Passenger Car and Light Trucks Cumulative Fuel Consumption and Cumulative Fuel Savings (billion gallons)

Calendar Year Range	Alternative CAFE Standards for Model Years 2011-2020						
	Alt. 1	Alt. 2	Alt. 3	Alt. 4	Alt. 5	Alt. 6	Alt. 7
	No Action	25% Below Optimized	Optimized (Preferred)	25% Above Optimized	50% Above Optimized	Total Costs Equal Total Benefits	Technology Exhaustion
Passenger Cars and Light Trucks Cumulative Fuel Consumption							
2010-2020	1,498.6	1,464.8	1,458.8	1,452.6	1,447.8	1,443.0	1,415.4

2010-2050	6,550.8	5,608.3	5,506.0	5,418.6	5,334.6	5,287.1	5,119.9
2010-2060	8,731.1	7,341.4	7,193.3	7,067.6	6,945.6	6,879.3	6,656.6
Passenger Cars and Light Trucks Cumulative Fuel Savings							
2010-2020	--	33.9	39.9	46.0	50.9	55.6	83.3
2010-2030	--	233.2	262.0	288.0	311.4	327.8	402.4
2010-2040	--	554.7	617.1	671.2	722.2	753.2	871.8
2010-2050	--	942.6	1,044.9	1,132.3	1,216.2	1,263.8	1,430.9
2010-2060	--	1,389.6	1,537.8	1,663.5	1,785.5	1,851.8	2,074.5

Table 2.5-11 shows the cumulative fuel consumption of the fleet of passenger cars and light trucks under the No Action Alternative and the six alternative CAFE standards in the High Scenario. By 2060, when the entire fleet is likely to comprise MY 2011 or later cars, cumulative fuel consumption (from 2010) reaches 8.7 trillion gallons under the No Action Alternative. Cumulative consumption declines across the alternatives from 7.2 trillion gallons under the Optimized Alternative (Alternative 3) to 6.7 trillion gallons under the Technology Exhaustion Alternative (Alternative 7), which represents cumulative savings of 2.1 trillion gallons relative to the High Scenario No Action Alternative.

2.5.2.2 Air Quality

2.5.2.2.1 Reference Case

Table 2.5-12 summarizes the cumulative national emissions of toxic and criteria pollutants in 2035, showing that the Reference Case No Action Alternative has the highest cumulative emissions of all the alternatives for all pollutants except CO, acetaldehyde, acrolein, and formaldehyde. Alternative 3 has the highest cumulative emissions of CO and acetaldehyde. Alternative 7 has the highest cumulative emissions of all the alternatives for acrolein and formaldehyde.

Table 2.5-12

Reference Case Alternative CAFE Standards Nationwide Criteria Pollutant Emissions and Toxic Air Pollutant Emissions from Passenger Cars and Light Trucks (tons/year)
Cumulative Effects with MY 2011-2015 Standards and Potential MY 2016-2020 Standards

	No Action	25% Below Optimized	Optimized	25% Above Optimized	50% Above Optimized	Total Costs Equal Total Benefits	Technology Exhaustion
Criteria Pollutant Emissions (tons/year) for Passenger Cars and Light Trucks							
Carbon monoxide (CO)	19,745,847	20,068,580	20,145,455	19,664,457	19,615,715	19,406,046	11,524,825
Nitrogen oxides (NO_x)	1,369,135	1,335,125	1,335,545	1,318,678	1,314,728	1,305,570	1,048,518
Particulate matter ($PM_{2.5}$)	99,707	95,588	95,468	94,650	94,333	94,305	89,788
Sulfur oxides (SO_x)	265,792	240,446	239,437	236,567	234,662	232,370	183,541
Volatile organic compounds (VOCs)	1,906,119	1,861,129	1,862,621	1,832,904	1,825,138	1,803,935	1,196,950
Toxic Air Pollutant Emissions (tons/year) for Passenger Cars and Light Trucks							
Acetaldehyde	8,209	8,224	8,229	8,211	8,214	8,183	7,974
Acrolein	351	362	361	377	381	392	758
Benzene	47,515	47,256	47,364	46,405	46,251	45,791	29,613
1,3-butadiene	3,885	3,852	3,854	3,839	3,839	3,803	3,331
Diesel particulate matter (DPM)	119,499	105,773	105,131	104,372	103,457	102,999	94,643
Formaldehyde	13,035	12,717	12,677	12,899	12,924	12,961	17,034

Localized increases in criteria and toxic air pollutant emissions could occur in some nonattainment areas as a result of implementation of the CAFE standards alternatives. These localized increases represent a slight decline in the rate of reductions being achieved by implementation of CAA standards. All of the action alternatives would reduce adverse health outcomes and health costs related to motor vehicle air pollution, and thus would have beneficial health effects that would not need mitigation.

2.5.2.2.2 High Scenario

Table 2.5-13 summarizes the national criteria and air toxic pollutant emissions in 2035 for the seven alternatives for the High Scenario. For the High Scenario, emissions with the action alternatives are generally lower than for the Reference Case. Localized increases in criteria and toxic air pollutant emissions could occur in some nonattainment areas as a result of implementation of the CAFE standards alternatives. These localized increases represent a slight decline in the rate of reductions being achieved by implementation of CAA standards. All of the action alternatives would reduce adverse health outcomes and health costs related to motor vehicle air pollution, and thus would have beneficial health effects that would not need mitigation.

Table 2.5-13

High Scenario Alternative CAFE Standards Nationwide Criteria Pollutant Emissions and Toxic Air Pollutant Emissions from Passenger Cars and Light Trucks (tons/year)
Cumulative Effects with MY 2011-2015 Standards and Potential MY 2016-2020 Standards

Formaldehyde	11,694	11,783	11,730	11,897	12,127	12,433	15,281

2.5.2.3 Climate

2.5.2.3.1 Reference Case

GHG Emissions

Total emissions reductions from 2010-2100 new passenger cars and light trucks for each of the seven alternatives for the Reference Case are shown in Table 2.5-14. Projections of emissions reductions over the 2010 to 2100 timeframe due to the MY 2011-2020 CAFE standards ranged from 24,321 to 49,157 $MMTCO_2$. Compared against global emissions of 4,850,000 $MMTCO_2$ over this period (projected by the IPCC A1B-medium scenario), the incremental impact of this rulemaking is expected to reduce global CO_2 emissions by about 0.5 to 1.0 percent.

Climate: CO_2 Concentration and Global Mean Surface Temperature

The mid-range results of MAGICC model simulations for the No Action Alternative and the six alternative CAFE levels, in terms of CO_2 concentrations and increase in global mean surface temperature in 2030, 2060, and 2100 are presented in Table 2.5-15 and Figures 2.5-1 to 2.5-4. As Figures 2.5-1 and 2.5-2 show, the impact on the growth in CO_2 concentrations and temperature is just a fraction of the total growth in CO_2 concentrations and global mean surface temperature. However, the relative impact of the CAFE alternatives is illustrated by the reduction in growth of both CO_2 concentrations and temperature in the Technology Exhaustion Alternative, which is nearly double that of the 25 Percent Below Optimized Alternative, as shown in Figures 2.5-3 to 2.5-4.

Table 2.5-14

Reference Case Cumulative Emissions and Emissions Reductions Due to the MY 2011-2015 Standards and Potential MY 2016-2020 CAFE Standards Projected for 2010-2100 ($MMTCO_2$)

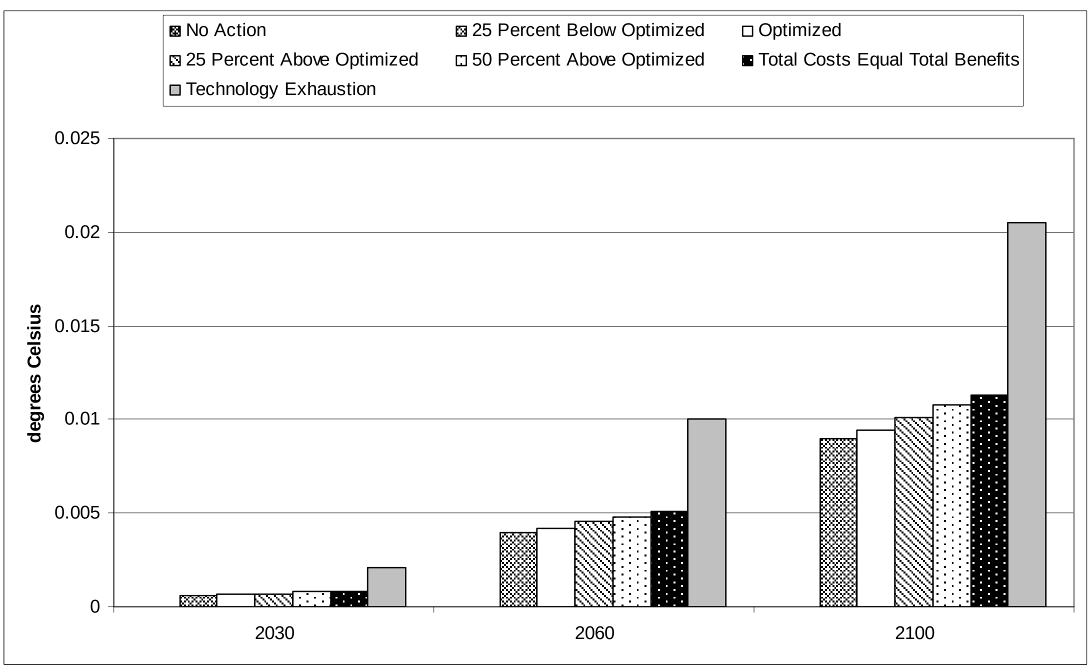
Figure 2.5-4. Reference Case MY 2011-2015 Standards and Potential MY 2016-2020 Standards Cumulative Impact on the Reduction in the Growth of Global Mean Temperature Using MAGICC (A1B a/)



a/ The A1B scenario is the SRES marker scenario used by the IPCC WGI to represent the SRES A1B (medium) storyline.

As shown in Table 2.5-15 and Figures 2.5-1 through 2.5-4, there is a fairly narrow band of estimated CO_2 concentrations as of 2100, from 712.6 ppm for the Technology Exhaustion Alternative to 717.2 ppm for the No Action Alternative. As CO_2 concentrations are the key driver of all the other climate effects, this narrow range implies that the differences among alternatives are difficult to distinguish. The MAGICC simulations of mean global surface air temperature increases are also shown below in Table 2.5-15. For all alternatives, the temperature increase is about 0.9 °C as of 2030, 1.9 °C as of 2060, and 2.9 °C as of 2100. The differences among alternatives are small. As of 2100, the reduction in temperature increase, with respect to the No Action Alternative, ranges from 0.009 °C to 0.02 °C. These estimates include considerable uncertainty due to a number of factors of which the climate sensitivity is the most important. The IPCC Fourth Assessment Report estimates a range of the climate sensitivity from 2.5 to 4.0 °C with a mid-point of 3.0 °C which directly relates to the uncertainty in the estimated global mean surface temperature.

Climate: Global Mean Rainfall and Global Mean Surface Temperature

The CAFE action alternatives for the Reference Case reduce temperature increases slightly with respect to the No Action Alternative. Thus, they also reduce predicted increases in precipitation slightly, as shown in Table 2.5-16. As shown in the Table 2.5-16 and Figures 2.5-1 through 2.5-4, there is a fairly narrow band of estimated precipitation increase reductions as of 2100, from 4.48 percent to 4.51 percent, and there is very little difference between the alternatives.

Table 2.5-16

Reference Case MY 2011-2015 Standards and Potential MY 2016-2020 CAFE Standards: Cumulative Impact on Reductions in Global Mean Precipitation Based on A1B a/ SRES Scenario, Using Increases in Global Mean Surface Temperature Simulated by MAGICC

Scenario	2020	2055	2090 b/

a/ The A1B scenario is the SRES marker scenario used by the IPCC WGI to represent the SRES A1B (medium) storyline.
b/ The difference in the years displayed for precipitation is due to choosing a mid-point from ranges developed by the IPCC

Climate: Impact on Sea-level Rise

The impact on sea-level rise from the CAFE Standards alternatives is presented in Table 2.5-18, showing sea-level rise in 2100 ranging from 37.10 cm in Alternative 1 (No Action) to 36.94 cm in the Technology Exhaustion Alternative, for a maximum reduction of 0.16 cm by 2100 from the CAFE alternatives for the Reference Case.

2.5.2.3.2 High Scenario

The results for the High Scenario are presented in Tables 2.5-17 and 2.5-18. Comparing High Scenario Table 2.5-17 with Reference Case Table 2.5-14 shows that total emissions under the High Scenario were lower for all alternatives except the Technology Exhaustion Alternative (which was the same for both scenarios). Correspondingly, emissions reductions compared to the No Action Alternative were higher for all alternatives under the High Scenario except the Technology Exhaustion Alternative (which was the same for both scenarios). The primary reason for this difference is the higher mpg and lower VMT forecasted under the High Scenario.

Table 2.5-17

4 25 Percent Above Optimized	0.3	1.7	3.8	0.001	0.007	0.016	0.00	0.05	0.14
5 50 Percent Above Optimized	0.3	1.8	4.1	0.001	0.008	0.017	0.00	0.05	0.15
6 Total Costs Equal Total Benefits	0.3	1.8	4.2	0.002	0.008	0.017	0.00	0.06	0.15
7 Technology Exhaustion	0.3	1.8	4.1	0.002	0.009	0.018	0.00	0.06	0.16

a/ The IPCC A1B scenario is the SRES marker scenario used by the IPCC WGI to represent the SRES A1B (medium) storyline.

Table 2.5-18 shows the resulting effects on CO_2 concentration, global mean surface temperature, and sea-level rise. Under the High Scenario, the resulting CO_2 concentration, global mean surface temperature, and sea-level rise were lower for all alternatives except the Technology Exhaustion Alternative (which were the same for both scenarios). Thus, the differences for the action alternatives compared to the No Action Alternative are greater for the High Scenario than the Reference Case.

2.5.3 Scenario Comparison

The data shown in Table 2.3-5, and graphed in Figure 2.5-5, show the required combined mpg standards for cars and light trucks associated with the seven alternatives across the Reference Case the three Input Scenarios. As noted above, the information provided in this FEIS, across alternatives for the Reference Case and the three Input Scenarios, is designed to allow the public and decisionmakers to evaluate environmental impacts for the entire range of feasible alternatives. Table 2.5-19 demonstrates the continuum of fuel savings and greenhouse gas reductions associated with the Optimized Alternatives of each Input Scenario. Table 2.5-20 compares energy and climate effect results for the alternatives of each Input Scenario.

Figure 2.5-5. MY 2015 Required MPG for Passenger Cars and Light Trucks by Alternative and Input Scenario

Chapter 3 Affected Environment and Environmental Consequences

3.1 INTRODUCTION

Council on Environmental Quality (CEQ) regulations for implementing the procedural provisions of the National Environmental Policy Act (NEPA) suggest a standard format for an environmental impact statement (EIS) that includes a section on affected environment and a section on environmental consequences. In this Final EIS (FEIS), the National Highway Traffic Safety Administration (NHTSA) addresses affected environment and potential environmental consequences of the proposed action and alternatives in sections under the heading for each resource area – energy (Section 3.2), air quality (Section 3.3), climate (Section 3.4), and various other potentially affected resource areas (Section 3.5). This structure enables the reader to readily learn about existing environmental conditions and potential environmental consequences related to each resource area.

The table below lists topics in a typical NEPA analysis and the section(s) in this chapter that address each topic.

Typical NEPA Topics	FEIS Sections
Water	3.4 Climate; 3.5.1 Water Resources
Ecosystems	3.4 Climate; 3.5.1 Water Resources; 3.5.2 Biological Resources
Threatened and endangered species	3.5.2.1.4 Endangered Species
Publicly owned parklands, recreational areas, wildlife and waterfowl refuges, historic sites, Section 4(f)-related issues	3.4 Climate; 3.5.1 Water Resources; 3.5.2 Biological Resources; 3.5.3 Land Use and Development; 3.5.6 Land Uses Protected under Section 4(f); 3.5.7 Historic and Cultural Resources
Properties and sites of historic and cultural significance	3.4 Climate; 3.5.3 Land Use and Development; 3.5.6 Land Uses Protected under Section 4(f); 3.5.7 Historic and Cultural Resources
Considerations relating to pedestrians and bicyclists	3.4 Climate; 3.5.3 Land Use and Development
Social impacts	3.2 Energy; 3.4 Climate; 3.5.3 Land Use and Development; 3.5.9 Environmental Justice
Noise	3.4 Climate; 3.5.3 Land Use and Development; 3.5.8 Noise
Air	3.2 Energy; 3.3 Air Quality; 3.4 Climate
Energy supply and natural resource development	3.2 Energy; 3.3 Air Quality; 3.4 Climate; 3.5.1 Water Resources; 3.5.2 Biological Resources; 3.5.3 Land Use and Development
Floodplain management evaluation	3.4 Climate; 3.5.1 Water Resources
Wetlands and coastal zones	3.4 Climate; 3.5.1 Water Resources; 3.5.2 Biological Resources
Construction impacts	3.2 Energy; 3.3 Air Quality; 3.4 Climate; 3.5.1 Water Resources; 3.5.2 Biological Resources; 3.5.3 Land Use and Development
Land use and urban growth	3.2 Energy; 3.3 Air Quality; 3.4 Climate; 3.5.1 Water Resources; 3.5.2 Biological Resources; 3.5.3 Land Use and Development
Human environment involving community disruption and relocation	3.2 Energy; 3.3 Air Quality; 3.4 Climate; 3.5.3 Land Use and Development; 3.5.4 Safety and Other Human Health Impacts; 3.5.5 Hazardous Materials and Regulated Wastes; 3.5.9 Environmental Justice

3.1.1 Direct and Indirect Impacts

CEQ regulations state that an EIS "shall succinctly describe" the environment to be affected by the alternatives under consideration and to provide data and analyses "commensurate with the importance of the impact[s]." 40 Code of Federal Regulations (CFR) §§ 1502.15, 1502.16. This chapter provides the analysis to determine and compare the significance of the direct and indirect effects of the proposed action and alternatives. Under NEPA, direct effects "are caused by the action and occur at the same time and place." 40 CFR §1508.8. CEQ regulations define indirect effects as those that "are caused by the action and are later in time or farther removed in distance but are still reasonably foreseeable. Indirect effects may include … effects on air and water and other natural systems, including ecosystems." 40 CFR §1508.8. Sections 3.2, 3.3, and 3.4 provide a quantitative analysis of the direct and indirect effects of the proposed action on energy, air, and climate, respectively. Impacts to other resource areas typically addressed in an EIS and the areas required by U.S. Department of Transportation (DOT) Order 5610, such as biological resources, water resources, noise, land use, and environmental justice, are described qualitatively in Section 3.5, because there were not enough data available in the literature for a quantitative analysis and because many of these effects are not localized. In this FEIS, such qualitative analysis is sufficient for NEPA purposes (DOT 1979).

3.1.2 Areas Not Affected

DOT's NEPA procedures[1] describe various areas that should be considered in an EIS. Many of these areas are covered in the sections below. NHTSA has considered the impact of the proposed action alternatives to all areas outlined by the procedures and has determined the following would not be directly or indirectly affected by the proposed action: human environment, including disruption and relocation, and considerations relating to pedestrians and bicyclists; floodplain management; and construction impacts. However, some of these areas could be affected by the cumulative impacts of the proposed action in combination with other foreseeable actions (*see* Chapter 4).

3.1.3 Approach to Scientific Uncertainty and Incomplete Information

3.1.3.1 CEQ Regulations

CEQ regulations recognize that many federal agencies encounter limited information and substantial uncertainties when analyzing the potential environmental impacts of their actions under NEPA. Accordingly, the regulations provide agencies with a means of formally acknowledging incomplete or unavailable information in NEPA documents. Where "information relevant to reasonably foreseeable significant adverse impacts cannot be obtained because the overall costs of obtaining it are exorbitant or the means to obtain it are not known," the regulations (40 CFR § 1502.22(b)) require an agency to include in its NEPA document:

1. A statement that such information is incomplete or unavailable

2. A statement of the relevance of the incomplete or unavailable information to evaluating reasonably foreseeable significant adverse impacts on the human environment

[1] *See* 42 United States Code (U.S.C.) § 4332 (requiring federal agencies to "identify and develop methods and procedures … which will insure that presently unquantified environmental amenities and values may be given appropriate consideration"); 40 CFR § 1502.23 (requiring an EIS to discuss the relationship between a cost-benefit analysis and any analyses of unquantified environmental impacts, values, and amenities); CEQ 1984 (recognizing that agencies are sometimes "limited to qualitative evaluations of effects because cause-and-effect relationships are poorly understood" or cannot be quantified).

3. A summary of existing credible scientific evidence relevant to evaluating the reasonably foreseeable significant adverse impacts on the human environment

4. The agency's evaluation of such impacts based on theoretical approaches or research methods generally accepted in the scientific community

Relying on these provisions is appropriate when an agency is performing a NEPA analysis that involves potential environmental impacts due to carbon dioxide (CO_2) emissions. *See*, for example, *Mayo Found. v. Surface Transp. Bd.*, 472 F.3d 545, 555 (8th Cir. 2006). CEQ regulations also authorize agencies to incorporate material into a NEPA document by reference to "cut down on bulk without impeding agency and public review of the action" (40 CFR § 1502.21).

Throughout this FEIS, NHTSA uses these two mechanisms – acknowledging incomplete or unavailable information and incorporation by reference – to address areas for which NHTSA cannot develop a credible estimate of the potential environmental impacts of the proposed action or alternatives. In particular, NHTSA recognizes that information about the potential environmental impacts of changes in emissions of CO_2 and other greenhouse gases (GHGs) and associated changes in temperature, including those expected to result from the proposed rule, is incomplete. NHTSA often relies on the Intergovernmental Panel on Climate Change (IPCC) 2007 Fourth Assessment Report as a recent "summary of existing credible scientific evidence which is relevant to evaluating the reasonably foreseeable significant adverse impacts on the human environment" (40 CFR § 1502.22(b)(3)).

3.1.3.2 Uncertainty with the IPCC Framework

The IPCC reports communicate uncertainty and confidence bounds using descriptive words in italics, such as *likely* and *very likely*, to represent levels of confidence in conclusions. This convention is briefly explained in the IPCC Fourth Assessment Synthesis Report and the IPCC Fourth Assessment Report Summary for Policymakers (IPCC 2007d, IPCC 2007c). A more detailed discussion of the IPCC treatment of uncertainty can be found in the IPCC Guidance Notes for Lead Authors of the IPCC Fourth Assessment Report on Addressing Uncertainties (IPCC 2005).

This FEIS uses the IPCC uncertainty language (always noted in italics) throughout Chapters 3 and 4 when discussing qualitative environmental impacts to certain resources. The reader should refer to the referenced IPCC documents above to gain a full understanding of the meaning of those uncertainty terms, because they might be used differently than similar language describing uncertainty in the FEIS, as required by the CEQ regulations described in Section 3.1.3.1.

3.1.4 Common Methodologies

The Corporate Average Fuel Economy (CAFE) Compliance and Effects Modeling System (referred to herein as the Volpe model) is a peer-reviewed modeling system developed by the DOT Volpe National Transportation Systems Center (Volpe Center). The Volpe model serves two fundamental purposes: (1) to identify technologies each manufacturer could apply to comply with a specified set of CAFE standards and (2) to calculate the costs and effects of manufacturers' application of technologies – including changes in fuel use and, therefore, CO_2 emissions. The Volpe model provides data that were used to analyze energy, air, and climate impacts.

The Volpe model begins with an initial state of the domestic vehicle market, which in this case is the market for passenger cars and light trucks to be sold during the period covered by the proposed rule. The vehicle market is defined on a model-by-model, engine-by-engine, and transmission-by-transmission basis, such that each defined vehicle model refers to a separately defined engine and a separately defined transmission.

For the model years covered by the current proposal, the light vehicle (passenger car and light truck) market forecast includes more than 3,000 vehicle models, more than 400 specific engines, and nearly 400 specific transmissions. This level of detail in the representation of the vehicle market is vital to an accurate analysis of manufacturer-specific costs and the analysis of reformed CAFE standards, and is much greater than the level of detail used by many other models and analyses relevant to light vehicle fuel economy.[2]

The Volpe model also uses several additional categories of data and estimates provided in various external input files for all vehicle categories (small, mid-size, and large sport utility vehicles [SUVs]; small and large pickups; minivans; sub-compact, compact, midsize, and large cars) including:

- Fuel-saving technology characteristics
  - Commercialization year
  - Effectiveness and cost
  - "Learning effect" cost coefficients
  - "Technology path" inclusion/exclusion
  - "Phase-in caps" on penetration rates
  - "Synergy" options
- Vehicular emissions rates, carbon monoxide (CO), volatile organic compounds (VOCs), nitrogen oxides (NO_x), particulate matter (PM), and sulfur dioxide (SO_2) for vehicular travel (that is, vehicle miles traveled [VMT])
- Economic and other data and estimates
  - Vehicle survival (percent of vehicles of a given vintage that remain in service)
  - Mileage accumulation (annual travel by vehicles of a given vintage)
  - Price/fuel taxation rates for seven fuels (such as gasoline and diesel)
  - Pump prices (including taxes) for vehicle fuel savings/retail price
  - Rebound effect coefficient (the elasticity of VMT in relation to per-mile cost of fuel)
  - Discount rate; "payback period" (the number of years purchasers consider when taking into account fuel savings)
  - Fuel economy "gap" (for example, laboratory versus actual)
  - Per-vehicle value of travel time (in dollars per hour)
  - The economic costs (in dollars per gallon) of petroleum consumption
  - Various external costs (all in dollars per mile) associated with changes in vehicle use

[2] Because CAFE standards apply to the average performance of each manufacturer's fleet of cars and light trucks, the impact of potential standards on individual manufacturers cannot be credibly estimated without analysis of manufacturers' planned fleets. Furthermore, because required CAFE levels under an attribute-based CAFE standard depend on manufacturers' fleet composition, the stringency of an attribute-based standard cannot be predicted without performing analysis at this level of detail.

- Damage costs (all on a dollar-per-ton basis) for each of the above-mentioned criteria pollutants
- The civil-penalties rate for noncompliance

- Properties of different fuels
  - Upstream CO_2 and criteria pollutant emissions rates (that is, U.S. emissions resulting from the production and distribution of each fuel)
  - Density (pounds per gallon); energy density (British thermal unit [BTU] per gallon)
  - Carbon content
  - Shares of fuel savings leading to reduced domestic refining
  - Relative shares of different gasoline blends

- Sensitivity analysis coefficients; high and low fuel price forecasts

- CAFE scenarios
  - Baseline (no action or business-as-usual)
  - Alternative scenarios defining coverage, structure, and stringency of CAFE standards

With all of the above input data and estimates, the modeling system develops an estimate of a set of technologies each manufacturer could apply in response to each specified CAFE scenario alternative.

The modeling system begins with the "initial state" (baseline) of each manufacturer's future vehicles and accumulates the estimated costs of progressive additions of fuel-saving technologies. Within a set of specified constraints, the system adds technologies following a cost-minimizing approach. At each step, the system evaluates the effective cost of applying available technologies to individual vehicle models, engines, or transmissions, and selects the application of technology that produces the lowest effective cost. The effective cost estimated to be considered by the manufacturer is calculated by adding the total incurred technology costs (in retail price equivalent [RPE]), subtracting the reduction in civil penalties owed for noncompliance with the CAFE standard, subtracting the estimated value of the reduction in fuel costs, and dividing the result by the number of affected vehicles.

In representing manufacturer decisions in response to a given CAFE standard, the modeling system accounts for the fact that, historically, some manufacturers have not been willing to pay penalties and some have. Thus, the system applies technologies until any of the following conditions are met: the manufacturer no longer owes civil penalties for failing to meet the applicable standard, the manufacturer has exhausted technologies expected to be available in that model year, or the manufacturer is estimated to be willing to pay civil penalties, and doing so is estimated to be less expensive than continuing to add technologies.

The system then progresses to the next model year (if included in the vehicle market and scenario input files), "carrying over" technologies where vehicle models are projected to be succeeded by other vehicle models. The Volpe model does not attempt to account for CAFE credits or intentional over-compliance (that is, achieving an average fuel economy higher than that required by law), or the "pull ahead" application of technologies.[3]

[3] Manufacturers might "pull ahead" the implementation of some technologies in response to CAFE standards that they know will be steadily increasing over time. For example, if a manufacturer plans to redesign many vehicles in

The Volpe model completes this compliance simulation for all manufacturers and all model years and produces various outputs from the effects of changes in fuel economy. The outputs include:

- Total cost (TC) of all applied technologies
- Year-by-year mileage accumulation – including the rebound effect
- Year-by-year fuel consumption
- CO_2 and criteria pollutants – domestic full fuel-cycle emissions,[4] monetary damages
- Total discounted/undiscounted national societal costs of year-to-year fuel consumption
- Additional travel – consumer surplus[5]
- Economic externalities – congestion, accidents, noise
- Value of time saved
- Total discounted/undiscounted societal benefits – including net social benefits and benefit-cost ratio (EIA 2008a)

The specific outputs associated with each alternative examined in this FEIS reflect the estimated values for key inputs into the Volpe model. The outputs of the Volpe model provide data used to analyze energy, air, and climate impacts, so these environmental impacts also reflect the inputs into the Volpe model. NHTSA acknowledges that appropriate model input values are subject to uncertainty and debate. In this FEIS, NHTSA addresses uncertainty by explicitly presenting analytical results for Reference Case model inputs, high case (High Scenario) model inputs, and several other scenarios with model inputs (such as fuel prices) and outputs (such as required miles per gallon) that fall between those in the Reference Case and High Scenarios. Table 2.5-19 in this FEIS shows how variations in key Volpe model input values affect Volpe model outputs (vehicle miles, miles per gallon [mpg], fuel consumption, and carbon emissions) across the range of input scenarios for the Optimized Alternative. For discussions of model inputs chosen for the various scenarios, refer to Chapter 10 of this FEIS.

Sections 3.3.3.2 through 3.3.4.9 describe the analysis of alternatives for the Reference Case model inputs (Sections 3.3.3.2 through 3.3.3.8) and then describe the impacts for the same alternatives under the High Scenario and two other scenarios – Mid-1 and Mid-2 – that have Volpe model inputs and outputs that fall between those of the Reference Case and High Scenario (Sections 3.3.4.2 through 3.3.4.9). This analytical structure is designed to fully inform the public and decisionmakers about the potential environmental impacts of any combination of economic inputs into the Volpe model, across the range of feasible alternatives.

model year (MY) 2011 and not in MY 2013, but the standard for MY 2013 is considerably higher than that for MY 2011, the manufacturer might find it less expensive during MY 2011 through MY 2013 (taken together) to apply more technology in MY 2011 than is necessary for compliance with the MY 2011 standard.

[4] Domestic full fuel-cycle emissions include the emissions associated with production, transportation, and refining operations, and the CO_2 emissions from fuel combustion.

[5] Consumer surplus measures the net benefits that drivers receive from additional travel and refers to the amount by which the benefits from additional travel exceed its costs (for fuel and other operating expenses).

3.2 ENERGY

Over the past decade and a half, energy intensity in the United States (energy use per dollar of gross domestic product [GDP]) has declined at about 2 percent per year (EIA 2008a). Despite the growth in population and the economy, energy intensity has fallen due to a combination of increased efficiency and a structural shift in the economy to less energy-intensive industries. Nevertheless, transportation fuel consumption has grown steadily and is the major component of the use of petroleum.

3.2.1 Affected Environment

Table 3.2-1 shows U.S. and global energy consumption by sector from the Energy Information Administration (EIA), which collects and provides the official energy statistics for the United States and whose data are the primary source for analysis and modeling of energy systems by government and private entities. Actual-consumption data show a steady increase in the United States in most of the sectors, particularly the transportation sector. By 2004, transportation was the second highest consumer of energy after industrial and comprised 27.8 and 17.3 percent of the U.S. and global (less U.S.) energy use, respectively.

Table 3.2-1

b/ **Forecasted United States data**: Annual Energy Outlook (AEO) 2008, http://www.eia.doe.gov/oiaf/aeo/excel/aeotab_2.xls
Forecasted World data: International Energy Outlook (IEO) 2007, http://www.eia.doe.gov/oiaf/ieo/excel/ieonuctab_1.xls

EIA projections show a steady increase in both U.S. and global transportation energy consumption (EIA 2008a). Despite efforts to increase the use of non-fossil fuels in transportation, fuel use remains largely petroleum based. In 2007, finished motor gasoline and on-road diesel constituted 66 percent of all finished petroleum products consumed in the United States. If other transportation fuels (aviation fuels, marine and locomotive diesel, and bunkers) are included, transportation fuels constitute approximately 79 percent of the finished petroleum products used.

Most U.S. gasoline and diesel is produced domestically (EIA 2008b). In 2007, 4 percent of finished motor gasoline and 6 percent of on-road diesel were imported. However, increasing volumes of crude oil are imported for processing in U.S. refineries because indigenous production is declining steadily. By 2006, petroleum imports equaled 60 percent of total liquids supplied, and by 2007 crude oil imports had surpassed 10 million barrels per day (EIA 2008b), a high proportion of it coming from volatile and unstable regions.

A fall in the demand for transportation fuels likely would affect the import of crude oil more than motor gasoline. Over the last decade there has been a shift in product imports, with volumes of finished gasoline stabilizing and declining slightly. However, volumes of motor gasoline blending components have been rapidly increasing, so that by 2007, the imports of blending components were twice that of finished gasoline.

According to the EIA, net imports, in part due to the changes in CAFE standards and in part due to biofuels, will fall to 51 percent in 2022 and then rise again to 54 percent in 2030. The impact on the industry and the environment in which it works will be felt largely by overseas producers. The actual impact on overseas producers and whether there is a decline in production, and a concomitant decline in emissions, would depend on the demand patterns in the developing nations.

The projections used in this FEIS do not include any large-scale, national efforts to reduce energy consumption or dramatically reduce fossil-fuel use as a result of national security or climate change-issues. NHTSA notes this only to remind readers that the FEIS projections are based on past trends and, in light of the current national focus on energy and climate-change concerns, do not project future regulations or initiatives that could arise but are not, at present, foreseeable. Any large-scale initiative such as this would obviously change the assumptions used in this analysis.

3.2.2 Methodology

The Volpe model, as described in Section 3.1.4, begins with an initial state of the domestic vehicle market, which in this case is the market for passenger cars and light trucks to be sold during the period covered by the proposed rule. It uses several categories of data and estimates for all vehicle categories to develop an estimate of a set of technologies each manufacturer could apply in response to the standard. The Volpe model produces various outputs, one of which is year-by-year fuel consumption, which NHTSA used in the analysis below. NHTSA estimated fuel consumption to 2060, at which point nearly all of the operating fleet of passenger cars and light trucks would be MY 2011-2015 or newer, thus achieving the maximum fuel savings under this rule.

3.2.3 Environmental Consequences

Table 3.2-2 lists the impact on fuel consumption for passenger cars from 2020 through 2060 (a period in which an increasing proportion of the fleet would be MY 2011-2015 cars), which shows the increasing impact of the CAFE alternatives over time. The table lists the total fuel consumption for passenger cars, both gasoline and diesel, under the No Action Alternative (Alternative 1) and the six action alternatives with the Reference Case inputs, as described in Table 2.2-1. By 2060, when the entire

Fuel Consumption							
2020	67.8	66.4	66.4	66.3	66.2	66.1	59.4
2030	78.9	76.3	76.2	76.1	75.9	75.7	64.3
2040	91.2	88.2	88.0	87.9	87.7	87.4	74.0
2050	105.7	102.1	102.0	101.8	101.6	101.2	85.7
2060	121.9	117.8	117.6	117.4	117.1	116.7	98.8
Fuel Savings Compared to No Action							
2020	--	1.4	1.4	1.5	1.6	1.7	8.4
2030	--	2.6	2.7	2.8	3.0	3.2	14.5
2040	--	3.1	3.2	3.3	3.6	3.8	17.2
2050	--	3.6	3.7	3.9	4.1	4.4	20.0
2060	--	4.1	4.3	4.4	4.7	5.1	23.0

fleet is likely to be composed of MY 2011 or later cars, fuel consumption reaches 121.9 billion gallons under the No Action Alternative. Consumption falls under all the action alternatives, from 117.6 billion gallons under the Optimized Alternative (Alternative 3) to 98.8 billion gallons under the Technology Exhaustion Alternative (Alternative 7). As a point of comparison, in 2007 the United States consumed 9.3 million barrels of fuel per day. Consumption under the Technology Exhaustion Alternative amounts to 6.4 million barrels of fuel per day.

Table 3.2-3 lists results for light trucks/SUVs for the same period and for the same alternatives. As in the previous table, fuel consumption is the total for both diesel and gasoline. Fuel consumption

Table 3.2-3

Reference Case Light Truck Annual Fuel Consumption and Fuel Savings (billion gallons)

	Alternative CAFE Standards for Model Years 2011-2015

Calendar Year	No Action	25% Below Optimized	Optimized	25% Above Optimized	50% Above Optimized	Total Cost Equal Total Benefit	Technology Exhaustion
Fuel Consumption							
2020	84.0	83.0	82.8	82.4	82.2	81.7	75.5
2030	93.5	91.4	91.0	90.4	89.9	89.2	77.5
2040	107.3	104.6	104.1	103.4	102.7	101.9	87.1
2050	124.0	120.8	120.2	119.4	118.5	117.5	100.2
2060	143.0	139.3	138.7	137.7	136.7	135.6	115.5
Fuel Savings Compared to No Action							
2020	--	1.0	1.2	1.6	1.8	2.2	8.5
2030	--	2.1	2.5	3.0	3.6	4.3	16.0
2040	--	2.7	3.2	3.9	4.6	5.4	20.2
2050	--	3.2	3.7	4.6	5.4	6.4	23.8
2060	--	3.7	4.3	5.3	6.3	7.4	27.5

under the No Action Alternative is 143.0 billion gallons in 2060. Consumption falls under the action alternatives from 138.7 under the Optimized Alternative to 115.5 billion gallons under the Technology Exhaustion Alternative, which represent a savings of 27.5 billion gallons from the No Action Alternative.

3.2.4 Input Scenarios

In response to public comments, and to test how different economic assumptions could affect estimates of fuel consumption, NHTSA ran a scenario using the High Scenario assumptions and compared the results below to the Reference Case. Table 3.2-4 lists the impact on fuel consumption under the High Scenario in the Volpe model for passenger cars from 2020 through 2060. The High Scenario uses the economic inputs described in Table 2.2-1. Table 3.2-4 lists total fuel consumption for passenger cars, both gasoline and diesel, under the No Action Alternative and the six action alternatives. With the assumption of higher fuel prices, lower consumption is expected across the alternatives. By 2060, when the entire fleet is likely to be composed of MY 2011 or later cars, fuel consumption reaches 106.2 billion gallons under the No Action Alternative. Consumption totals 96.6 billion gallons under the Optimized Alternative, as opposed to 117.6 billion gallons under the Optimized Alternative in the Reference Case. Consumption under the Technology Exhaustion Alternative is 86.1 billion gallons, equivalent to 5.6 million barrels per day.

Table 3.2-4

High Scenario Passenger Car Annual Fuel Consumption and Fuel Savings (billion gallons)

	Alternative CAFE Standards for Model Years 2011-2015						
	Alt. 1	Alt. 2	Alt. 3	Alt. 4	Alt. 5	Alt. 6	Alt. 7
Calendar Year	No Action	25% Below Optimized	Optimized	25% Above Optimized	50% Above Optimized	Total Cost Equal Total Benefit	Technology Exhaustion
Fuel Consumption							
2020	62.1	59.3	58.8	58.3	57.9	57.3	54.5
2030	71.1	65.7	64.9	64.0	63.5	62.6	58.0
2040	81.4	75.0	74.1	73.1	72.4	71.4	66.0
2050	93.2	85.9	84.8	83.7	82.9	81.8	75.6
2060	106.2	97.8	96.6	95.3	94.4	93.1	86.1
Fuel Savings Compared to No Action							
2020	--	2.8	3.3	3.9	4.3	4.8	7.7
2030	--	5.4	6.2	7.1	7.6	8.5	13.1
2040	--	6.4	7.4	8.4	9.0	10.0	15.4
2050	--	7.3	8.4	9.6	10.3	11.5	17.6
2060	--	8.4	9.6	10.9	11.7	13.1	20.1

Table 3.2-5 shows the High Scenario results for light trucks/SUVs for the same period and the same alternatives. As in previous tables, fuel consumption is the total for diesel and gasoline. Fuel consumption under the No Action Alternative is 124.6 billion gallons in 2060. Consumption under the Optimized Alternative is 113.6 billion gallons, compared to 138.7 billion gallons under the Optimized Alternative in the Reference Case. Consumption under the Technology Exhaustion Alternative is 100.6 billion gallons.

To further assess how different economic assumptions could affect estimates of fuel consumption, NHTSA ran two additional scenarios in the Volpe model: the Mid-1 Scenario and the Mid-2 Scenario. As the names of the scenarios suggest, results from the two additional scenarios fall between those of the Reference Case and the High Scenario. These scenarios use the economic inputs listed in Table 2.2-1. *See* Appendix B for a summary of Mid-1 and Mid-2 Scenario results.

3.3 AIR QUALITY

3.3.1 Affected Environment

3.3.1.1 Relevant Pollutants and Standards

The new CAFE standards would affect air pollution and air quality, which in turn, has potential effects on public health and welfare. The primary federal legislation that addresses air quality is the Clean Air Act (CAA). Under the authority of the CAA and its amendments, the U.S. Environmental Protection Agency (EPA) has established National Ambient Air Quality Standards (NAAQS) for six criteria pollutants (relatively commonplace pollutants that can accumulate in the atmosphere as a result of normal levels of human activity). The air quality analysis assesses the impacts of the alternatives in relation to criteria pollutants and some hazardous air pollutants from mobile sources (also known as mobile source air toxics [MSATs]).

The criteria pollutants are CO, nitrogen dioxide (NO_2) (one of several oxides of nitrogen, ozone, SO_2, suspended PM of 10 microns diameter or less (PM_{10}) and 2.5 microns diameter or less ($PM_{2.5}$), and lead. Ozone is not emitted directly from vehicles, but is evaluated based on emissions of the ozone precursor pollutants NO_x and VOCs.

The U.S. transportation sector is a major source of emissions of certain criteria pollutants or their chemical precursors. Total emissions from on-road mobile sources (cars and trucks) have declined dramatically since 1970 as a result of pollution controls on vehicles and regulation of the chemical content of fuels, despite continuing increases in the amount of vehicle travel. From 1970 to 2006, the most recent year for which data are available, emissions from on-road mobile sources declined 67 percent for CO, 48 percent for NO_x, 62 percent for PM_{10}, 31 percent for SO_2, and 77 percent for VOCs. Emissions of $PM_{2.5}$ from onroad mobile sources declined 62 percent from 1990, the earliest year of available data, to 2006 (EPA 2006c).

On-road mobile sources are responsible for 54 percent of total U.S. emissions of CO, 5 percent of $PM_{2.5}$ emissions, and 1 percent of PM_{10} emissions (EPA 2006c). Almost all of the PM in vehicle exhaust is $PM_{2.5}$; therefore, this analysis focuses on $PM_{2.5}$ rather than PM_{10}. On-road mobile sources also contribute 22 percent of total nationwide emissions of VOCs and 36 percent of NO_x, which are chemical precursors of ozone. On-road mobile sources contribute only 1 percent of SO_2, but SO_2 and other oxides of sulfur (SO_x) are important because they contribute to the formation of $PM_{2.5}$ in the atmosphere. With the elimination of lead in gasoline, lead is no longer emitted in more than negligible quantities from motor vehicles, and is no longer a pollutant of significance for transportation projects. Lead is not assessed further in this analysis.

Table 3.3-1 lists the primary and secondary NAAQS for each criteria pollutant. Primary standards are set at levels intended to protect against adverse effects on human health; secondary standards are intended to protect against adverse effects on public welfare, such as damage to agricultural crops or vegetation, and damage to buildings or other property. Because each criteria pollutant has different potential effects on human health and public welfare, the NAAQS specify different permissible levels for each pollutant. NAAQS for some pollutants include standards for both short- and long-term average levels. Short-term standards, which typically specify higher levels of a pollutant, are intended to protect against acute health effects from short-term exposure to higher levels of a pollutant; long-term standards are established to protect against chronic health effects resulting from long-term exposure to lower levels of a pollutant.

Table 3.3-1

National Ambient Air Quality Standards

Pollutant	Primary Standards		Secondary Standards	
	Level a/	Averaging Time	Level a/	Averaging Time
Carbon monoxide	9 ppm ($10\ mg/m^3$)	8 hours b/	None	
	35 ppm ($40\ mg/m^3$)	1 hour b/		
Lead	$1.5\ \mu g/m^3$	Quarterly Average	Same as Primary	
Nitrogen dioxide	0.053 ppm ($100\ \mu g/m^3$)	Annual (Arithmetic Mean)	Same as Primary	
Particulate matter (PM_{10})	$150\ \mu g/m^3$	24 hours c/	Same as Primary	
Particulate matter ($PM_{2.5}$)	$15.0\ \mu g/m^3$	Annual d/ (Arithmetic Mean)	Same as Primary	
	$35\ \mu g/m^3$	24 hours e/	Same as Primary	
Ozone	0.075 ppm (2008 std.)	8 hours f/	Same as Primary	
	0.08 ppm (1997 std.)	8 hours g/ h/	Same as Primary	
	0.12 ppm	1 hour i/ j/ (Applies only in limited areas)	Same as Primary	
Sulfur dioxide	0.03 ppm	Annual (Arithmetic Mean)	0.5 ppm ($1300\ \mu g/m^3$)	3 hours b/
	0.14 ppm	24 hours b/		

a/ Units of measure for the standards are parts per million (ppm) by volume, milligrams per cubic meter of air (mg/m^3), and micrograms per cubic meter of air ($\mu g/m^3$).
b/ Not to be exceeded more than once per year.
c/ Not to be exceeded more than once per year on average over 3 years.
d/ To attain this standard, the 3-year average of the weighted annual mean $PM_{2.5}$ concentrations from single or multiple community-oriented monitors must not exceed $15.0\ \mu g/m^3$.
e/ To attain this standard, the 3-year average of the 98th percentile of 24-hour concentrations at each population-oriented monitor within an area must not exceed $35\ \mu g/m^3$ (effective December 17, 2006).
f/ To attain this standard, the 3-year average of the fourth-highest daily maximum 8-hour average ozone concentrations measured at each monitor within an area over each year must not exceed 0.075 ppm (effective May 27, 2008).
g/ To attain this standard, the 3-year average of the fourth-highest daily maximum 8-hour average ozone concentrations measured at each monitor within an area over each year must not exceed 0.08 ppm.
h/ The 1997 standard—and the implementation rules for that standard—will remain in place for implementation purposes as EPA undertakes rulemaking to address the transition from the 1997 ozone standard to the 2008 ozone standard.
i/ The standard is attained when the expected number of days per calendar year with maximum hourly average concentrations above 0.12 ppm is less than 1.
j/ As of June 15, 2005, EPA revoked the 1-hour ozone standard in all areas except the 8-hour ozone nonattainment Early Action Compact (EAC) Areas.

Source: 40 CFR 50, as presented in EPA 2008c.

Under the CAA, EPA is required to review NAAQS every 5 years and to change the levels of the standards if warranted by new scientific information. NAAQS formerly included an annual standard, but EPA revoked the annual PM_{10} standard in 2005 based on an absence of evidence of health effects associated with annual PM_{10} levels. In September 2006, EPA tightened the 24-hour $PM_{2.5}$ standard from

65 micrograms per cubic meter (μg/m^3) to 35 μg/m^3. In March 2008, EPA tightened the 8-hour ozone standard from 0.08 parts per million (ppm) to 0.075 ppm. EPA currently is considering further changes to the $PM_{2.5}$ standards.

The air quality of a geographic region is usually assessed by comparing the levels of criteria air pollutants found in the atmosphere to the levels established by NAAQS. Concentrations of criteria pollutants within the air mass of a region are measured in parts of a pollutant per million parts of air or in micrograms of a pollutant per cubic meter of air present in repeated air samples taken at designated monitoring locations. These ambient concentrations of each criteria pollutant are compared to the permissible levels specified by NAAQS to assess whether the region's air quality could be unhealthful.

When the measured concentrations of a criteria pollutant within a geographic region are below those permitted by NAAQS, EPA designates the region as an attainment area for that pollutant; regions where concentrations of criteria pollutants exceed federal standards are called nonattainment areas. Former nonattainment areas that have attained NAAQS are designated as maintenance areas. Each nonattainment area is required to develop and implement a State Implementation Plan (SIP), which documents how the region will reach attainment levels within periods specified in the CAA. In maintenance areas, the SIP documents how the state intends to maintain compliance with NAAQS. When EPA changes a NAAQS, states must revise their SIPs to address how they will attain the new standard.

Toxic air pollutants emitted from vehicles are known as mobile source air toxics (MSATs). The MSATs included in this analysis are acetaldehyde, acrolein, benzene, 1,3-butadiene, diesel particulate matter (DPM), and formaldehyde. EPA and the Federal Highway Administration (FHWA) have identified these air toxics as the MSATs of concern for impacts of highway vehicles (EPA 2007c, FHWA 2006). DPM is a component of exhaust from diesel-fueled vehicles and falls almost entirely within the $PM_{2.5}$ particle-size class.

Section 3.4 addresses the major GHGs – CO_2, methane (CH_4), and nitrous oxides (N_2O); these GHGs are not included in this air quality analysis, except that N_2O, as one of the oxides of nitrogen (NO_x), is included in the evaluation of NO_x.

3.3.1.2 Health Effects of Criteria Pollutants

The health effects of the six federal criteria pollutants are briefly summarized below. (This section is adapted from EPA 2008e.) Though we did not conduct a formal analysis of health impacts, the alternatives considered in this FEIS will contribute to reductions in criteria pollutants that will improve public health and welfare.

- Ozone is a photochemical oxidant and the major component of smog. Ozone is not emitted directly into the air but is formed through complex chemical reactions between precursor emissions of VOCs and NO_x in the presence of the ultraviolet component of sunlight. Ground-level ozone causes health problems because it irritates the mucous membranes, damages lung tissue, reduces lung function, and sensitizes the lungs to other irritants. Exposure to ozone for several hours at relatively low concentrations has been found to substantially reduce lung function and induce respiratory inflammation in normal, healthy people during exercise. There is also evidence that short-term ozone exposure directly or indirectly contributes to non-accidental and cardiopulmonary-related mortality.

- PM includes dust, dirt, soot, smoke, and liquid droplets directly emitted into the air, and particles formed in the atmosphere by condensation or the transformation of emitted gases such as SO_2 and VOCs. PM is emitted by both gasoline-fueled and diesel-fueled vehicles.

Particles composed of elemental carbon (carbon black or black carbon) are included in the definition of PM. Heavy-duty diesel vehicles (large trucks and buses) are a major source of PM emissions. In general, the smaller the PM, the deeper it can penetrate into the respiratory system, and the more damage it can cause. Depending on the size and composition, PM can damage lung tissue, aggravate existing respiratory and cardiovascular diseases, alter the body's defense systems against foreign materials, damage lung tissue, and cause cancer and premature death. As noted above, EPA regulates PM according to two particle size classifications: PM_{10} and $PM_{2.5}$.

- CO is a colorless, odorless, and poisonous gas produced by incomplete burning of carbon in fuels. Motor vehicles are the largest source of CO emissions nationally. When CO enters the bloodstream, it acts as an asphyxiant by reducing the delivery of oxygen to the body's organs and tissues. It can impair the brain's ability to function properly. Health threats are most serious for those who suffer from cardiovascular disease, particularly those with angina or peripheral vascular disease.

- Lead is a toxic heavy metal used in industry, such as in battery manufacturing, and formerly in widespread use as an additive in paints. Lead exposure can occur through multiple pathways, including inhalation of air and ingestion of lead in food, water, soil, or dust. Excessive lead exposure can cause seizures, mental retardation, behavioral disorders, severe and permanent brain damage, and death. Even low doses of lead can lead to central nervous system damage. Because of the prohibition of lead as an additive in liquid fuels, transportation sources are no longer a major source of lead pollution.

- SO_2, one of various oxides of sulfur (SO), is a gas formed from combustion of fuels containing sulfur. Most SO_2 emissions are produced by stationary sources such as power plants. SO_2 is also formed when gasoline is extracted from crude oil in petroleum refineries, and in other industrial processes. High concentrations of SO_2 cause severe respiratory distress (difficulty breathing), irritate the upper respiratory tract, and can aggravate existing respiratory and cardiovascular disease. SO_2 also is a primary contributor to acid deposition, or acid rain, which causes acidification of lakes and streams and can damage trees, crops, historic buildings, and statues.

- NO_2 is a reddish-brown, highly reactive gas, one of the oxides of nitrogen formed by high-temperature combustion (as in vehicle engines) of nitrogen and oxygen. Most NO_x created in the combustion reaction consists of nitric oxide (NO), and the NO oxidizes to NO_2 in the atmosphere. NO_2 can irritate the lungs and mucous membranes, cause bronchitis and pneumonia, and lower resistance to respiratory infections. Nitrogen oxides are an important precursor both to ozone and acid rain, and can affect both terrestrial and aquatic ecosystems.

3.3.1.3 Health Effects of Mobile Source Air Toxics

The health effects of the MSATs of concern are briefly summarized below (adapted from EPA 2007c.)

- Acetaldehyde is a probable human carcinogen based on increased incidence of nasal tumors in rats and throat tumors in hamsters after inhalation exposure. Acetaldehyde is also a potent respiratory irritant.

- Acrolein, an aldehyde, is a respiratory irritant. Its potential carcinogenic effects are uncertain.

- Benzene, an aromatic hydrocarbon, is a known human carcinogen (causing leukemia) by all routes of exposure. Benzene also affects the immune system.

- 1,3-butadiene, a hydrocarbon, is characterized as carcinogenic to humans by inhalation. It also damages the reproductive system.

- Diesel particulate matter is a component, along with diesel exhaust organic gases, of diesel exhaust. EPA has not established a particle size classification for regulating DPM. The DPM particles are very fine, with most particles smaller than 1 micron, and their small size allows inhaled DPM to reach the lungs. Particles typically have a carbon core coated by condensed organic compounds, which include mutagens and carcinogens. DPM also includes elemental carbon (carbon black or black carbon) particles emitted from diesel engines. Diesel exhaust is likely to be carcinogenic to humans by inhalation from environmental exposure.

- Formaldehyde is a probable human carcinogen, based on evidence in humans and in rats, mice, hamsters, and monkeys. Formaldehyde also is a respiratory and eye irritant.

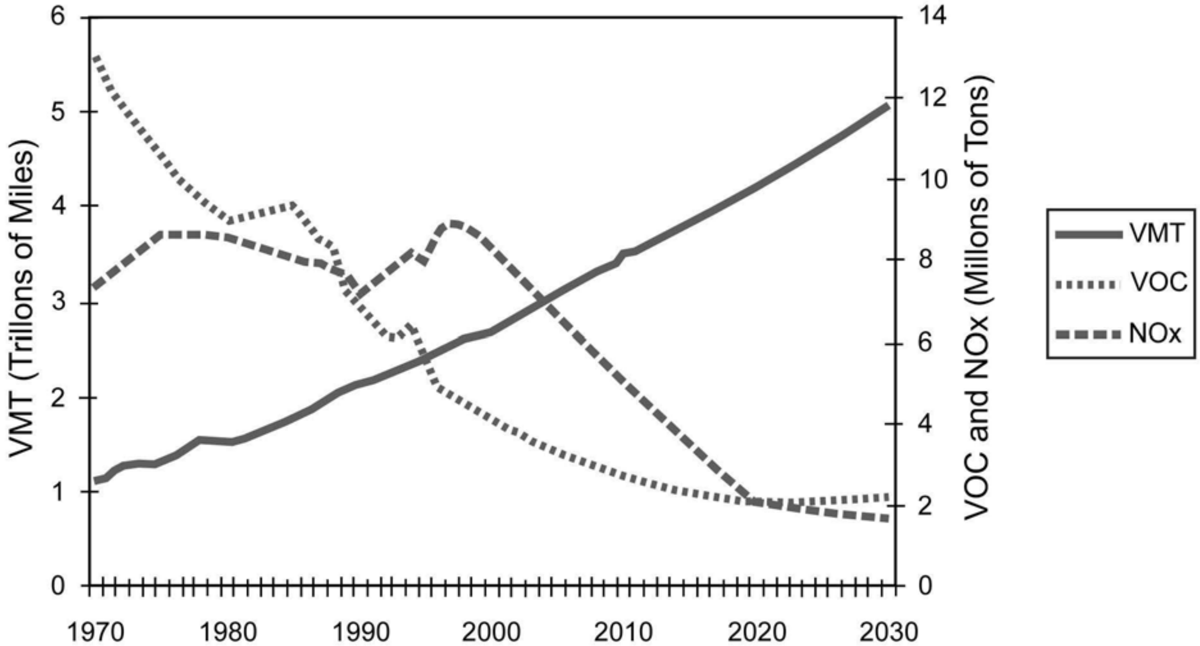
3.3.1.4 Clean Air Act and Conformity Regulations

3.3.1.4.1 Vehicle Emissions Standards

Under the CAA, EPA has established emissions standards for vehicles. EPA has tightened the emissions standards over time as more effective emission control technologies have become available. These reductions in the levels of the standards are responsible for the declines in total emissions from motor vehicles, as discussed above. The emissions standards that will apply to MY 2011-2015 passenger cars and light trucks were established by the EPA Tier 2 Vehicle & Gasoline Sulfur Program, which went into effect in 2004 (EPA 1999b). Under the Tier 2 standards, emissions from passenger cars and light trucks will continue to decline. In 2004, the Nation's refiners and importers of gasoline began to manufacture gasoline with sulfur levels capped at 300 ppm, approximately a 15-percent reduction from the previous industry average of 347 ppm. By 2006, refiners met a 30-ppm average sulfur level with a cap of 80 ppm. These fuels enable post-2006 model year vehicles to use emissions controls that reduce tailpipe emissions of NO_x by 77 percent for passenger cars and by as much as 95 percent for pickup trucks, vans, and SUVs compared to 2003 levels. Figure 3.3-1 shows that cleaner vehicles and fuels will result in continued reductions in emissions from passenger cars and light trucks, despite increases in travel. Figure 3.3-1 illustrates current trends in travel and emissions from passenger cars and light trucks under the current CAFE standards. Figure 3.3-1 does not show the effects of the alternatives, which are discussed in 3.3.3.

From 1970 to 1999, aggregate emissions traditionally associated with vehicles substantially decreased (with the exception of NO_x) even as vehicle miles traveled have increased by approximately 149 percent. NO_x emissions increased between 1970 and 1999 by 16 percent, due mainly to emissions from light-duty trucks and heavy-duty vehicles. However, as future trends show, vehicle travel is having a smaller and smaller impact on emissions as a result of stricter EPA standards for vehicle emissions and the chemical composition of fuels, even with additional growth in VMT (Smith 2002). This general trend will continue, to a greater or lesser degree, with implementation of any of the alternative CAFE standards.

Figure 3.3-1. Vehicle Miles Traveled (VMT) vs. Vehicle Emissions



EPA is addressing air toxics through its MSAT rules (EPA 2007c). These rules limit the benzene content of gasoline beginning in 2011. They also limit exhaust emissions of hydrocarbons (many VOCs and MSATs are hydrocarbons) from passenger cars and light trucks when they are operated at cold temperatures. The cold-temperature standard will be phased in from 2010 to 2015. The MSAT rules also adopt nationally the California evaporative emissions standards. EPA projects that these controls will substantially reduce emissions of acetaldehyde, acrolein, benzene, 1,3-butadiene, and formaldehyde.

3.3.1.4.2 Conformity Regulations

Section 176(c) of the CAA prohibits federal agencies from taking actions in nonattainment or maintenance areas that do not “conform” to the SIP. The purpose of this conformity requirement is to ensure that general activities do not interfere with meeting the emissions targets in the SIPs, do not cause or contribute to new violations of NAAQS, and do not impede the ability to attain or maintain NAAQS. The EPA has issued two sets of regulations to implement CAA Section 176(c):

- The Transportation Conformity Rules (40 CFR 51, Subpart T), which apply to transportation plans, programs, and projects funded under title 23 U.S.C. or the Federal Transit Act. Highway and transit infrastructure projects funded by FHWA or the Federal Transit Administration (FTA) usually are subject to transportation conformity.
- The General Conformity Rules (40 CFR 51, Subpart W) apply to all other federal actions not covered under transportation conformity. The General Conformity Rules established emissions thresholds, or *de minimis* levels, for use in evaluating the conformity of a project. If the net emissions increases due to the project are less than these thresholds, then the project is presumed to conform and no further conformity evaluation is required. If the emissions increases exceed any of these thresholds, then a conformity determination is required. The conformity determination can entail air quality modeling studies, consultation with EPA and

state air quality agencies, and commitments to revise the SIP or to implement measures to mitigate air quality impacts.

The CAFE standards and associated program activities are not funded under title 23 U.S.C. or the Federal Transit Act. Further, CAFE standards are established by NHTSA and are not an action undertaken by FHWA or FTA. Accordingly, the CAFE standards and associated rulemakings are not subject to transportation conformity.

The General Conformity Rules contain several exemptions applicable to federal actions, which the conformity regulations define as: "any activity engaged in by a department, agency, or instrumentality of the Federal Government, or any activity that a department, agency or instrumentality of the Federal Government supports in any way, provides financial assistance for, licenses, permits, or approves, other than activities [subject to transportation conformity]." 40 CFR 51.852. "Rulemaking and policy development and issuance" are exempted at 40 CFR 51.853(c)(2)(iii). Because NHTSA's CAFE standards involve a rulemaking process, NHTSA's action is exempt from general conformity. Also, emissions for which a federal agency does not have a "continuing program responsibility" are not considered "indirect emissions" subject to general conformity under 40 CFR 51.852. "Emissions that a Federal agency has a continuing program responsibility for means emissions that are specifically caused by an agency carrying out its authorities, and does not include emissions that occur due to subsequent activities, unless such activities are required by the Federal agency" (40 CFR 51.852). Emissions that occur as a result of the CAFE standards are not caused by NHTSA carrying out its statutory authorities and clearly occur due to subsequent activities, including vehicle manufacturers' production of passenger-car and light-truck fleets and consumer purchases and driving behavior. Thus, changes in any emissions that result from NHTSA's new CAFE standards are not those for which the agency has a "continuing program responsibility" and therefore a general conformity determination is not required. Nonetheless, NHTSA is evaluating the potential impacts of air emissions for the purposes of NEPA.

3.3.2 Methodology

3.3.2.1 Overview

NHTSA analyzed air quality impacts by calculating the emissions from passenger cars and light trucks that would occur under each alternative, and assessing the changes in emissions in relation to the No Action Alternative (Alternative 1). Many of the factors that affect air quality at any given location, such as meteorology and atmospheric processes, cannot be accounted for when evaluating human health and environmental impacts; such analysis cannot be performed without a full-scale photochemical air quality modeling analysis. NHTSA did not perform full-scale photochemical air quality modeling for this analysis; therefore, the FEIS does not characterize the ambient air quality impacts associated with each alternative. Full-scale photochemical air quality modeling is necessary to accurately project levels of $PM_{2.5}$, ozone, and air toxics. A national-scale air quality modeling analysis would analyze the combined impacts of each alternative on $PM_{2.5}$, ozone, and MSATs. The atmospheric chemistry related to ambient concentrations of $PM_{2.5}$, ozone, and air toxics is very complex, and making predictions based solely on emissions changes is extremely difficult. The analysis of the alternatives is predicated on the common-sense proposition that assessing emissions is a valid approach to assessing air quality impacts because emissions, ambient concentrations, and health effects are connected. Lower emissions should result in lower ambient concentrations of pollutants on an overall average basis, which should lead to decreased health effects of those pollutants.

The No Action Alternative consists of the existing CAFE standards with no changes in the future. The basic method used to estimate emissions entails multiplying activity levels of passenger cars and light trucks expressed as VMT, by emissions factors in grams of pollutant emitted per VMT. National emissions estimates were provided by the Volpe model. The Volpe model entails the EPA's MOBILE6.2 emissions factor model (EPA 2004d). MOBILE6.2 is EPA's required model for calculating emissions factors for onroad vehicles. In calculating emissions factors, MOBILE6.2 accounts for EPA's emission control requirements for passenger cars and light trucks, including exhaust (tailpipe) emissions, evaporative emissions, and the Tier 2 Vehicle & Gasoline Sulfur Program.

Higher CAFE standards would create an incentive to drive more because they would decrease the vehicle's fuel cost per mile. The total amount of passenger car and light truck VMT would increase slightly due to this "rebound effect." Emissions from passenger cars and light trucks would increase proportionately to the rebound effect. Although higher CAFE standards would decrease the total amount of fuel consumed despite the rebound effect, the decrease in fuel usage cannot be linked directly to any decrease in emissions. The EPA emissions standards and the NHTSA CAFE standards are separate sets of requirements and do not depend on each other. Vehicle manufacturers must meet both the EPA emissions standards and the CAFE standards simultaneously, but neither EPA nor NHTSA dictates the design and technology choices that manufacturers must make to comply. For example, a manufacturer could use a technique that increases fuel economy but also increases emissions, as long as the manufacturer's production still meets both the EPA emissions standards and the CAFE standards. For this reason, the air quality methodology does not assume any emissions benefits solely due to fuel economy improvements.

The new standards also would lead to reductions in "upstream" emissions, which are emissions associated with extraction, refining, storage, and distribution of the fuel. Upstream emissions would decrease with the new CAFE standards because the total amount of fuel used by passenger cars and light trucks would decrease. At the national scale, the reduction in upstream emissions would offset the rebound effect, resulting in a slight net decrease in emissions from passenger cars and light trucks.

While the rebound effect is assumed to affect all areas equally as a percentage of regional VMT, upstream emissions vary by region because fuel refining and storage facilities are not uniformly distributed across the country. An individual region could experience either a net increase or a net decrease in emissions due to the new CAFE standards. To assess regional differences in the effects of the alternatives, net emissions changes were calculated for individual nonattainment areas. Nonattainment areas were used because these are the regions in which are quality problems have been greatest. All nonattainment areas assessed were in nonattainment for ozone or $PM_{2.5}$ because these are the pollutants for which emissions from passenger cars and light trucks are of greatest concern. NHTSA did not quantify PM_{10} emissions separately from $PM_{2.5}$. The road-dust component of PM_{10} emissions from passenger cars and light trucks would increase in proportion to the rebound effect, but because almost all PM from vehicle exhaust consists of $PM_{2.5}$, the alternatives would have almost no effect on exhaust PM_{10}. There are no longer any nonattainment areas for annual PM_{10} because EPA revoked the annual PM_{10} standard.

3.3.2.2 Time Frames for Analysis

Ground-level concentrations of criteria and toxic air pollutants generally respond quickly to changes in emissions rates. The longest averaging period for NAAQS is 1 year. (The ozone and $PM_{2.5}$ NAAQS use annual averages over a 3-year period to account for meteorological variations). The air quality analysis considers the emissions that would occur over annual periods, consistent with NAAQS. Calendar years were selected that are meaningful for the timing of likely effects of the alternatives.

Passenger cars and light trucks remain in use for many years, so the change in emissions due to any change in the CAFE standards would also continue for many years. The influence of vehicles of a particular model year declines with age as vehicles are driven less or scrapped. The Volpe model defines vehicle lifetime as the point at which 2 percent of the vehicles originally produced in a model year survive. Under this definition, cars can survive in the fleet to 26 years of age and light trucks can survive to 37. Any individual vehicle might not necessarily survive to these ages. The survival of vehicles and the amount they are driven can be forecast with reasonable accuracy for a decade or two, while the influences of fuel prices and general economic conditions are less certain. To evaluate air quality impacts, specific years must be selected for which emissions will be estimated and effects calculated. The air quality analysis was conducted in two ways that affect the choice of analysis years: for the NEPA environmental consequences analysis, we assumed that the CAFE standards for MY 2011-2015 would remain in force indefinitely at the 2015 level. Potential CAFE standards for MY 2016-2020 were not included because they are not within the scope of this rulemaking. However, under NEPA, the analysis of cumulative impacts must include potential future actions that are "reasonably foreseeable." In the cumulative impacts analysis (Chapter 4) we included potential CAFE standards for MY 2016-2020 because they are considered a reasonably foreseeable action. With the potential MY 2016-2020 standards, model years after 2020 would continue to meet the MY 2020 standards.

The analysis years used in this FEIS and the rationales for each are listed below.

- 2015 – Required attainment date for most $PM_{2.5}$ nonattainment areas; first year of complete implementation of the MY 2011-2015 CAFE standards; year of highest overall emissions from passenger cars and light trucks following complete implementation.

- 2020 – Latest required attainment date for 8-hour ozone nonattainment areas (2020 is latest full year, as last attainment date is June 2021 for South Coast Air Basin, California); by this point a large proportion of passenger car and light truck VMT would be in vehicles that meet the MY 2011-2015 standards; first year of complete implementation of potential MY 2016-2020 CAFE standards (Section 4.3).

- 2025 – By this point, a large proportion of passenger car and light truck VMT would be in vehicles that meet the potential MY 2016-2020 standards.

- 2035 – By 2035, almost all passenger cars and light trucks in operation would meet at least the MY 2011-2015 standards and the impact of the standards would start to come only from VMT growth rather than further tightening of the standards. The impacts of the CAFE and EPA standards on a year-by-year basis by 2035 will change little from model year turnover, and most changes in emissions from year to year will come from the rebound effect. Year 2035 represents a reasonable limit to the ability to forecast important variables such as survival rates and mileage accrual rates of vehicles in the fleet, future EPA emissions standards, emission control technologies, and the emissions rates from vehicles. NHTSA believes the year 2035 is a practical maximum for impacts of criteria and toxic air pollutants to be considered reasonably foreseeable rather than speculative.

- 2100 – Used for climate change effects but not criteria and toxic air pollutants; NHTSA believes that given the current state of the science, the year 2100 is a practical maximum for impacts of climate change to be considered reasonably foreseeable rather than speculative.

3.3.2.3 Treatment of Incomplete or Unavailable Information

As noted above, the estimates of emissions rely on models and forecasts that contain numerous assumptions and data that are uncertain. Examples of areas in which information is incomplete or unavailable include future emissions rates, vehicle manufacturers' decisions on vehicle technology and design, the mix of vehicle types and model years, emissions from fuel refining and distribution, and economic factors. A full-scale photochemical air quality modeling analysis to estimate the ambient concentrations of PM, ozone, and air toxics was not conducted. The lack of air quality modeling data limited the conclusions that could be made about health and environmental impacts associated with each alternative. Instead, screening-level estimates of health outcomes in the form of cases per ton of criteria pollutant emissions reduced, and of monetized health benefits, in the form of dollars per ton of criteria pollutant emissions reduced, were used to approximate the health benefits associated with each alternative. The use of such dollars-per-ton numbers, however, does not account for all potential health and environmental benefits, which leads to an underestimate of total criteria pollutant benefits.

Where information in the analysis included in the FEIS is incomplete or unavailable, NHTSA has relied on CEQ regulations regarding incomplete or unavailable information. See 40 CFR § 1502.22(b). NHTSA has used the best available models and supporting data. The models used for the FEIS were subjected to scientific review and have received the approval of the agencies that sponsored their development. NHTSA believes that the FEIS assumptions regarding uncertain conditions reflect the best available information and are valid and sufficient for this analysis.

3.3.2.4 Allocation of Exhaust Emissions to Nonattainment Areas

The Volpe model provided national emissions estimates. The national emissions were allocated to the county level using VMT data and projected population for each county. Passenger car and light truck VMT was determined for all counties in the United States with data from the National County Database (NCD) included in the National Mobile Inventory Model (NMIM) (EPA 2006d). NMIM contains MOBILE6.2 and other models, and all parameters necessary to estimate on- and off-road mobile emissions in the United States. EPA uses NMIM in its rulemakings and NMIM is the best available tool for this purpose. The passenger car and light truck VMT data was queried from the NCD for all counties as the sum over all roadway types in each county, for all passenger-car and light-truck types included in MOBILE6.2. The VMT data used in the NCD were projected from traffic counts taken by counties and states on major roadways, and therefore are subject to some uncertainty. Most nonattainment areas comprise one or more counties, and because the county-level VMT are aggregated for each nonattainment, this uncertainty carries over to the estimates of VMT within each nonattainment area.

Over time, some counties will grow faster than others, and VMT growth rates will also vary. NTHSA accounted for differing growth rates by adjusting each county's fraction of national VMT according to United States Census population trends projected for 2007 through 2012 (the latest projection year available). Emissions for each county were calculated as national emissions times the population-adjusted fraction of national VMT that occurred in the county. This method assumes that population growth patterns across U.S. urban areas will follow 2007 through 2012 trends to 2035, and that per capita VMT will remain unchanged at the county level. For example, areas that currently are growing rapidly are assumed to continue to grow rapidly, and areas that currently have high per capita VMT are assumed to continue to have high per capita VMT. Because changes in urban growth patterns can alter driving behavior in an area, this adjustment introduces some uncertainty into the nonattainment area-level VMT estimates. This uncertainty increases as the projection period lengthens, such as analysis year 2035 compared to 2015. The adjusted VMT was used to derive the county-level emissions from the national emissions. From the county-level emissions, the emissions for each nonattainment area were derived by summing the emissions for the counties in each nonattainment area.

The geographical definitions of ozone and $PM_{2.5}$ nonattainment areas came from the current EPA Greenbook list (EPA 2008b). For nonattainment areas that include portions of counties, we calculated the proportion of county population that falls within the nonattainment area boundary as a proxy for the proportion of county VMT that occurs within the nonattainment area boundary. This method assumes that per capita VMT is constant within each county, so that the proportion of county population in the partial county area reflects the VMT in that area. Partial county boundaries were taken from geographic information system files based on 2006 nonattainment area definitions. In some cases, partial counties within nonattainment areas as currently defined were not included in the 2006 nonattainment areas. In those cases, we did not add any part of the missing counties' VMT to our nonattainment area totals, on the basis that partial counties added to nonattainment areas between 2006 and 2008 likely represent relatively small additions to total nonattainment area VMT. Several urban areas are in nonattainment for both ozone and $PM_{2.5}$. Where boundary areas differ between the two pollutants, we use the ozone nonattainment area boundary, which is larger in all cases.

Table 3.3-2 lists the current nonattainment and maintenance areas.

Table 3.3-2

Nonattainment Areas for Ozone and $PM_{2.5}$

	Classification a/		General Conformity Threshold b/

3.3.2.4.1 Allocation of Upstream Emissions to Nonattainment Areas

Upstream emissions from light-duty vehicles (LDV) are generated when fuel products are produced, processed, and transported. Upstream emissions are typically divided into four categories:

- Feedstock Recovery (petroleum extraction)
- Feedstock Transportation
- Fuel Refining
- Fuel Transportation, Storage, and Distribution (T&S&D)

Feedstock recovery refers to the extraction or production of fuel feedstocks. In the case of petroleum, this is the stage of crude oil extraction. During the next stage, feedstock transportation, crude oil is shipped to refineries. Fuel refining refers to the processing of crude oil into gasoline and diesel. T&S&D refers to the movement of gasoline and diesel from refineries to bulk terminals, storage at bulk terminals, and transportation of fuel from bulk terminals to retail outlets. Emissions of pollutants at each stage are associated with expenditure of energy and spillage and evaporation of fuel products.

The Greenhouse Gases, Regulated Emissions, and Energy Use in Transportation (GREET) model (Argonne 2002) estimates upstream emissions associated with various vehicle fuel pathways for light-duty vehicles in the United States. GREET includes various assumptions about the production and transportation of feedstocks and fuels. The model assumes that more than half of the crude oil supplied to U.S. refineries arrives by ocean tanker from foreign countries and Alaska. More than a third of crude oil is produced domestically. Once in the lower 48 states, almost all (92 percent) of crude oil is transported to refineries by pipeline.

The model assumes that nearly all (96 percent) of gasoline and diesel consumed in the United States comes from U.S. refineries. Around three quarters of that fuel is transported from refineries to bulk terminals by pipeline, an average distance of 400 miles. Smaller shares are transported by ocean tanker, barge, and rail. Fuel is transported from bulk terminals to retail outlets by truck an average distance of 30 miles. The current version of GREET does not account for the most recent EPA emissions standards for heavy trucks, locomotives, and marine vessels. For the analysis of upstream emissions, we updated the model inputs to account for the most recent EPA emissions standards. This update reduces the modeled upstream emissions from fuel transport, and therefore lessens the effect of the alternatives in reducing upstream emissions.

GREET and Volpe modeling provided changes in upstream emissions of NO_x, PM, VOCs, SO_x, and CO and four air toxics (acetaldehyde, benzene, butadiene, DPM, and formaldehyde) associated with the proposed action and alternatives. The Volpe model shows that nationwide upstream emissions would be reduced by all of the alternatives examined. Increasing the fuel economy of light duty vehicles will cause less fuel to be consumed, which will in turn reduce upstream emissions of criteria pollutants associated with feedstock and fuel production, processing, and transportation.

The analysis of upstream emissions considered only emissions occurring domestically and did not consider emissions occurring internationally, such as during transport of crude oil or refined gasoline to the United States. The upstream emissions data used in the GREET model assumed that, first, 50 percent of the fuel savings with the alternatives would reduce imports of refined gasoline, and therefore would reduce domestic emissions only during fuel T&S&D and would not reduce emissions from feedstock recovery, feedstock transportation, and fuel refining. Second, 90 percent of the reduction in domestic fuel refining reduces imports of crude petroleum (and therefore does not reduce domestic emissions from feedstock recovery and feedstock transportation), while only 10 percent reduces domestic production of crude petroleum (which does reduce domestic emissions from feedstock recovery and feedstock transportation). NHTSA estimated these percentages using several scenarios from EIA's *Annual Energy Outlook* (AEO) (EIA 2008a).

To analyze the impact of the alternatives on individual nonattainment areas, we allocated emissions reductions to geographic areas according to the following methodology:

- Feedstock Recovery – We assumed that little to no extraction of crude oil occurs in nonattainment areas. Of the top 50 highest producing oil fields in the United States, only nine are in nonattainment areas. These nine fields account for just 10 percent of domestic production, or 3 percent of total crude-oil imports and domestic production (EIA 2006, EIa 2008b). Therefore, NHTSA ignored emissions reductions from feedstock recovery in nonattainment areas.

- Feedstock Transportation – We assumed that little to no crude oil is transported through nonattainment areas. Most refineries are outside of, or on the outskirts of, urban areas. Crude oil is typically transported hundreds of miles from extraction points and ports to reach refineries. Most transportation is by ocean tanker and pipeline. Probably only a very small proportion of criteria pollutants emitted in the transport of crude oil occur in nonattainment areas. Therefore, NHTSA ignored emissions reductions from feedstock transportation in nonattainment areas.

- Fuel Refining – Fuel refining is the largest source of upstream emissions of criteria pollutants. Depending on the specific fuel and pollutant, fuel refining accounts for between one third and three quarters of all upstream emissions (based on outputs of the Volpe model). NHTSA compiled a list of all crude oil refineries in the United States along with their locations and refining capacity, and then calculated each nonattainment area's share of total nationwide refining capacity (NPRA 2008, EIA 2008e). It is assumed that fuel refining will decrease uniformly across all refineries nationwide as a result of the alternatives. For the nonattainment areas examined, we estimated the change in emissions from fuel refining as a share of the total national emissions, proportional to the area's share of national refining capacity.

- Fuel T&S&D – Based on the assumptions of the GREET model, we assume that most T&S&D emissions occur near the point of fuel sale and use. The pipelines that carry fuel from refineries to bulk hubs are a relatively low emissions mode. The trucks that carry the fuel to retail outlets are likely to be the largest source of emissions in this category. If the average distance a truck hauls the fuel is 30 miles, then the truck is likely to emit most criteria pollutants within the same airshed as that in which the fuel will be purchased and used. NHTSA used county-level light-duty VMT data from EPA's NMIM to estimate the proportion of national fuel demand in each nonattainment area, and population forecasts by county to account for likely shifts in demand in future years, as discussed above. Finally, we apportioned the national T&S&D emissions to nonattainment areas based on their total share of national fuel demand.

Because we ignore emissions changes from the first two upstream stages, our assumptions produce conservative estimates of emissions reductions in nonattainment areas.

For acetaldehyde, benzene, butadiene, and formaldehyde, the GREET modeling provided proportions of total upstream emissions by only two categories: feedstock recovery and transportation, and fuel refining and T&S&D. No split between emissions from fuel refining and emissions from T&S&D was provided. NHTSA assumed that all upstream emissions of these pollutants from fuel refining and T&S&D occur during fuel refining. This assumption results in over-assignment of emissions of these pollutants to nonattainment areas that have refineries and under-assignment of emissions to those that have none.

The GREET model also provided no information on upstream emissions of acrolein; therefore, we did not apply upstream emissions reductions for acrolein. As a result, the emissions of acrolein given in the FEIS are conservative (high) because they account only for the increase due to the rebound effect.

3.3.2.4.2 Health Outcomes and Costs

This section describes NHTSA's approach to addressing public comments on the need to provide more quantitative estimates of adverse health effects of conventional air pollutants associated with each alternative.

Adverse Health Impact Evaluation

The EPA *Report to Congress on The Benefits and Cost of the Clean Air Act 1990 to 2010* (EPA-410-R-99-001) (EPA 1999a) documents a quantitative assessment of air pollutant emissions impacts in 1990, 2000, and 2010 from implementation of the 1970 Clean Air Act, 1977 Amendments (CAAA), and the 1990 Amendments. The assessment includes air quality modeling of the impacts associated with and without implementation of the Clean Air Act and quantifying health-related outcomes on a nationwide basis. Appendix D of the EPA report to Congress describes the basis and methodology used to assess the impacts on human health from the effects of changes in criteria air pollutants. The study found substantial health benefits from implementation of the CAAA, especially as a consequence of reductions in fine particulate matter ($PM_{2.5}$). In particular, incidences of mortality, chronic bronchitis, and asthma are associated with changes in $PM_{2.5}$ concentrations. Thus, an approximation of changes in $PM_{2.5}$ emissions can be used to characterize impacts on the most adverse health effects for mortality, chronic bronchitis, emergency room visits for asthma, and work-loss days. Other health endpoints have more complex relationships, either with other pollutants or by undergoing non-linear atmospheric transformation processes, which would require air quality modeling, exposure modeling, and application of unit risk factors to assess final health impacts.

In EPA's report (Appendix D,[6] Table D-21) endpoint outcomes for mortality, chromic bronchitis, emergency room visits for asthma, and work-loss days are reported on a nationwide basis for 2010 for the 5^{th}, mean, and 95^{th} percentiles. The report also quantifies the nationwide changes in $PM_{2.5}$ from pre-CAAA and post-CAAA for 2010 by source category (utility, point, area, non-road, and on-road motor vehicle). Because the CAFE standards will impact emissions nationwide and the CAAA also acts nationwide, it is anticipated that spatial patterns of mobile source emissions will have similar spatial distributions. Thus, in this assessment we use this information from Table 2-3 from the EPA report for pre- and post-CAAA $PM_{2.5}$ emissions reduction changes from motor vehicles to estimate adverse health impacts from changes in motor vehicle $PM_{2.5}$ emissions. Table 2-3 shows that emissions of $PM_{2.5}$ are reduced by 90,000 tons per year with implementation of the CAAA and are 30 percent (90,000/300,000) of the total $PM_{2.5}$ emissions reduction. This fraction would then be used with the endpoint values in Table D-21 (*e.g.*, mean mortality end point, MME_{CAAA}, along with the emissions reductions between alternatives (*e.g.*, Alternative 1 [No Action] and Alternative 6 [Total Costs Equal Total Benefits], $PM_{2.5\ A1\text{-}A6}$) to determine the mean mortality endpoint between alternatives.

This can be expressed mathematically as:

$$MME_{CAAA} \times (0.30) \times (PM_{2.5\ A1\text{-}An}/90{,}000) = MME_{A1\text{-}An}$$

Where n refers to the each of the alternatives:

A1 is the No Action Alternative and
An is the alternative number.

For example, the mean mortality (number of deaths > 30 years of age) avoided in 2010 for post-CAAA versus pre-CAAA is 23,000 (see Table D-21). In 2035, Alternative 3 (Optimized) would reduce $PM_{2.5}$ emissions by 498 tons per year compared to Alternative 1 (No Action) (see Table 3.3-3 in Section 3.3.3.2.1). Then the number of deaths avoided with Alternative 3 is (23,000) x (0.30) x (498/90,000) = 38.

This procedure is applied for each year analyzed (2015, 2020, 2025, and 2035) for each alternative for the mean health outcome, which provides an estimate of the credible interval of the number of avoided cases for each endpoint.

[6] The approach used in this study followed the design of EPA's retrospective Section 812 study (EPA 1997b) using a sequence of linked analytical models (emissions, air quality, and health benefits) to estimate benefits. The most important aspects of the health benefit analysis are the forecasted change in pollutant concentrations over the study period and the concentration response functions that quantify the relationship between the forecasted changes in exposure and expected change in specific health outcomes. Further details on the underlying assumptions and uncertainty in the pre- and post-CAAA scenarios are discussed in Appendix A (emissions), Appendix C (air quality models) and Appendix D (health benefit models) in EPA (1999a).

Underlying Assumptions

The assumptions used in the analysis are based on extrapolation of the EPA 1999b health impact numbers to this analysis:

- That motor vehicle related changes pre- and post-CAAA have the same spatial distribution in motor vehicle emissions as in the FEIS.
- That the health effects scale linearly with the emissions and that the PM health effects are attributable to primary $PM_{2.5}$ emissions. This is conservative because the secondary PM formation is responsible for a portion of the $PM_{2.5}$. Also, not considering the associated reductions in other air pollutants in the CAAA study might underestimate the health benefits of the CAAA reductions.
- That at least for $PM_{2.5}$ we can assign the pre-CAAA and post-CAAA motor vehicle emissions proportionately to the other source categories. This is a reasonable assumption because nearly all of the $PM_{2.5}$ in 2010 pre- and post-CAAA is from on-road, non-road, and area sources. These are generally low-level sources close to populations.
- The population distribution across the United States is the same now as it was when the analysis was done for the CAAA report, and the future population projections would be the same (because the change in incidence is calculated for each population grid cell).
- The baseline mortality and respiratory disease rate have remained the same. The prior analysis used county-specific incidence rates and national incidence rates, and baseline incidence rates from the health studies.
- That the CAAA analysis assumed that the concentration-response (C-R) relationships should only be applied to those subpopulations matching the original study population. This might underestimate the whole population benefits of reductions in pollutant exposures.

Although more recent data are available on air pollution and mortality effects, the studies used here are generally considered to be appropriate for air quality impact analysis. These studies have been used in other EPA documents published since 1999, in analyses for the private sector, and by international health agencies.

Economic Impacts Evaluation

The EPA Office of Transportation and Air Quality (OTAQ) funded a study (EPA 2003) that examined the economic impacts from future changes in VMT. The study looked at 10-percent increase and 10-percent decrease in VMT nationwide, and evaluated the economic costs through air quality modeling of emissions changes in the motor vehicle fleet. The study examined the economic impacts from changes in ambient PM concentrations and ozone. The study looked at target years 2015, 2020, and earlier years. For this analysis, we use 2015 and 2020 and the associated economic impacts associated with a 10-percent decrease in VMT for 2015 and 2020 associated with the air quality impacts on ozone and particulate matter. The associated changes in air emissions from the study are available for on-road motor vehicles for 2015 and 2020.

Table 3-2 of the OTAQ study (EPA 2003) provides an estimate of the daily average emissions changes for NO_x, VOCs, SO_2 and $PM_{2.5}$ for all on-road vehicles separated into light and heavy-duty vehicles. The study developed an ACCESS™-database display tool that has information on a wide variety of economic scenarios, including the economic costs over the entire U.S. modeling domain for each analysis year. This information, in conjunction with the emissions changes calculated from Table 3.2 of the OTAQ report can be used to estimate the economic impacts for each of the alternative emissions changes in the FEIS (see Table 3.3-4) in a manner analogous to the health impact assessment. However, because the economic impacts from the EPA/OTAQ study are only available for ozone and particulate matter, an assumption was made as to the emissions contribution from each of the major emissions types: SO_2, VOCs, NO_x, $PM_{2.5}$, and NO_x. For ozone, the principal precursors are NO_x and VOCs. EPA's policy for addressing $PM_{2.5}$ concentrations is to include the precursor emissions of NO_x, $PM_{2.5}$, and SO_2 (EPA 2007a). As a first approximation, we split the emissions change for NO_x equally between ozone and PM formation. This enables an economic impact analysis for each alternative for each year and can be expressed mathematically for ozone as:

$$E_{A1\text{-}An,\ YYYY,\ O3} = (0.5*NOX_{A1\text{-}An,\ YYYY} + VOC_{A1\text{-}An,YYYY})/(0.5*NOX_{-10\%,YYYY} + VOC_{-10\%,YYYY}) * E_{-10\%,YYYY,O3}$$

Where:

E = dollar value of economic impact in year 2000 dollars
A1 = Alternative 1 (No Action)
An = the alternative number
VOC = emissions rate for volatile organic compounds
NO_x = emissions rate for nitrogen oxides
O_3 = ozone
YYYY = analysis year
10% = 10 percent reduction scenario

So for example, in 2020, the 10-percent VMT reduction in the EPA/OTAQ study found a 12.73 million dollar economic improvement. The sum of one-half NO_x emissions and VOCs for the EPA/OTAQ study is 2,281 tons per day, while the sum of one-half NO_x emissions and VOCs for Alternative 1 (No Action) versus Alternative 3 (Optimized) in 2020 High Scenario cumulative is only 206 tons per day. Thus, the economic impact between Alternative 1 and Alternative 3 can be determined as follows:

$$(206)/(2{,}281) \times (12.73 \text{ million dollars}) = 1.15 \text{ million dollars}$$

This same procedure is applied for 2015 and a similar approach is used to estimate the impacts for 2025 and 2035, but with the base year emissions based on the best available future year of 2020 year.

The same approach can be applied for $PM_{2.5}$, but instead of VOCs, both SO_2 and $PM_{2.5}$ emissions are added. Expressed mathematically,

$$E_{A1\text{-}An,\ YYYY,\ PM2.5} = (0.5*NOX_{A1\text{-}An,\ YYYY} + SO_{2A1\text{-}An,YYYY} + PM_{2.5A1\text{-}An,YYYY})/(0.5*NOX_{-10\%,YYYY} + SO_{2\text{-}10\%,YYYY} + PM_{2.5\text{-}10\%,YYYY}) * E_{-10\%,YYYY,,PM2.5}$$

Where:

E = dollar value of economic impact in year 2000 dollars
A1 = Alternative 1 (No Action)
An = the alternative number
$PM_{2.5}$ = emissions rate for particulate matter less than 2.5 microns

SO_2 = emissions rate for sulfur dioxide
NO_x = emissions rates for nitrogen oxides
YYYY = analysis year
10% = 10 percent reduction scenario

Underlying Assumptions

The assumptions used in the analysis are based on the EPA/OTAQ 2003 social costs of air pollution analysis, as follows:

- That motor vehicle emissions changes from the 10-percent reduction in VMT are spatially distributed the same in the FEIS. This assumes that the VMT reductions are spread equally as a percent reduction of baseline VMT and that the fuel economy improvements are approximately proportional to the VMT.
- That the economic effects scale linearly with the emissions changes.
- That the ozone and particulate matter changes capture the economic effects that emissions contribution for ozone is principally from NO_x and VOCs, that the important precursor for $PM_{2.5}$ is the emissions of NO_x, and SO_2, and as a first approximation, that the emissions change for NO_x is equal between ozone and PM formation.
- The population distribution across the United States is the same now as it was when the analysis was done for the EPA/OTAQ study and the future population projections would be the same.
- The 10-percent change in VMT is assumed proportionality to the vehicle emissions change. This is not strictly true, because emissions associated with different vehicle classes do vary within each class, but these changes are relatively small.
- Assuming linear scaling of emissions with only a 10-percent reduction in VMT allows an estimate of the associated economic impact, assuming linear economic effects.
- That the concentration-response (C-R) functions as used in the EPA/OTAQ and Abt Associates (2001) are appropriate for the FEIS. Both studies focus on changes in motor vehicle emissions, so C-R functions should behave similarly.
- The unit dollar values of the economic endpoints used in the EPA/OTAQ study for the value of a statistical life, willingness to pay to reduce chronic bronchitis, value of hospital admissions due to respiratory problems, and other respiratory ailments not causing hospital admissions.

3.3.3 Environmental Consequences

3.3.3.1 Results of the Emissions Analysis

The CAA has been a success in reducing emissions from on-road mobile sources. As discussed in Section 3.3.1, pollutant emissions from vehicles have been declining since 1970 and EPA projects that they will continue to decline. However, as future trends show, vehicle travel is having a smaller and smaller impact on emissions as a result of stricter EPA standards for vehicle emissions and the chemical composition of fuels, even with additional growth in VMT (Smith 2002). This general trend will continue, to a greater or lesser degree, with implementation of any of the alternative CAFE standards. The analysis by alternative in this section shows that the alternative CAFE standards will lead to both reductions and increases in emissions from passenger cars and light trucks, compared to current trends without the alternative CAFE standards. The amounts of the reductions and increases would vary by pollutant, calendar year, and alternative CAFE standard. The more restrictive alternatives generally would result in greater emissions reductions compared to the No Action Alternative. Under some of the action alternatives there would be emissions increases that would exceed the general conformity thresholds in some nonattainment areas.

Sections 3.3.3.2 through 3.3.3.8 describe the results of the emissions analysis for Alternatives 1 through 7 for the Reference Case.

3.3.3.2 Reference Case Alternative 1: No Action

3.3.3.2.1 Criteria Pollutants

With the No Action Alternative, the CAFE standards would remain at the MY 2010 level in future years. Current trends in the levels of emissions from vehicles would continue, with emissions continuing to decline due to the EPA emissions standards, despite a growth in total VMT. The EPA vehicle emissions standards regulate all criteria pollutants except SO_2, which is regulated through fuel sulfur content. The No Action Alternative would not change the current CAFE standards and so would not result in any change in criteria pollutant emissions, other than current trends, in nonattainment and maintenance areas throughout the United States.

Table 3.3-3 summarizes the total national emissions from passenger cars and light trucks for the No Action Alternative for each of the criteria pollutants and analysis years. The action alternatives (Alternatives 2 through 7) are presented left to right in order of increasing fuel economy requirements. Figure 3.3-2 illustrates this information graphically. Table 3.3-3 and Figure 3.3-2 show that emissions change very little between the No Action Alternative and Alternatives 2 and 3. In the case of PM, SO_X, NO_x, and VOC, the No Action Alternative results in the highest emissions. Emissions of PM, SO_X, NO_x, and VOC generally decline as fuel economy standards increase across alternatives. In the case of CO, emissions under Alternative 2 or 3 are slightly higher than under the No Action Alternative. Emissions of CO decline as fuel economy standards increase across Alternatives 4 through 7.

Table 3.3-3

Reference Case Alternative CAFE Standards
Nationwide Criteria Pollutant Emissions from Passenger Cars and Light Trucks (tons/year)

Pollutant and Year	Alt. 1	Alt. 2	Alt. 3	Alt. 4	Alt. 5	Alt. 6	Alt. 7

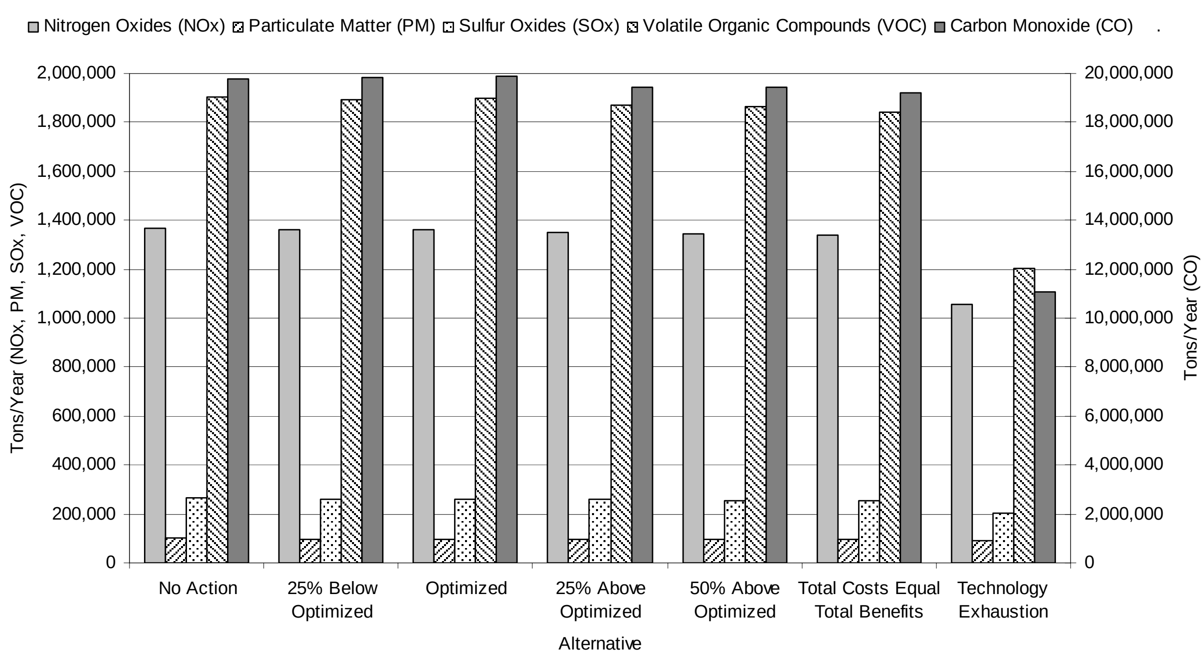
Figure 3.3-2. Reference Case Alternative CAFE Standards Nationwide Criteria Pollutant Emissions from Passenger Cars and Light Trucks for 2035 (tons/year)



Total emissions are composed of four components: tailpipe emissions and upstream emissions for light duty vehicles, and tailpipe emissions and upstream emissions for light-duty trucks. To show the relationship among these four components for criteria pollutants, Table 3.3-4 breaks down the total emissions of criteria pollutants by component for calendar year 2035.

Table 3.3-5 lists the net change in nationwide emissions from passenger cars and light trucks for the No Action Alternative for each of the criteria pollutants and analysis years. The table presents the action alternatives (Alternatives 2 through 7) left to right in order of increasing fuel economy requirements. In Table 3.3-5 the nationwide emissions reductions generally become greater from left to right, reflecting the increasing fuel economy requirements that are assumed under successive alternatives. Emissions of CO under Alternatives 2 and 3 are exceptions, showing increases compared to the No Action Alternative.

2035	0	-11,721	-9,847	-36,613	-42,768	-61,839	-700,397

a/ Emissions changes have been rounded to the nearest whole number.
b/ Negative emissions changes indicate reductions; positive emissions changes are increases.
c/ Emissions changes for the No Action Alternative are shown as zero because the No Action Alternative is the baseline to which the emissions for the other alternatives are compared.

3.3.3.2.2 Air Toxics

Under Alternative 1, No Action, the CAFE standards would remain at the MY 2010 level in future years. As with the criteria pollutants, current trends in the levels of air toxics emissions from vehicles would continue, with emissions continuing to decline due to the EPA emissions standards, despite a growth in total VMT. An exception to this general trend is DPM, for which emissions are projected to increase over time with the No Action Alternative. Also, the trends of declining emissions of benzene and formaldehyde are projected to reverse by 2035 absent other regulatory action, although emissions of benzene and formaldehyde in 2035 with the No Action Alternative will still be well below existing levels. The EPA regulates air toxics from motor vehicles through vehicle emissions standards and fuel quality standards, as discussed in Section 3.3.1. The No Action Alternative would not change the current CAFE standards and therefore would not result in any change in toxic air pollutant emissions, other than current trends, in nonattainment and maintenance areas throughout the United States.

Table 3.3-6 summarizes the total national emissions of air toxics from passenger cars and light trucks under the No Action Alternative for each of the pollutants and analysis years. Figure 3.3-3 lists the total national emissions of air toxics from passenger cars and light trucks by alternative. Emissions of benzene, 1,3-butadiene, and DPM are generally highest with the No Action Alternative and decrease with successive alternatives as fuel economy requirements increase. Emissions of formaldehyde, on the other hand, generally increase with successive alternatives and are highest with Alternative 7. The trend for acetaldehyde across the alternatives is mixed. Table 3.3-6 shows increases for acrolein generally with successive alternatives because data on upstream emissions reductions were not available. The emissions for acrolein in Table 3.3-6 reflect only the changes due to the rebound effect and technological changes

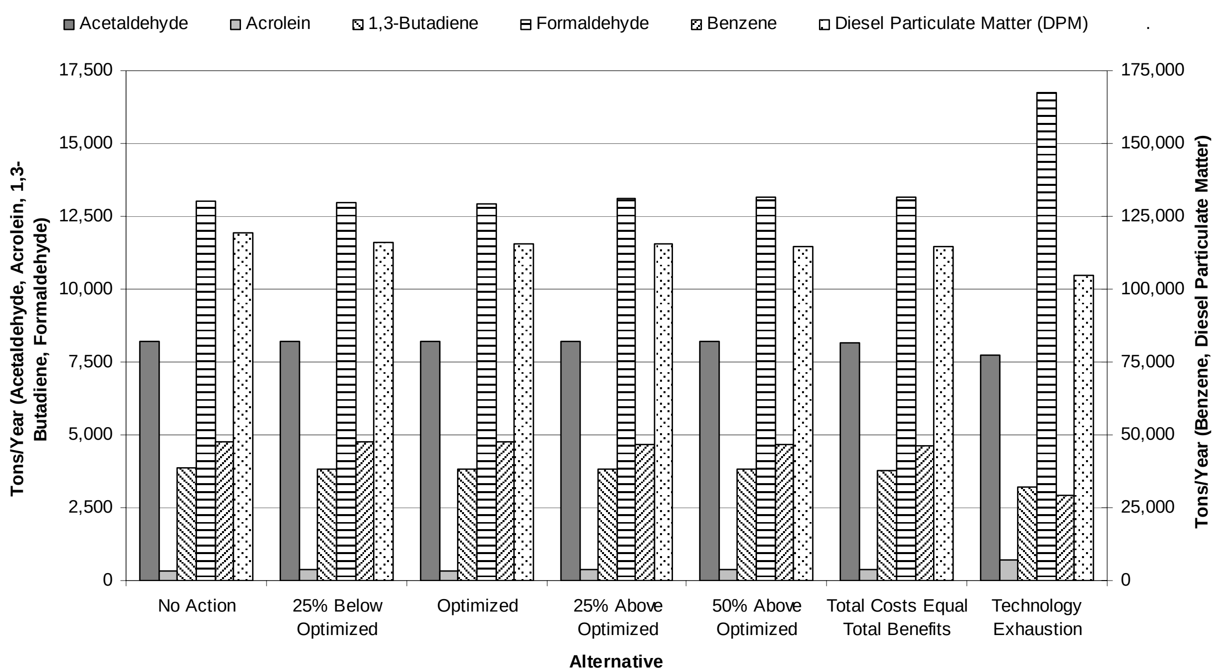
a/ Data on upstream emissions reductions were not available for acrolein. Thus, the emissions for acrolein reflect only the change in tailpipe emissions.

Figure 3.3-3. Reference Case Alternative CAFE Standards Nationwide Toxic Air Pollutant Emissions from Passenger Cars and Light Trucks for 2035 (tons/year)



analyzed in the Volpe model. Because the upstream emissions reductions result from the decline in the amount of fuel processed, it is reasonable that upstream acrolein emissions actually should vary as the other pollutants' upstream emissions do. Thus, the acrolein emissions given in Table 3.3-6 are an upper-bound estimate.

Total emissions are composed of four components: tailpipe emissions and upstream emissions for light duty vehicles, and tailpipe emissions and upstream emissions for light-duty trucks. To show the relationship among these four components for toxic air pollutants, Table 3.3-7 breaks down the total emissions of toxic air pollutants by component for calendar year 2035. The unavailability of data on upstream emissions of acrolein, as discussed in relation to Table 3.3-6, is evident in the zero values reported for upstream acrolein emissions in Table 3.3-7.

Table 3.3-8 lists the net change in nationwide emissions from passenger cars and light trucks for each of the air toxic pollutants and analysis years. After the No Action Alternative (Alternative 1), the action alternatives (Alternatives 2 through 7) are presented left to right in order of increasing fuel economy requirements. In Table 3.3-8, the nationwide emissions changes are uneven with respect to pollutant and alternative though most demonstrate reductions, reflecting the changes in VMT and emissions by cars versus trucks and gasoline versus diesel engines that are projected to occur with the increasing fuel economy requirements assumed under successive alternatives. Data on upstream emissions reductions were not available for acrolein, as noted above. Thus, the acrolein emissions changes given in Table 3.3-8 are an upper-bound estimate.

2035	0	-86	-120	87	106	133	3,709

a/ Emissions changes have been rounded to the nearest whole number.
b/ Negative emissions changes indicate reductions; positive emissions changes are increases.
c/ Emissions changes for the No Action Alternative are shown as zero because the No Action Alternative is the baseline to which emissions from the action alternatives are compared.
d/ Data on upstream emissions reductions were not available for acrolein. Thus, the emissions for acrolein reflect only the change in tailpipe emissions.

3.3.3.2.3 Health Outcomes and Costs

Under Alternative 1, No Action, the CAFE standards would remain at the MY 2010 level in future years. Current trends in the levels of criteria pollutants and air toxics emissions from vehicles would continue, with emissions continuing to decline due to the EPA emissions standards, despite a growth in total VMT. The human health effects and health-related costs that occur under current trends would continue, and are expected to decline in the future as a result of declines in pollutant emissions. The No Action Alternative would not result in any other increase or decrease in human health effects and health-related costs throughout the United States.

3.3.3.3 Reference Case Alternative 2: 25 Percent Below Optimized

3.3.3.3.1 Criteria Pollutants

Under the 25 Percent Below Optimized Alternative (Alternative 2), generally the CAFE standards would require increased fuel economy compared to the No Action Alternative (Alternative 1). Alternative 2 would increase fuel economy less than would Alternatives 3 through 7. There would be reductions in nationwide emissions of NO_x, $PM_{2.5}$, SO_x, and VOC under Alternative 2 compared to the No Action Alternative. Depending on the year, NO_x emissions would be reduced 0.1 to 0.7 percent, $PM_{2.5}$ emissions would be reduced 0.2 to 1.0 percent, SO_x emissions would be reduced 0.5 to 2.4 percent, and VOC emissions would be reduced 0.1 to 0.6 percent. There would be increases of CO emissions. CO emissions would increase 0.1 to 1.3 percent with Alternative 2 depending on the year.

At the nationwide level, the reduction in upstream emissions of criteria air pollutants tends to offset the increase in VMT and emissions due to the rebound effect. However, the reductions in upstream emissions are not uniformly distributed to individual nonattainment areas. For example, a nonattainment area that contains petroleum refining facilities, such as Houston-Galveston-Brazoria, Texas, would experience more reductions in upstream emissions than an area that has none. Net emissions reductions can occur if the reduction in upstream emissions in the nonattainment area more than offsets the increase within the area due to the rebound effect. With Alternative 2, all nonattainment areas would experience reductions in emissions of NO_x, SO_x and VOC. Most nonattainment areas would experience increases of CO and $PM_{2.5}$ emissions. The increases in CO and $PM_{2.5}$ emissions are the result of increased tailpipe emissions due to the rebound effect. Although $PM_{2.5}$ emissions would increase in most nonattainment areas the increase in each area is quite small. The decreases in nationwide $PM_{2.5}$ emissions are the result of the decreases in upstream emissions and do not occur in all nonattainment areas. Although $PM_{2.5}$ emissions would decrease in fewer nonattainment areas the decreases in each area are much larger. The net result is decreased $PM_{2.5}$ emissions nationwide.

Tables in Appendix B-2 list the emissions reductions for each nonattainment area. Table 3.3-9 summarizes the criteria air pollutant results by nonattainment area.

Table 3.3-9

Reference Case Alternative CAFE Standards
Changes in Criteria Pollutant Emissions from Passenger Cars and Light Trucks,
Maximum Changes by Nonattainment Area a/

Criteria Pollutant	Increase/ Decrease	Change (tons/year)	Year	Alt. No.	Nonattainment Area
CO	Maximum Increase	5,956	2035	3	Los Angeles South Coast Air Basin, CA
	Maximum Decrease	-432,141	2035	7	Los Angeles South Coast Air Basin, CA
NO_x	Maximum Increase	1	2035	3	Charlotte-Gastonia-Rock Hill, NC-SC
	Maximum Decrease	-16,115	2035	7	Los Angeles South Coast Air Basin, CA
$PM_{2.5}$	Maximum Increase	62	2035	7	Atlanta, GA
	Maximum Decrease	-1,344	2035	7	Houston-Galveston-Brazoria, TX
SO_x	Maximum Increase	No SO_x increases			
	Maximum Decrease	-5,624	2035	7	Houston-Galveston-Brazoria, TX
VOCs	Maximum Increase	No VOC increases			
	Maximum Decrease	-35,062	2035	7	Los Angeles South Coast Air Basin, CA

a/ Emissions changes have been rounded to the nearest whole number.

3.3.3.3.2 Air Toxics

There would be reductions in nationwide emissions of all toxic air pollutants (except acrolein) under Alternative 2 compared to the No Action Alternative.

Alternative 2 would have the same or higher emissions of acetaldehyde, acrolein, 1,3-butadiene, DPM, and formaldehyde, but lower emissions of benzene, compared to Alternative 3. Compared to Alternatives 4 through 7, Alternative 2 would have higher emissions of benzene, 1,3-butadiene (except in 2015), and DPM, but lower emissions of acrolein and formaldehyde, and mixed results for acetaldehyde depending on the year and alternative. At the nationwide level, the reduction in upstream emissions of toxic air pollutants tends to offset the increase in VMT and emissions due to the rebound effect. However, as noted above, the reductions in upstream emissions are not uniformly distributed to individual nonattainment areas. For example, a nonattainment area that contains petroleum refining facilities, such as Houston-Galveston-Brazoria, Texas, would experience more reductions in upstream emissions than an area that has none. Net emissions reductions can occur if the reduction in upstream emissions in the nonattainment area more than offsets the increase within the area due to the rebound effect.

Under Alternative 2, many nonattainment areas would experience net increases in emissions of one or more toxic air pollutants in at least one of the analysis years (see Appendix B-2). However, the sizes of the emissions increases would be quite small, as shown in Appendix B-2, and emissions increases would be distributed throughout each nonattainment area.

3.3.3.3.3 Health Outcomes and Costs

There would be reductions in adverse health effects nationwide under Alternative 2 compared to the No Action Alternative (see Table 3.3-10). These reductions primarily reflect the projected $PM_{2.5}$ reductions, because $PM_{2.5}$ tends to be the largest contributor to adverse health effects. In comparison to the No Action Alternative, Alternative 2 would reduce mortalities by 78 and the number of work-loss days by 13,877 in 2035. Data are not available to estimate reliably the number of adverse health effects due to the other pollutants. Table 3.3-11 lists the corresponding reductions in health costs under Alternative 2 compared to the No Action Alternative. Alternative 2 would reduce health costs by $173 million in 2035.

2035	0	-173	-179	-307	-349	-435	-3,329

a/ Negative changes indicate economic benefit; positive emissions changes are economic costs.
b/ Changes for the No Action Alternative are shown as zero because the No Action Alternative is the baseline to which emissions under the action alternatives are compared.

3.3.3.4 Reference Case Alternative 3: Optimized

3.3.3.4.1 Criteria Pollutants

Under the Optimized Alternative (Alternative 3), generally the CAFE standards would increase fuel economy more than would Alternative 2 but less than would Alternatives 4 through 7. There would be reductions in nationwide emissions of NO_x, $PM_{2.5}$, SO_x, and VOC under Alternative 3 compared to the No Action Alternative. Depending on the year, NO_x emissions would be reduced 0.1 to 0.6 percent,

$PM_{2.5}$ emissions would be reduced 0.2 to 1.1 percent SO_x emissions would be reduced 0.5 to 2.6 percent, and VOC emissions would be reduced 0.1 to 0.5 percent. These emissions reductions are generally greater (except for VOC) than would occur with Alternative 2 but less than would occur with Alternatives 4 through 7. There would be increases of CO emissions. CO emissions would increase 0.1 to 0.6 percent depending on the year. With Alternative 3, all nonattainment areas would experience reductions in emissions of SO_x and VOC, and almost all would experience reductions in NO_x emissions. Most nonattainment areas would experience increases of CO and $PM_{2.5}$ emissions. The increases in CO and $PM_{2.5}$ emissions are the result of increased tailpipe emissions due to the rebound effect. Although $PM_{2.5}$ emissions would increase in most nonattainment areas the increase in each area is quite small. The decreases in nationwide $PM_{2.5}$ emissions are the result of the decreases in upstream emissions and do not occur in all nonattainment areas. Although $PM_{2.5}$ emissions would decrease in fewer nonattainment areas the decreases in each area are much larger. The net result is decreased $PM_{2.5}$ emissions nationwide.

Tables in Appendix B-2 list the emissions reductions for each nonattainment area. Table 3.3-12 summaries the criteria air pollutant results by nonattainment area.

Table 3.3-12

Reference Case Alternative CAFE Standards
Changes in Toxic Air Pollutant Emissions from Passenger Cars and Light Trucks, Maximum Changes by Nonattainment Area

Hazardous Air Pollutant	Increase/Decrease	Change (tons/year)	Year	Alt. No.	Nonattainment Area
Acetaldehyde	Maximum increase	11	2020	7	New York-N. New Jersey-Long Island, NY-NJ-CT
	Maximum decrease	-41	2035	7	Houston-Galveston-Brazoria, TX
Acrolein	Maximum increase	18	2035	7	Los Angeles South Coast Air Basin, CA
	Maximum decrease	-0.02	2015	3	Los Angeles South Coast Air Basin, CA
Benzene	Maximum increase	7	2035	3	Atlanta, GA
	Maximum decrease	-960	2035	7	Los Angeles South Coast Air Basin, CA
1,3-butadiene	Maximum increase	1	2015	7	New York-N. New Jersey-Long Island, NY-NJ-CT
	Maximum decrease	-35	2035	7	Los Angeles South Coast Air Basin, CA
Diesel particulate matter	Maximum increase	No increase			
	Maximum decrease	-697	2035	7	Los Angeles South Coast Air Basin, CA
Formaldehyde	Maximum increase	161	2035	7	Los Angeles South Coast Air Basin, CA
	Maximum decrease	-72	2035	7	Houston-Galveston-Brazoria, TX

a/ Emissions changes have been rounded to the nearest whole number except to present values greater than zero but less than one.

3.3.3.4.2 Air Toxics

Alternative 3 would reduce air toxics emissions compared to the No Action Alternative for all air toxics (except acrolein in all analysis years and benzene in 2035). Alternative 3 would have higher emissions of benzene, 1,3-butadiene (except in 2015), and DPM compared to Alternatives 4 through 7. Alternative 3 would have lower emissions of acrolein and formaldehyde compared to Alternatives 4 through 7, and mixed results for acetaldehyde depending on the year and alternative.

At the nationwide level, emissions of toxic air pollutants can decrease because the reduction in upstream emissions more than offsets the increase in VMT and emissions due to the rebound effect.

However, as with Alternative 2, the reductions in upstream emissions are not uniformly distributed to individual nonattainment areas. Under Alternative 3, many nonattainment areas would experience net increases in emissions of one or more toxic air pollutants in at least one of the analysis years (see Appendix B-2). However, the sizes of the emissions increases would be quite small, as shown in Appendix B-2, and emissions increases would be distributed throughout each nonattainment area.

3.3.3.4.3 Health Outcomes and Costs

There would be reductions in adverse health effects nationwide with the Optimized Alternative compared to the No Action Alternative, as shown in Table 3.3-10. These reductions primarily reflect the projected $PM_{2.5}$ reductions, because $PM_{2.5}$ tends to be the largest contributor to adverse health effects. In comparison to the No Action Alternative, Alternative 3 would reduce mortalities by 83 and the number of work-loss days by 14,789 in 2035. Data are not available to estimate reliably the number of adverse health effects due to the other pollutants. Table 3.3-11 lists the corresponding reductions in health costs under Alternative 3 compared to the No Action Alternative. Alternative 3 would reduce health costs by $179 million in 2035.

3.3.3.5 Reference Case Alternative 4: 25 Percent Above Optimized

3.3.3.5.1 Criteria Pollutants

Under the 25 Percent Above Optimized Alternative (Alternative 4), the CAFE standards would increase fuel economy more than would Alternatives 1 through 3 but less than would Alternatives 5 through 7. There would be reductions in nationwide emissions of all criteria pollutants under Alternative 4. Percent reductions would range from 0.1 to 3.2, depending on the year and pollutant. These emissions reductions are greater than would occur with Alternative 3 but less than would occur with Alternatives 5 through 7. With Alternative 4, all nonattainment areas would experience reductions in emissions of CO, NO_x, SO_x and VOC. Most nonattainment areas would experience increases of $PM_{2.5}$ emissions in 2015 and 2020 compared to the No Action Alternative. Tables in Appendix B-2 list the emissions reductions for each nonattainment area.

3.3.3.5.2 Air Toxics

Alternative 4 would reduce air toxics emissions of acetaldehyde (in 2035), benzene, 1,3-butadiene, and DPM, but would increase emissions of acetaldehyde (except in 2035), acrolein, and formaldehyde compared to the No Action Alternative.

Alternative 4 would have higher emissions of benzene, 1,3-butadiene (except in 2015), and DPM compared to Alternatives 5 through 7. Alternative 4 would have lower emissions of acrolein and formaldehyde compared to Alternatives 5 through 7, and mixed results for acetaldehyde depending on the year and alternative.

At the nationwide level, emissions of toxic air pollutants might decrease, because the reduction in upstream emissions more than offsets the increase in VMT and emissions due to the rebound effect. However, as with Alternative 3, the reductions in upstream emissions are not uniformly distributed to individual nonattainment areas. Under Alternative 4, many nonattainment areas would experience net increases in emissions of one or more toxic air pollutants in at least one of the analysis years (see Appendix B-2). However, the sizes of the emissions increases would be quite small, as shown in Appendix B-2. Potential air quality impacts from these increases would be minor, because the VMT and emissions increases would be distributed throughout each nonattainment area.

3.3.3.5.3 Health Outcomes and Costs

There would be reductions in adverse health effects nationwide under Alternative 4 compared to the No Action Alternative, as shown in Table 3.3-10. These reductions primarily reflect the projected $PM_{2.5}$ reductions, because $PM_{2.5}$ tends to be the largest contributor to adverse health effects. In comparison to the No Action Alternative, Alternative 4 would reduce mortalities by 126 and the number of work-loss days by 22,456 in 2035. Data are not available to estimate reliably the number of adverse health effects due to the other pollutants. Table 3.3-11 lists the corresponding reductions in health costs under Alternative 4 compared to the No Action Alternative. Alternative 4 would reduce health costs by $307 million in 2035.

3.3.3.6 Reference Case Alternative 5: 50 Percent Above Optimized

3.3.3.6.1 Criteria Pollutants

Under the 50 Percent Above Optimized Alternative (Alternative 5), the CAFE standards would increase fuel economy more than would Alternatives 1 through 4 but less than would Alternatives 6 and 7. There would be reductions in nationwide emissions of all criteria pollutants under Alternative 5. Reductions would be greater than under Alternative 4 but less than under Alternatives 6 and 7. Percent reductions would range from 0.1 to 3.7 compared to the No Action Alternative, depending on the year and pollutant. All individual nonattainment areas would experience reductions in emissions of CO, NO_x, SO_x, and VOCs. $PM_{2.5}$ emissions would increase in most nonattainment areas in 2015 and 2020 and would decrease in some compared to the No Action Alternative. Tables in Appendix B-2 list the emissions reductions for each nonattainment area.

3.3.3.6.2 Air Toxics

Alternative 5 would reduce air toxics emissions of acetaldehyde (in 2035), benzene, 1,3-butadiene, and DPM, but would increase emissions of acetaldehyde (except 2035), acrolein, and formaldehyde compared to the No Action Alternative. Alternative 5 would have higher emissions of benzene, 1,3-butadiene (except for Alternative 7 in 2015), and DPM compared to Alternatives 6 and 7. Alternative 5 would have lower emissions of acrolein and formaldehyde compared to Alternatives 6 and 7, and mixed results for acetaldehyde depending on the year and alternative.

At the nationwide level, emissions of toxic air pollutants could decrease because the reduction in upstream emissions more than offsets the increase in VMT and emissions due to the rebound effect. However, as with the Alternative 4, the reductions in upstream emissions are not uniformly distributed to individual nonattainment areas. Under Alternative 5, many nonattainment areas would experience net increases in emissions of one or more toxic air pollutants in at least one of the analysis years (see Appendix B-2). However, the sizes of the emissions increases would be quite small, as shown in Appendix B-2, and emissions increases would be distributed throughout each nonattainment area.

3.3.3.6.3 Health Outcomes and Costs

There would be reductions in adverse health effects nationwide under Alternative 5 compared to the No Action Alternative, as shown in Table 3.3-10. These reductions primarily reflect the projected $PM_{2.5}$ reductions, because $PM_{2.5}$ tends to be the largest contributor to adverse health effects. Compared to the No Action Alternative, Alternative 5 would reduce mortalities by 142 and the number of work-loss days by 25,339 in 2035. Data are not available to estimate reliably the number of adverse health effects due to the other pollutants. Table 3.3-11 lists the corresponding reductions in health costs under

Alternative 5 compared to the No Action Alternative. Alternative 5 would reduce health costs by $349 million in 2035.

3.3.3.7 Reference Case Alternative 6: Total Costs Equal Total Benefits

3.3.3.7.1 Criteria Pollutants

Under the Total Costs Equal Total Benefits Alternative (Alternative 6), the CAFE standards would increase fuel economy more than would Alternatives 1 through 5 but less than would Alternative 7. There would be reductions in nationwide emissions of all criteria pollutants under Alternative 6 compared to the No Action Alternative. Reductions would be greater than under Alternative 5 (except for $PM_{2.5}$ in 2035) but less than under Alternative 7. Compared to the No Action Alternative, percent reductions would range from 0.1 to 4.4, depending on the year and pollutant. All individual nonattainment areas would experience reductions in emissions of CO, NO_x, SO_x, and VOCs. $PM_{2.5}$ emissions would increase in most nonattainment areas and decrease in some compared to the No Action Alternative. Tables in Appendix B-2 list the emissions reductions for each nonattainment area.

3.3.3.7.2 Air Toxics

Alternative 6 would reduce air toxics emissions of acetaldehyde (in 2025 and 2035), benzene, 1,3-butadiene, and DPM, but would increase emissions of acetaldehyde (in 2015 and 2020), acrolein, and formaldehyde compared to the No Action Alternative. Alternative 6 would have higher emissions of acetaldehyde (in 2025 and 2035), benzene, 1,3-butadiene (except in 2015), and DPM compared to Alternative 7. Alternative 6 would have lower emissions of acetaldehyde (in 2015 and 2020), acrolein, 1,3-butadiene (except in 2015), and formaldehyde compared to Alternative 7.

At the nationwide level, emissions of toxic air pollutants could decrease because the reduction in upstream emissions more than offsets the increase in VMT and emissions due to the rebound effect. However, as with the Alternative 6, the reductions in upstream emissions are not uniformly distributed to individual nonattainment areas. Under Alternative 6, many nonattainment areas would experience net increases in emissions of one or more toxic air pollutants in at least one of the analysis years (see Appendix B-2). However, the sizes of the emissions increases would be quite small, as shown in Appendix B-2, and emissions increases would be distributed throughout each nonattainment area.

3.3.3.7.3 Health Outcomes and Costs

There would be reductions in adverse health effects nationwide under Alternative 6 compared to the No Action Alternative, as shown in Table 3.3-10. These reductions primarily reflect the projected $PM_{2.5}$ reductions, because $PM_{2.5}$ tends to be the largest contributor to adverse health effects. Compared to the No Action Alternative, the Alternative 6 would reduce mortalities by 142 and the number of work-loss days by 25,233 in 2035. Data are not available to estimate reliably the number of adverse health effects due to the other pollutants. Table 3.3-11 lists the corresponding reductions in health costs under Alternative 6 compared to the No Action Alternative. Alternative 6 would reduce health costs by $435 million in 2035.

3.3.3.8 Reference Case Alternative 7: Technology Exhaustion

3.3.3.8.1 Criteria Pollutants

Under the Technology Exhaustion Alternative (Alternative 7), the CAFE standards would increase fuel economy more than all the other alternatives. There would be greater reductions in nationwide emissions of criteria pollutants under Alternative 7 than with any other alternative: between 0.8 percent and 44 percent compared to the No Action Alternative, depending on year and pollutant. All individual nonattainment areas would experience reductions in emissions of CO, NO_x, SO_x, and VOCs. $PM_{2.5}$ emissions would increase in most nonattainment areas and decrease in some compared to the No Action Alternative. Tables in Appendix B-2 list the emissions reductions for each nonattainment area.

3.3.3.8.2 Air Toxics

Alternative 7 would reduce air toxics emissions of acetaldehyde (in 2025 and 2035), benzene, 1,3-butadiene (except in 2015), and DPM, but would increase emissions of acetaldehyde (in 2015 and 2020), acrolein, 1,3-butadiene (in 2015), and formaldehyde compared to the No Action Alternative.

At the nationwide level, emissions of toxic air pollutants could decrease because the reduction in upstream emissions more than offsets the increase in VMT and emissions due to the rebound effect. However, as with the Alternative 6, the reductions in upstream emissions are not uniformly distributed to individual nonattainment areas. Under Alternative 7, many nonattainment areas would experience net increases in emissions of one or more toxic air pollutants in at least one of the analysis years (see Appendix B-2). In general, of all the Alternatives, Alternative 7 results in the largest emissions changes (either increases or decreases) relative to the No Action Alternative. As shown in Appendix B-2, and emissions increases would be distributed throughout each nonattainment area.

3.3.3.8.3 Health Outcomes and Costs

There would be reductions in adverse health effects nationwide under Alternative 7 compared to the No Action Alternative, as shown in Table 3.3-10. These reductions primarily reflect the projected $PM_{2.5}$ reductions, because $PM_{2.5}$ tends to be the largest contributor to adverse health effects. Compared to the No Action Alternative, Alternative 7 would reduce mortalities by 660 and the number of work-loss days by 117,617 in 2035. Data are not available to estimate reliably the number of adverse health effects due to the other pollutants. Table 3.3-11 lists the corresponding reductions in health costs under Alternative 7 compared to the No Action Alternative. Alternative 7 would reduce health costs by $3.329 billion in 2035.

3.3.4 Input Scenarios

3.3.4.1 Results of the Emissions Analysis

The CAA has been a success in reducing emissions from on-road mobile sources. As discussed in Section 3.3.1, pollutant emissions from vehicles have been declining since 1970, and EPA projects that they will continue to decline. This trend will continue regardless of the alternative chosen for future CAFE standards. The analysis by alternatives in this section shows that the alternative CAFE standards from the High, Mid-1, and Mid-2 Scenarios would lead to further reductions in emissions from passenger cars and light trucks. The amount of the reductions would vary by alternative. The more restrictive High Scenario alternatives would result in greater emissions reductions compared to the No Action Alternative. Under all of the High Scenario action alternatives, there are no emissions increases that would exceed any of the general conformity thresholds.

3.3.4.2 High Scenario Alternative 1: No Action

3.3.4.2.1 Criteria Pollutants

With the High Scenario No Action Alternative, the CAFE standards would remain at the MY 2010 level in future years. Current trends in the levels of emissions from vehicles would continue, with emissions continuing to decline due to the EPA emissions standards, despite a growth in total VMT. The EPA vehicle emissions standards regulate all criteria pollutants except SO_2, which is regulated through fuel sulfur content. The High Scenario No Action Alternative would not change the current CAFE standards and so would not result in any change in criteria pollutant emissions, other than current trends, in nonattainment and maintenance areas throughout the United States.

Table 3.3-13 summarizes the total national emissions from passenger cars and light trucks for the High Scenario No Action Alternative for each of the criteria pollutants and analysis years. The table presents the other High Scenario alternatives (Alternatives 2 through 7) left to right in order of increasing fuel economy requirements. Table 3.3-13 shows that the No Action Alternative has the highest emissions of all the High Scenario alternatives for all criteria pollutants.

Table 3.3-13

2025	0	-53,185	-54,699	-85,314	-99,389	-121,326	-362,236
2035	0	-89,537	-88,453	-137,767	-163,320	-202,421	-628,326

a/ Emissions changes have been rounded to the nearest whole number.
b/ Negative changes indicate reductions; positive emissions changes are increases.
c/ Changes for the No Action Alternative are shown as zero because the No Action Alternative is the baseline to which emissions under the action alternatives are compared.

3.3.4.2.2 Air Toxics

With the High Scenario No Action Alternative, the CAFE standards would remain at the MY 2010 level in future years. As with the criteria pollutants, current trends in the levels of air toxics emissions from vehicles would continue, with emissions continuing to decline due to the EPA emissions standards, despite a growth in total VMT. The EPA regulates air toxics from motor vehicles through vehicle emissions standards and fuel quality standards, as discussed in Section 3.3.1. The High Scenario No Action Alternative would not change the current CAFE standards and therefore would not result in any change in toxic air pollutant emissions, other than current trends, in nonattainment and maintenance areas throughout the United States.

Table 3.3-15 summarizes the total national emissions of air toxics from passenger cars and light trucks with the High Scenario No Action Alternative for each of the pollutants and analysis years. The Table presents Alternatives 2 through 7 left to right in order of increasing fuel economy requirements. Emissions of acetaldehyde (except in 2015 and 2020), benzene, 1,3-butadiene (except in 2015), and DPM

2025	11,716	11,893	11,857	11,946	12,080	12,250	14,238
2035	11,694	11,933	11,878	12,000	12,178	12,394	15,022

a/ Data on upstream emissions reductions were not available for acrolein. Thus, the emissions for acrolein reflect only the change in tailpipe emissions.

are generally highest under the No Action Alternative. Emissions of acetaldehyde (in 2015 and 2020), acrolein, and formaldehyde are generally lowest with High Scenario Alternative 1. Table 3.3-15 shows increases for acrolein with High Scenario Alternatives 2 through 7, because data on upstream emissions reductions were not available. The emissions for acrolein in Table 3.3-15 reflect only the increases due to the rebound effect and manufacturer changes in response to the fuel economy standards. Thus, the acrolein emissions given in Table 3.3-15 are an upper-bound estimate.

Table 3.3-16 lists the net change in nationwide emissions from passenger cars and light trucks for the High Scenario No Action Alternative for each of the air toxic pollutants and analysis years. The table presents Alternatives 2 through 7 left to right in order of increasing fuel economy requirements. In Table 3.3-16 the nationwide emissions reductions or increases tend to become greater from left to right, reflecting the increasing fuel economy requirements that are assumed under successive alternatives, except for the cases noted above and for acrolein.

2035	0	239	185	306	484	700	3,328

a/ Emissions changes have been rounded to the nearest whole number.
b/ Negative changes indicate reductions; positive emissions changes are increases.
c/ Changes for the No Action Alternative are shown as zero because the No Action Alternative is the baseline to which emissions under the action alternatives are compared.
d/ Data on upstream emissions reductions were not available for acrolein. Thus, the emissions for acrolein reflect only the change in tailpipe emissions.

3.3.4.2.3 Health Outcomes and Costs

With the High Scenario No Action Alternative, the CAFE standards would remain at the MY 2010 level in future years. Current trends in the levels of criteria pollutants and air toxics emissions from vehicles would continue, with emissions continuing to decline due to the EPA emissions standards, despite a growth in total VMT. The human health effects and health-related costs that occur under current trends would continue and are expected to decline in the future as a result of declines in pollutant emissions. The High Scenario No Action Alternative would not result in any other increase or decrease in human health effects and health-related costs throughout the United States.

3.3.4.3 High Scenario Alternative 2: 25 Percent Below Optimized

3.3.4.3.1 Criteria Pollutants

With High Scenario Alternative 2, the CAFE standards would require increased fuel economy compared to the High Scenario No Action Alternative. Generally, High Scenario Alternative 2 would increase fuel economy less than would High Scenario Alternatives 3 through 7. There would be reductions in nationwide emissions of criteria pollutants with High Scenario Alternative 2 compared to the High Scenario No Action Alternative in 2020. High Scenario Alternative 2 would reduce emissions less than would High Scenario Alternatives 3 through 7.

All individual nonattainment areas would experience reductions in emissions of all criteria pollutants except $PM_{2.5}$ for all analysis years. Emissions of criteria pollutants decrease in part because the reduction in upstream emissions, among other effects related to technology changes introduced by manufacturers in response to CAFE standards, more than offsets the increase in VMT and emissions due to the rebound effect in every nonattainment area. Emissions of $PM_{2.5}$ are projected to increase in some nonattainment areas with the High Scenario as a result of the combined effects of technology changes introduced by manufacturers in response to CAFE standards, the rebound effect, and travel-demand changes due to population changes. Appendix B-2 contains tables that list the emissions reductions for each nonattainment area. Table 3.3-17 summarizes maximum and minimum criteria air pollutant results by nonattainment area.

Table 3.3-17

High Scenario Alternative CAFE Standards
Changes in Criteria Pollutant Emissions from Passenger Cars and Light Trucks,
Maximum Changes by Nonattainment Area a/

Criteria Pollutant	Increase/ Decrease	Change (tons/year)	Year	Alt. No.	Nonattainment Area
CO	Maximum increase	No increase			
	Maximum decrease	-387,673	2035	7	Los Angeles South Coast Air Basin, CA
NO_x	Maximum increase	No increase			
	Maximum decrease	-14,457	2035	7	Los Angeles South Coast Air Basin, CA
$PM_{2.5}$	Maximum increase	56	2035	7	Atlanta, GA
	Maximum decrease	-1,206	2035	7	Houston-Galveston-Brazoria, TX
SO_x	Maximum increase	No increase			
	Maximum decrease	-5,045	2035	7	Houston-Galveston-Brazoria, TX
VOCs	Maximum increase	No increase			
	Maximum decrease	-31,454	2035	7	Los Angeles South Coast Air Basin, CA

a/ Emissions changes have been rounded to the nearest whole number.

3.3.4.3.2 Air Toxics

There would be reductions in nationwide emissions of benzene, 1,3-butadiene, and DPM under the High Scenario Alternative 2 compared to the High Scenario No Action Alternative. There would be increases in nationwide emissions of acetaldehyde (except in 2025 and 2035), acrolein, and formaldehyde compared to the High Scenario No Action Alternative.

The High Scenario Alternative 2 would have generally higher emissions than would High Scenario Alternatives 3 through 7 for acetaldehyde (in 2025 and 2035 except Alternative 3), benzene (except Alternative 3 in 2025 and 2035), 1,3-butadiene (except Alternative 3 in 2025 and 2035), and DPM. High Scenario Alternative 2 would have generally lower emissions than would High Scenario Alternatives 3 through 7 for acetaldehyde (in 2015), acrolein, and formaldehyde (except Alternative 3 in 2020-2035). Emissions under the High Scenario tend to be lower than those under the Reference Case for Alternative 2.

At the nationwide level, the reduction in upstream emissions of toxic air pollutants tends to offset the increase in VMT and emissions due to the rebound effect. However, the reductions in upstream emissions are not uniformly distributed to individual nonattainment areas. Net emissions reductions can occur if the reduction in upstream emissions in the nonattainment area more than offsets the increase within the area due to the rebound effect. With High Scenario Alternative 2, many nonattainment areas would experience net increases in emissions of one or more toxic air pollutants in at least one of the analysis years (see Appendix B-2). Table 3.3-18 summarizes the maximum and minimum criteria air pollutant results by nonattainment area.

Table 3.3-18

High Scenario Alternative CAFE Standards
Changes in Toxic Air Pollutant Emissions from Passenger Cars and Light Trucks,
Maximum Changes by Nonattainment Area a/

Hazardous Air Pollutant	Increase/Decrease	Change (tons/year)	Year	Alt. No.	Nonattainment Area
Acetaldehyde	Maximum Increase	10	2020	7	New York-N. New Jersey-Long Island, NY-NJ-CT
	Maximum Decrease	-37	2035	7	Houston-Galveston-Brazoria, TX
Acrolein	Maximum Increase	16	2035	7	Los Angeles South Coast Air Basin, CA
	Maximum Decrease	No decreases (upstream emissions decreases not included for acrolein)			
Benzene	Maximum Increase	No increases			
	Maximum Decrease	-862	2035	7	Los Angeles South Coast Air Basin, CA
1,3-butadiene	Maximum Increase	1	2015	7	New York-N. New Jersey-Long Island, NY-NJ-CT
	Maximum Decrease	-35	2035	7	Los Angeles South Coast Air Basin, CA
Diesel particulate matter	Maximum Increase	No increases			
	Maximum Decrease	-625	2035	7	Los Angeles South Coast Air Basin, CA
Formaldehyde	Maximum Increase	145	2035	7	Los Angeles South Coast Air Basin, CA
	Maximum Decrease	-65	2035	7	Houston-Galveston-Brazoria, TX

a/ Emissions changes have been rounded to the nearest whole number.

3.3.4.3.3 Health Outcomes and Costs

There would be reductions in adverse health effects nationwide with High Scenario Alternative 2 compared to the High Scenario No Action Alternative, as shown in Table 3.3-19. These reductions primarily reflect the projected $PM_{2.5}$ reductions, because $PM_{2.5}$ tends to be the largest contributor to adverse health effects. In comparison to the High Scenario No Action Alternative, High Scenario Alternative 2 would reduce mortalities by 214 and the number of work-loss days by 38,172 in 2035. Data are not available to estimate reliably the number of adverse health effects due to the other pollutants. Table 3.3-20 lists the corresponding reductions in health costs with High Scenario Alternative 2 compared to the High Scenario No Action Alternative. High Scenario Alternative 2 would reduce health costs by $632 million in 2035.

Table 3.3-19

2035	0	-632	-677	-888	-1,027	-1,202	-2,987

a/ Negative changes indicate economic benefit; positive emissions changes are economic costs.
b/ Changes for the No Action Alternative are shown as zero because the No Action Alternative is the baseline to which emissions under the action alternatives are compared.

3.3.4.4 High Scenario Alternative 3: Optimized

3.3.4.4.1 Criteria Pollutants

With High Scenario Alternative 3, generally the CAFE standards would increase fuel economy more than would the High Scenario No Action Alternative and High Scenario Alternative 2, but less than would High Scenario Alternatives 4 through 7. There would be greater reductions in nationwide emissions of criteria pollutants with High Scenario Alternative 3 compared to High Scenario Alternative 2, except for CO in 2020-2035 and VOC in 2035. High Scenario Alternative 3 would reduce emissions less than would High Scenario Alternatives 4 through 7, except that High Scenario Alternative 3 would reduce $PM_{2.5}$ emissions more than would High Scenario Alternative 4 in 2020-2035.

All individual nonattainment areas would experience reductions in emissions of all criteria pollutants, except for $PM_{2.5}$, for all analysis years. Emissions of criteria pollutants decrease in part because the reduction in upstream emissions, among other effects related to technology changes introduced by manufacturers in response to CAFE standards, more than offsets the increase in VMT and emissions due to the rebound effect in every nonattainment area. Emissions of $PM_{2.5}$ are projected to increase in some nonattainment areas with the High Scenarios as a result of the combined effects of technology changes introduced by manufacturers in response to CAFE standards, the rebound effect, and travel-demand changes due to population changes. Appendix B-2 contains tables that list the emissions reductions for each nonattainment area.

3.3.4.4.2 Air Toxics

There would be reductions in nationwide emissions of benzene, 1,3-butadiene, and DPM under the High Scenario Alternative 3 compared to the High Scenario No Action Alternative. There would be increases in nationwide emissions of acetaldehyde (except in 2025 and 2035), acrolein, and formaldehyde compared to the High Scenario No Action Alternative.

The High Scenario Alternative 3 would have generally higher emissions than would High Scenario Alternatives 4 through 7 for acetaldehyde (in 2025 and 2035), benzene, 1,3-butadiene, and DPM. High Scenario Alternative 3 would have generally lower emissions than would High Scenario Alternatives 4 through 7 for acetaldehyde (in 2015 except Alternative 4 and 2020 except Alternatives 4 and 5), acrolein, and formaldehyde. Emissions under the High Scenario tend to be lower than those under the Reference Case for Alternative 3.

At the nationwide level, the reduction in upstream emissions of toxic air pollutants tends to offset the increase in VMT and emissions due to the rebound effect. However, the reductions in upstream emissions are not uniformly distributed to individual nonattainment areas. Net emissions reductions can occur if the reduction in upstream emissions in the nonattainment area more than offsets the increase within the area due to the rebound effect. With High Scenario Alternative 3, many nonattainment areas would experience net increases in emissions of one or more toxic air pollutants in at least one of the analysis years (see Appendix B-2).

3.3.4.4.3 Health Outcomes and Costs

There would be reductions in adverse health effects nationwide with High Scenario Alternative 3 compared to the No Action Alternative, as shown in Table 3.3-19. These reductions primarily reflect the projected $PM_{2.5}$ reductions, because $PM_{2.5}$ tends to be the largest contributor to adverse health effects. In comparison to the High Scenario No Action Alternative, High Scenario Alternative 3 would reduce mortalities by 245 and the number of work-loss days by 43,678 in 2035. Data are not available to estimate reliably the number of adverse health effects due to the other pollutants. Table 3.3-20 lists the corresponding reductions in health costs with High Scenario Alternative 3 compared to the No Action Alternative. High Scenario Alternative 3 would reduce health costs by $677 million in 2035.

3.3.4.5 High Scenario Alternative 4: 25 Percent Above Optimized

3.3.4.5.1 Criteria Pollutants

With High Scenario Alternative 4, generally the CAFE standards would increase fuel economy more than would High Scenarios Alternatives 1 through 3 but less than would High Scenario Alternatives 5 through 7. There would be greater reductions in nationwide emissions of criteria pollutants with High Scenario Alternative 4 than with High Scenario Alternatives 1 through 3 (except for $PM_{2.5}$ in 2020-2035). High Scenario Alternative 4 would produce smaller reductions in criteria pollutant emissions than with High Scenario Alternatives 5 through 7.

All individual nonattainment areas would experience reductions in emissions of all criteria pollutants, except $PM_{2.5}$, for all analysis years, compared to the High Scenario No Action Alternative. Emissions of criteria pollutants decrease in part because the reduction in upstream emissions, among other effects related to technology changes introduced by manufacturers in response to CAFE standards, more than offsets the increase in VMT and emissions due to the rebound effect in every nonattainment area. Emissions of $PM_{2.5}$ are projected to increase in some nonattainment areas with the High Scenarios because of the combined effects of technology changes introduced by manufacturers in response to CAFE standards, the rebound effect, and travel-demand changes due to population changes. Appendix B-2 contains tables that list the emissions reductions for each nonattainment area.

3.3.4.5.2 Air Toxics

There would be reductions in nationwide emissions of acetaldehyde (except in 2015), benzene, 1,3-butadiene, and DPM under the High Scenario Alternative 4 compared to the High Scenario No Action Alternative. There would be increases in nationwide emissions of acetaldehyde (in 2015), acrolein, and formaldehyde compared to the High Scenario No Action Alternative.

The High Scenario Alternative 4 would have generally higher emissions than would High Scenario Alternatives 5 through 7 for acetaldehyde (in 2035), benzene, 1,3-butadiene (except in 2015), and DPM. High Scenario Alternative 4 would have generally lower emissions than would High Scenario Alternatives 5 through 7 for acetaldehyde (except in 2035), acrolein, and formaldehyde. Emissions under the High Scenario tend to be lower than those under the Reference Case for Alternative 4.

At the nationwide level, the reduction in upstream emissions of toxic air pollutants tends to offset the increase in VMT and emissions due to the rebound effect. However, the reductions in upstream emissions are not uniformly distributed to individual nonattainment areas. Net emissions reductions can occur if the reduction in upstream emissions in the nonattainment area more than offsets the increase within the area due to the rebound effect. With High Scenario Alternative 4, many nonattainment areas would experience net increases in emissions of one or more toxic air pollutants in at least one of the analysis years (see Appendix B-2).

3.3.4.5.3 Health Outcomes and Costs

There would be reductions in adverse health effects nationwide with High Scenario Alternative 4 compared to the No Action Alternative, as shown in Table 3.3-19. These reductions primarily reflect the projected $PM_{2.5}$ reductions, because $PM_{2.5}$ tends to be the largest contributor to adverse health effects. In comparison to the High Scenario No Action Alternative, High Scenario Alternative 4 would reduce mortalities by 234 and the number of work-loss days by 41,794 in 2035. Data are not available to estimate reliably the number of adverse health effects due to the other pollutants. Table 3.3-20 lists the corresponding reductions in health costs with High Scenario Alternative 4 compared to the High Scenario No Action Alternative. High Scenario Alternative 4 would reduce health costs by $888 million in 2035.

3.3.4.6 High Scenario Alternative 5: 50 Percent Above Optimized

3.3.4.6.1 Criteria Pollutants

With High Scenario Alternative 5, the CAFE standards would increase fuel economy more than would High Scenario Alternatives 1 through 4 but less than would High Scenario Alternatives 6 and 7. There would be greater reductions in nationwide emissions of all criteria pollutants with High Scenario Alternative 5 than with High Scenario Alternatives 1 through 4. There would be smaller reductions than with High Scenario Alternatives 6 and 7.

All individual nonattainment areas would experience reductions in emissions of all criteria pollutants, except for $PM_{2.5}$, for all analysis years. Emissions of criteria pollutants decrease in part because the reduction in upstream emissions, among other effects related to technology changes introduced by manufacturers in response to CAFE standards, more than offsets the increase in VMT and emissions due to the rebound effect in every nonattainment area. Emissions of $PM_{2.5}$ are projected to increase in some nonattainment areas with the High Scenarios as a result of the combined effects of technology changes introduced by manufacturers in response to CAFE standards, the rebound effect, and travel-demand changes due to population changes. Tables in Appendix B-2 list the emissions reductions for each nonattainment area.

3.3.4.6.2 Air Toxics

There would be reductions in nationwide emissions of acetaldehyde (except in 2015 and 2020), benzene, 1,3-butadiene (except in 2015), and DPM under the High Scenario Alternative 5 compared to the High Scenario No Action Alternative. There would be increases in nationwide emissions of acetaldehyde (in 2015 and 2020), acrolein, and formaldehyde compared to the High Scenario No Action Alternative.

The High Scenario Alternative 5 would have generally higher emissions than would High Scenario Alternatives 6 through 7 for acetaldehyde (in 2035), benzene, 1,3-butadiene (except in 2015), and DPM. High Scenario Alternative 5 would have generally lower emissions than would High Scenario Alternatives 6 through 7 for acetaldehyde (except in 2035), acrolein, and formaldehyde. Emissions under the High Scenario tend to be lower than those under the Reference Case for Alternative 5.

At the nationwide level, the reduction in upstream emissions of toxic air pollutants tends to offset the increase in VMT and emissions due to the rebound effect. However, the reductions in upstream emissions are not uniformly distributed to individual nonattainment areas. Net emissions reductions can occur if the reduction in upstream emissions in the nonattainment area more than offsets the increase within the area due to the rebound effect. With High Scenario Alternative 5, many nonattainment areas would experience net increases in emissions of one or more toxic air pollutants in at least one of the analysis years (see Appendix B-2).

3.3.4.6.3 Health Outcomes and Costs

There would be reductions in adverse health effects nationwide with High Scenario Alternative 5 compared to the High Scenario No Action Alternative, as shown in Table 3.3-19. These reductions primarily reflect the projected $PM_{2.5}$ reductions, because $PM_{2.5}$ tends to be the largest contributor to adverse health effects. In comparison to the High Scenario No Action Alternative, High Scenario Alternative 5 would reduce mortalities by 283 and the number of work-loss days by 50,445 in 2035. Data are not available to estimate reliably the number of adverse health effects due to the other pollutants. Table 3.3-20 lists the corresponding reductions in health costs with High Scenario Alternative 5. High Scenario Alternative 5 would reduce health costs by $1.027 billion in 2035.

3.3.4.7 High Scenario Alternative 6: Total Costs Equal Total Benefits

3.3.4.7.1 Criteria Pollutants

With High Scenario Alternative 6, the CAFE standards would increase fuel economy more than would High Scenario Alternatives 1 through 5 but less than would High Scenario Alternative 7. There would be greater reductions in nationwide emissions of criteria pollutants with the High Scenario Alternative 6 than with High Scenario Alternatives 1 through 5. There would be lesser reductions than with High Scenario Alternative 7.

All individual nonattainment areas would experience reductions in emissions of all criteria pollutants except $PM_{2.5}$ for all analysis years. Emissions of criteria pollutants except $PM_{2.5}$ decrease because the reduction in upstream emissions more than offsets the increase in VMT and emissions due to the rebound effect and technology changes introduced by manufacturers in response to CAFE standards in every nonattainment area. Emissions of $PM_{2.5}$ are projected to increase in some nonattainment areas with the High Scenarios as a result of the combined effects of technology changes introduced by manufacturers in response to CAFE standards, the rebound effect, and travel-demand changes due to population changes. Appendix B-2 contains tables that list the emissions reductions for each nonattainment area.

3.3.4.7.2 Air Toxics

There would be reductions in nationwide emissions of acetaldehyde (except in 2015 and 2020), benzene, 1,3-butadiene, and DPM under the High Scenario Alternative 6 compared to the High Scenario

No Action Alternative. There would be increases in nationwide emissions of acetaldehyde (in 2015 and 2020), acrolein, and formaldehyde compared to the High Scenario No Action Alternative.

The High Scenario Alternative 6 would have generally higher emissions than would High Scenario Alternative 7 for acetaldehyde (in 2035), benzene, 1,3-butadiene (except in 2015), and DPM. High Scenario Alternative 6 would have generally lower emissions than would High Scenario Alternative 7 for acetaldehyde (except in 2035), acrolein, 1,3-butadiene (in 2015), and formaldehyde. Emissions under the High Scenario tend to be lower than those under the Reference Case for Alternative 6.

At the nationwide level, the reduction in upstream emissions of toxic air pollutants tends to offset the increase in VMT and emissions due to the rebound effect. However, the reductions in upstream emissions are not uniformly distributed to individual nonattainment areas. For example, a nonattainment area that contains petroleum refining facilities, such as Houston-Galveston-Brazoria, Texas, would experience more reductions in upstream emissions than an area that has none. Net emissions reductions can occur if the reduction in upstream emissions in the nonattainment area more than offsets the increase within the area due to the rebound effect. With High Scenario Alternative 6, many nonattainment areas would experience net increases in emissions of one or more toxic air pollutants in at least one of the analysis years (see Appendix B-2).

3.3.4.7.3 Health Outcomes and Costs

There would be reductions in adverse health effects nationwide with High Scenario Alternative 6 compared to the High Scenario No Action Alternative, as shown in Table 3.3-19. These reductions primarily reflect the projected $PM_{2.5}$ reductions, because $PM_{2.5}$ tends to be the largest contributor to adverse health effects. In comparison to the High Scenario No Action Alternative, High Scenario Alternative 6 would reduce mortalities by 317 and the number of work-loss days by 56,437 in 2035. Data are not available to estimate reliably the number of adverse health effects due to the other pollutants. Table 3.3-20 lists the corresponding reductions in health costs with Alternative 6 compared to the High Scenario No Action Alternative. In comparison to the High Scenario No Action Alternative, High Scenario Alternative 6 would reduce health costs by $1.202 billion in 2035.

3.3.4.8 High Scenario Alternative 7: Technology Exhaustion

3.3.4.8.1 Criteria Pollutants

With the High Scenario Alternative 7, the CAFE standards would increase fuel economy the most of all the alternatives. There would be greater reductions in nationwide emissions of criteria pollutants with the High Scenario Alternative 7 than with any other alternative. All individual nonattainment areas would experience reductions in emissions of all criteria pollutants except $PM_{2.5}$ for all analysis years. Emissions of criteria pollutants decrease in part because the reduction in upstream emissions, among other effects related to technology changes introduced by manufacturers in response to CAFE standards, more than offsets the increase in VMT and emissions due to the rebound effect in every nonattainment area. Emissions of $PM_{2.5}$ are projected to increase in some nonattainment areas under High Scenario Alternative 7 because of the combined effects of technology changes introduced by manufacturers in response to CAFE standards, the rebound effect, and travel-demand changes due to population changes. Appendix B-2 contains tables that list the emissions reductions for each nonattainment area.

3.3.4.8.2 Air Toxics

There would be reductions in nationwide emissions of acetaldehyde (in 2025 and 2035), benzene, 1,3-butadiene (except in 2015), and DPM with High Scenario Alternative 7 compared to the High Scenario No Action Alternative.

At the nationwide level, the reduction in upstream emissions of toxic air pollutants tends to offset the increase in VMT and emissions due to the rebound effect. However, the reductions in upstream emissions are not uniformly distributed to individual nonattainment areas. Net emissions reductions can occur if the reduction in upstream emissions in the nonattainment area more than offsets the increase within the area due to the rebound effect. With High Scenario Alternative 7, many nonattainment areas would experience net increases in emissions of one or more toxic air pollutants in at least one of the analysis years (see Appendix B-2).

3.3.4.8.3 Health Outcomes and Costs

There would be reductions in adverse health effects nationwide with High Scenario Alternative 7 compared to the High Scenario No Action Alternative, as shown in Table 3.3-19. These reductions primarily reflect the projected $PM_{2.5}$ reductions, because $PM_{2.5}$ tends to be the largest contributor to adverse health effects. In comparison to the High Scenario No Action Alternative, High Scenario Alternative 7 would reduce mortalities by 592 and the number of work-loss days by 105,514 in 2035. Data are not available to estimate reliably the number of adverse health effects due to the other pollutants. Table 3.3-20 lists the corresponding reductions in health costs with High Scenario Alternative 7 compared to the High Scenario No Action Alternative. In comparison to the High Scenario No Action Alternative, High Scenario Alternative 7 would reduce health costs by $2.987 billion in 2035.

3.3.4.9 Mid-1 and Mid-2 Scenarios

For the Mid-1 Scenario, NHTSA used the AEO 2008 high fuel prices, a social cost of carbon of $33 per ton (2007 dollars), oil import externalities of $0.116 per gallon, and discount rates of 3 percent for the present value of carbon reduction benefits and 7 percent for other costs and benefits (*see* Table 2.2-1).

Compared to the Reference Case, total emissions of criteria and toxic air pollutants under the Mid-1 Scenario were generally lower for all alternatives. Emissions with the Mid-1 Scenario Alternative 6 were higher for acrolein in 2025 and 2035. Emissions with the Mid-1 Scenario Alternatives 2 through 6 were higher for 1,3-butadiene in some years. Most of the differences between the action alternatives and the No Action Alternative are greater under the Mid-1 Scenario than under the Reference Case. The emissions differences between the Reference Case and the Mid-1 Scenario reflect the differences in the forecast levels of fuel economy, VMT, and diesel vehicle share of the vehicle fleet.

For the Mid-2 Scenario, NHTSA used the AEO 2008 high fuel prices, a social cost of carbon of $2.00 per ton (2007 dollars), oil import externalities of $0.382 per gallon, and discount rates of 3 percent for the present value of carbon reduction benefits and 7 percent for other costs and benefits (*see* Table 2.2-1).

Compared to the Reference Case, total emissions of criteria and toxic air pollutants under the Mid-2 Scenario were lower for all action alternatives. Most of the differences between the action alternatives and the No Action Alternative are greater under the Mid-2 Scenario than under the Reference Case. The emissions differences between the Reference Case and the Mid-2 Scenario reflect the differences in the forecast levels of fuel economy, VMT, and diesel vehicle share of the vehicle fleet.

Emissions of criteria pollutants would be generally higher with the Mid-2 Scenario than with the Mid-1 Scenario for Alternatives 2 through 6, and equivalent for Alternative 7. Emissions of toxic air pollutants would be generally higher with the Mid-2 Scenario than with the Mid-1 Scenario for benzene, 1,3-butadiene, and DPM for Alternatives 2 through 6. Emissions of toxic air pollutants would be generally lower with the Mid-2 Scenario than with the Mid-1 Scenario for acrolein and formaldehyde for Alternatives 2 through 6. Results between the Mid-1 and Mid-2 Scenarios for acetaldehyde vary by year for Alternatives 2 through 6. Emissions of toxic air pollutants with the Mid-1 and Mid-2 Scenarios would be equivalent for Alternative 7.

Appendix B-2, Tables B2-97 through B2-113, list the full results from the Mid-1 and Mid-2 Scenarios.

3.4 CLIMATE

This section describes the environment the CAFE standards would affect. Because there is little precedent for addressing climate change within the structure of an EIS, several reasonable judgments were called for when deciding where to draw the line between the direct and indirect effects of the alternatives (Chapter 3) and the cumulative impacts associated with the alternatives (Chapter 4).

NHTSA determined that the scope of climate change issues covered in Chapter 3 would be more tailored than the scope of those in Chapter 4 in two respects: (1) the discussion in Chapter 3 focuses on impacts associated with GHGs only due to the MY 2011-2015 CAFE standards (which affect cars and light trucks built from 2010-2015, and are then assumed to remain in place at the MY 2015 levels from 2015 through 2100), and (2) the discussion of consequences focuses on emissions and effects on the climate system, for example, atmospheric CO_2 concentrations, temperature, sea level, and precipitation. Chapter 4 is broader in that it (1) covers foreseeable effects of the MY 2011-2015 standards, which include a set of more stringent CAFE standards for MY 2016-2020 (the MY 2020 levels would affect cars and light trucks built from 2020-2100), and (2) extends the discussion of consequences to include not only the effects on the climate system, but also the impacts of climate on key resources (such as freshwater resources, terrestrial ecosystems, coastal ecosystems). Thus, the reader is encouraged to explore the cumulative impacts discussion in Chapter 4 to fully understand NHTSA's approach to climate change in this FEIS.

Section 3.4.1 introduces key topics in GHGs and climate change, Section 3.4.2 outlines the methodology NHTSA used to evaluate climate effects, Section 3.4.3 describes the affected environment, and Section 3.4.4 describes consequences.

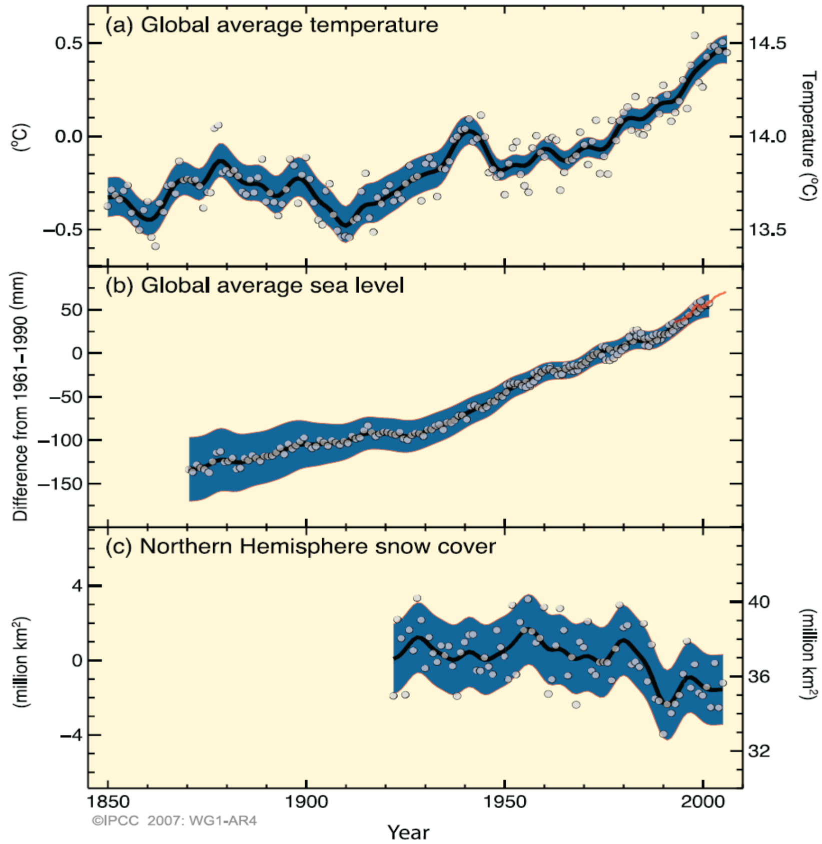
3.4.1 Introduction - Greenhouse Gases and Climate Change

A series of intensive and extensive analyses have been conducted by the Intergovernmental Panel on Climate Change (IPCC), the scientific body tasked by the United Nations to evaluate the risk of human-induced climate change, the U.S. Climate Change Science Program (USCCSP), and many other government-, non-government-, and industry-sponsored programs. Our discussion relies heavily on the most recent, thoroughly peer-reviewed, and credible assessments of global and U.S. climate change: the IPCC Fourth Assessment Report (*Climate Change 2007*), and reports by the USCCSP and the National Science and Technology Council that include the *Scientific Assessment of the Effects of Global Change on the United States* and Synthesis and Assessment Products. These sources and the studies they review are quoted frequently throughout this FEIS. Because new evidence is continuously emerging on the subject of climate change impacts, the discussions on climate impacts in this FEIS also draw on more recent studies, where possible.

3.4.1.1 What is Climate Change?

Global climate change refers to long-term fluctuations in global surface temperatures, precipitation, ice cover, sea levels, cloud cover, ocean temperatures and currents, and other climatic conditions. Scientific research has shown that in the past century, Earth's surface temperature has risen by an average of about 1.3 degrees Fahrenheit (°F) (0.74 degree Centigrade [°C]) (IPCC 2007c); sea levels have risen 6.7 inches (0.17 meter) (IPCC 2007c); Arctic sea ice has shrunk by 2.7 percent per decade, with larger decreases of 7.4 percent in summer, and mountain glaciers and snow cover have decreased (IPCC 2007c) (*see* Figure 3.4-1).

Figure 3.4-1. Changes in Temperature, Sea Level, and Northern Hemisphere Snow Cover (source: IPCC 2007c)



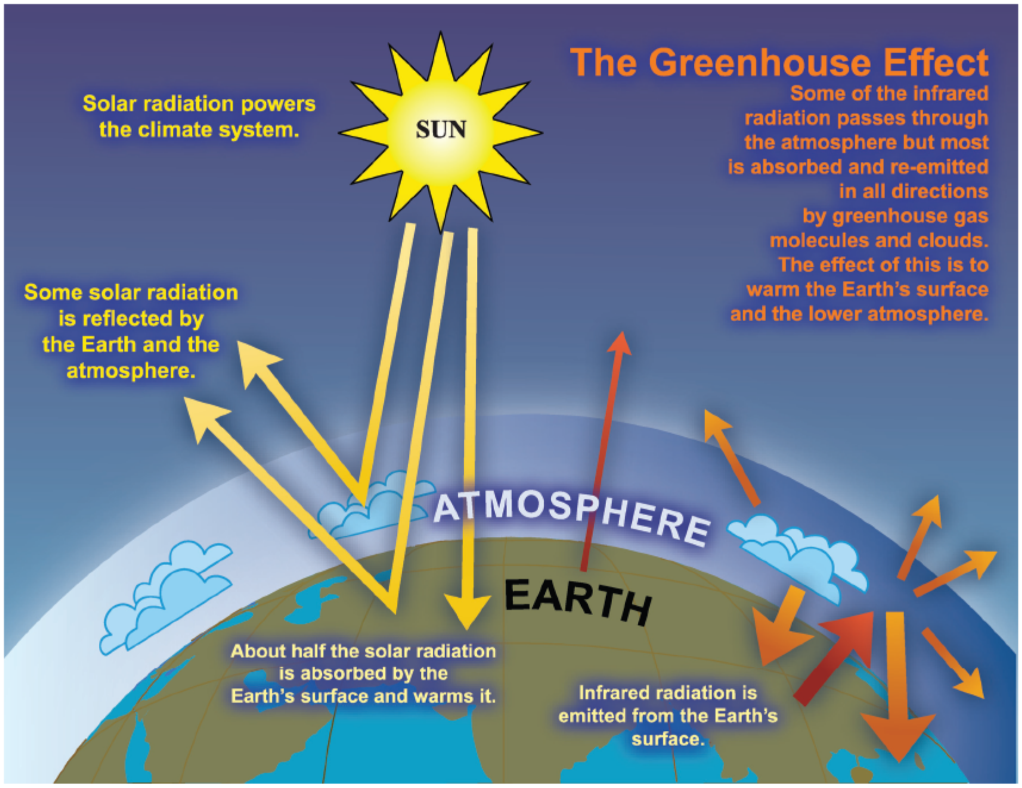
3.4.1.2 What Causes Climate Change?

Earth absorbs heat energy from the sun and returns some of this heat to space as terrestrial infrared radiation. GHGs trap heat in the troposphere (the atmosphere close to Earth's surface) and reradiate it back to Earth, thereby causing warming. This process—known as the "greenhouse effect"—is responsible for maintaining surface temperatures that are warm enough to sustain life (*see* Figure 3.4-2). Human activities, particularly fossil-fuel combustion, contribute to the presence of GHGs in the atmosphere. There are increasing concerns that the buildup of GHGs in the atmosphere is upsetting Earth's energy balance.

Most scientists now agree that this climate change is largely a result of GHG emissions from human activities. The IPCC recently asserted that, "Most of the observed increase in global average temperatures since the mid-20th Century is *very likely* due to the observed increase in anthropogenic [human-caused] greenhouse gas concentrations" (IPCC 2007c).[7]

[7] The IPCC uses standard terms to "define the likelihood of an outcome or result where this can be estimated probabilistically." The term "very likely," cited in italics above and elsewhere in this section, corresponds to a greater than 90-percent probability of an occurrence or outcome, whereas the term "likely" corresponds to a greater than 66-percent probability. This section uses these two terms; Section 4.5 uses and defines a more expansive set of IPCC terminology regarding likelihood

Figure 3.4-2. The Greenhouse Effect (source: Le Treut *et al.* 2007)



Most GHGs, including CO_2, methane (CH_4), nitrous oxide (N_2O), water vapor, and ozone, are naturally occurring. Human activities such as the combustion of fossil fuel, the production of agricultural commodities, and the harvesting of trees can contribute to increased concentrations of these gases in the atmosphere. In addition, a number of very potent anthropogenic (human-made) GHGs, including hydrofluorocarbons (HFCs), perfluorocarbons (PFCs), and sulfur hexafluoride (SF_6), are created and emitted through industrial processes.

3.4.1.3 What are the Anthropogenic Sources of Greenhouse Gases?

Human activities that emit GHGs to the atmosphere include the combustion of fossil fuels, industrial processes, solvent use, land-use change and forestry, agriculture production, and waste management. Atmospheric concentrations of CO_2, CH_4, and N_2O—the most important anthropogenic GHGs—have increased approximately 35, 150, and 18 percent, respectively, since the beginning of the Industrial Revolution in the mid-1700s (IPCC 2007c). The rise in GHGs in the past century is widely attributed to the combustion of fossil fuels (coal, petroleum, and gas) used to produce electricity, heat buildings, and run motor vehicles and planes, among other uses.

Contributions to the build-up of GHG in the atmosphere vary greatly from country to country, and depend heavily on the level of industrial and economic activity. The U.S. transportation sector contributed 31.3 percent of total U.S. CO_2 emissions in 2006 (EPA 2008a), with cars and light trucks accounting for 61.4 percent of total U.S. CO_2 emissions from transport (EPA 2008a). Thus, 19.2 percent of total U.S. CO_2 emissions come from cars and light trucks. With the United States accounting for 19.6 percent of global CO_2 emissions (WRI 2008), cars and light trucks in the United States account for roughly 3.8 percent of global CO_2 emissions.

3.4.1.4 Evidence of Climate Change

Observations and studies across the globe are reporting evidence that the earth is currently undergoing climatic change much more quickly than would be expected from natural variations. Global temperatures are increasing, with 11 of the hottest 12 years on record occurring over the past 12 years (IPCC 2007c). Sea levels have risen, caused by thermal expansion of the ocean and melting snow and ice. More frequent weather extremes such as droughts, floods, severe storms, and heat waves have also been observed (IPCC 2007c).

3.4.1.5 Future Climactic Trends and Expected Impacts

As the world population grows and developing countries industrialize, fossil fuel use and resulting GHG emissions are expected to grow substantially over the next century. Based on the current trajectory, the IPCC predicts that CO_2 concentrations could rise to more than three times the pre-industrial level by 2100 (Meehl *et al.* 2007).

Among other trends forecasted, the average global surface temperature is *likely* to rise 2.0 to 11.5 °F (1.1 to 6.4 °C) over the next century, accompanied by a *likely* sea level rise of approximately 0.6 to 1.9 feet (0.18 to 0.59 meter) (IPCC 2007c). In addition to rising temperatures and sea levels, climate change is expected to have many environmental, human health, and economic consequences.

For a more in-depth analysis on the future impacts of climate change on various sectors, *see* the Cumulative Impacts discussion in Chapter 4.

3.4.2 Affected Environment

This section describes the affected environment in terms of current and anticipated trends in GHG emissions and climate. Both emissions and climate involve very complex processes with considerable variability, which complicates the measurement and detection of change. Recent advances in the state of the science, however, are contributing to an increasing body of evidence that anthropogenic GHG emissions are affecting climate in detectable ways.

This section opens with a discussion of emissions, and then turns to climate. Both discussions start with a description of conditions in the United States, followed by a description in the global environment. As global conditions are a macrocosm of U.S. conditions, many themes in the U.S. discussions reappear in the global discussions.[8]

3.4.2.1 Greenhouse Gas Emissions (Historic and Current)

3.4.2.1.1 U.S. Emissions

GHG emissions for the United States in 2006 were estimated at 7,054 million metric tons of carbon dioxide ($MMTCO_2$) equivalent[9] (EPA 2008a), and, as noted earlier, comprise about 15 to 20

[8] For NEPA purposes, it is appropriate for NHTSA to consider global environmental impacts. *See* CEQ, *Council on Environmental Quality Guidance on NEPA Analyses for Transboundary Impacts* (July 1, 1997), *available at* http://ceq.hss.doe.gov/nepa/regs/transguide.html (last visited June 16, 2008) (stating that "agencies must include analysis of reasonably foreseeable transboundary effects of proposed actions in their [NEPA] analysis of proposed actions in the United States").
[9] Each GHG has a different level of radiative forcing, that is, the ability to trap heat. To compare their relative contributions, gases are converted to carbon dioxide equivalent using their unique global warming potential (GWP).

percent of total global emissions[10] (WRI 2008). Annual U.S. emissions, which have increased 15 percent since 1990 and typically increase each year, are heavily influenced by "general economic conditions, energy prices, weather, and the availability of non-fossil alternatives" (EPA 2008a).

Carbon dioxide is by far the primary GHG emitted in the United States, representing nearly 85 percent of all U.S. GHG emissions in 2006 (EPA 2008a). The other gases include CH_4, N_2O, and a variety of fluorinated gases, including HFCs, PFCs, and SF_6. The fluorinated gases are collectively referred to as high global warming potential (GWP) gases. Methane accounts for 8 percent of the remaining GHGs on a GWP-weighted basis, followed by N_2O (5 percent), and the high-GWP gases (2 percent) (EPA 2008a).

GHGs are emitted from a wide variety of sectors, including energy, industrial processes, waste, agriculture, and forestry. Most U.S. emissions are from the energy sector, largely due to CO_2 emissions from the combustion of fossil fuels, which alone account for 80 percent of total U.S. emissions (EPA 2008a). These emissions are due to fuels consumed in the electric power (41 percent of fossil fuel emissions); transportation (33 percent); industry (15 percent); residential (6 percent); and commercial (4 percent) sectors (EPA 2008a). However, when U.S. CO_2 emissions are apportioned by end use, transportation is the single leading source of U.S. emissions from fossil fuels, at approximately one-third of total CO_2 emissions from fossil fuels (EPA 2008a).

Cars and light-duty trucks, which include SUVs, pickup trucks, and minivans, accounted for more than half of U.S. transportation emissions, and emissions from these vehicles have increased by 21 percent since 1990 (EPA 2008a). This increase was driven by two factors: an increase in travel demand and a relatively stagnant average fuel economy. Population growth and expansion, economic growth, and low fuel prices led to more miles traveled, while the rising popularity of SUVs and other light trucks resulted in a slight decline in average combined fuel economy of new cars and light trucks (EPA 2008a).

3.4.2.1.2 Global Emissions

Although humans have always contributed to some level of GHG emissions to the atmosphere through activities like farming and land clearing, substantial contributions did not begin until the mid-1700s, with the onset of the Industrial Revolution. People began burning coal, oil, and natural gas to light their homes, power trains and cars, and run factories and industrial operations. Today the burning of fossil fuels is still the predominant source of GHG emissions.

Levels of atmospheric CO_2 have been rising rapidly. For about 10,000 years prior to the Industrial Revolution, atmospheric CO_2 levels were 280 ppm (plus or minus 20 ppm). Since the Industrial Revolution, CO_2 levels have risen to 367 ppm in 1999 and to 379 ppm in 2005. In addition, other GHGs have been on the increase. Direct atmospheric measurements since 1970 have detected a 150-percent increase in CH_4 and an 18-percent increase in N_2O (IPCC 2007c).

In 2000, global GHG emissions were estimated at 44,378 $MMTCO_2$ equivalent, a 6-percent increase since 1990[11] (WRI 2008). In general, global GHG emissions have increased regularly, though annual increases vary according to a variety of factors (weather, energy prices, and economic factors).

As in the United States, the primary GHGs emitted globally are CO_2, CH_4, N_2O, and the fluorinated gases HFCs, PFCs, and SF_6. In 2000, CO_2 emissions comprised 79 percent of global

[10] The United States contributes about 20 percent of gross GHG emissions, but only 15 percent of net emissions, which take into account carbon sinks from forestry and agriculture.
[11] All GHG estimates cited in this section include contributions from land-use change and forestry, where applicable.

emissions on a GWP-weighted basis, followed by CH_4 (14 percent) and N_2O (7 percent). Collectively, fluorinated gases represented 1 percent of global emissions (WRI 2008).

Various sectors contribute to global GHG emissions, including energy, industrial processes, waste, agriculture, land-use change and forestry, and international bunkers. The energy sector is the largest contributor of global GHG emissions, accounting for 61 percent of global emissions in 2000. In this sector, the generation of electricity and heat accounts for 26 percent of total global emissions. The next highest contributors to emissions are land-use change and forestry (17 percent), agriculture (13 percent), and transportation (12 percent; this is included in the 61 percent for the energy sector) (WRI 2008).

Emissions from transportation are primarily due to the combustion of petroleum to power vehicles such as cars, trucks, trains, planes, and ships. In 2000, transportation represented 12 percent of total emissions and 15 percent of CO_2 emissions; transportation emissions have increased 11 percent since 1990 (WRI 2008).

3.4.2.2 Climate Change Effects and Impacts (Historic and Current)

3.4.2.2.1 U.S. Climate Change Effects

This section describes observed historical and current climate change effects and impacts for the United States. Much of the discussion that follows is drawn from the USCCSP's *Scientific Assessment of the Effects of Global Change on the United States* (CCSP 2008d) and citations therein.

Observed Changes to the Climate

The past decade has been the warmest in more than a century of direct observations, with average temperatures for the contiguous United States rising at a rate near 0.6 °F per decade in the past few decades. Since 1950, the frequency of heat waves has increased, although those recorded in the 1930s remain the most severe. There were also fewer unusually cold days in the past few decades with fewer severe cold waves for the most recent 10-year period in the record (CCSP 2008d).

Over the contiguous United States, total annual precipitation increased about 6 percent from 1901 to 2005, with the greatest increases occurring in the northern Midwest and the South; heavy precipitation also increased, primarily during the last three decades of the 20^{th} Century, and mainly over eastern regions. Most regions experienced decreases in drought severity and duration during the second half of the 20^{th} Century, although there was severe drought in the Southwest from 1999 to 2007; the Southeast has also recently experienced severe drought (CCSP 2008d).

Relative sea level is rising 0.8 to 1.2 inches per decade along most of the Atlantic and Gulf Coasts, and a few inches per decade along the Louisiana Coast (due to land subsidence); sea level is falling (due to land uplift) at the rate of a few inches per decade in parts of Alaska (CCSP 2008d).

Observed Impacts from the Changing Climate

Streamflow decreased about 20 percent over the past century in the central Rocky Mountain region, while in the East it increased 25 percent in the past 60 years. Annual peak streamflow (dominated by snowmelt) in western mountains is occurring at least a week earlier than in the middle of the 20^{th} Century. Winter streamflow is increasing in seasonal snow-covered basins and the fraction of annual precipitation falling as rain (rather than snow) has increased in the past half century (CCSP 2008d). Spring and summer snow cover has decreased in the West, and in mountainous regions of the western

United States, April snow water equivalent has declined 15 to 30 percent since 1950, particularly at lower elevations and primarily due to warming (Field *et al.* 2007 as cited in CCSP 2008d). However, total snow-cover area in the United States increased in the November-to-January season from 1915 to 2004 (CCSP 2008d).

Annual average Arctic sea ice extent decreased 2.7 plus or minus 0.6 percent per decade from 1978 to 2005. In 2007, sea ice extent was approximately 23 percent less than the previous all-time minimum observed in 2005. Average sea ice thickness in the central Arctic *very likely* has decreased up to approximately 3 feet from 1987 to 1997. These area and thickness reductions allow winds to generate stronger waves, which have increased shoreline erosion along the Alaskan coast. Alaska has also experienced permafrost thawing of up to 1.6 inches per year since 1992 (CCSP 2008d).

Rivers and lakes are freezing over later (at an average rate of 5.8 plus or minus 1.6 days per century) with ice breakup taking place earlier (at an average rate of 6.5 plus or minus 1.2 days per century). Loss of glacier mass is occurring in the Northwest and has been especially rapid in Alaska since the mid-1990s (CCSP 2008d).

Sea-level rise extends the zone of impact from storm surge and waves from tropical and other storms, causing coastal erosion and other damage. It is *likely* that the numbers of tropical storms, hurricanes, and major hurricanes each year in the North Atlantic have increased during the past 100 years (CCSP SAP 3.3 2008 as cited in CCSP 2008d) and that Atlantic sea-surface temperatures have increased over the same period; however, these trends are complicated by multi-decadal variability and data-quality issues. In addition, there is evidence of an increase in extreme wave-height characteristics over the past 2 decades, associated with more frequent and more intense hurricanes (CCSP 2008d).

3.4.2.2.2 Global Climate Change Effects

This section describes observed historical and current climate change effects and impacts at a global scale. As with the discussion of effects for the United States, much of the material that follows is drawn from the following studies, including the citations therein: the IPCC WGI *Summary for Policymakers* (IPCC 2007c) and the USCCSP *Scientific Assessment of the Effects of Global Change on the United States* (CCSP 2008d).

In their most recent assessment of climate change, the IPCC states that "Warming of the climate system is unequivocal, as is now evident from observations of increases in global average air and ocean temperatures, widespread melting of snow and ice and rising global average sea level" (IPCC 2007c).

<u>Observed Changes to the Climate</u>

Global temperatures have been increasing over the past century. The 100-year linear trend (1906 to 2005) is 0.13 plus or minus 0.03 °F per decade, while the corresponding 50-year linear trend of 0.23 plus or minus 0.05 °F per decade is nearly twice that (CCSP 2008d). Average Arctic temperatures have increased at almost twice the global average rate in the past 100 years. Permafrost top layer temperatures have generally increased since the 1980s (about 5 °F in the Arctic), while the maximum area covered by seasonal frozen ground has decreased since 1900 by about 7 percent in the Northern Hemisphere, with a decrease in spring of up to 15 percent (IPCC 2007c).

Extreme temperatures have been observed to change extensively over the past 50 years. Hot days, hot nights, and heat waves have become more frequent; cold days, cold nights, and frost have become less frequent (IPCC 2007c).

Average atmospheric water vapor content has increased since at least the 1980s over land and the oceans, and in the upper troposphere, largely consistent with air temperature increases. As a result, heavy precipitation events have increased in frequency over most land areas (CCSP 2008d).

Average ocean temperatures have increased since 1961 to depths of at least 10,000 feet, with the ocean absorbing more than 80 percent of the heat added to the climate system. As seawater warms, it expands and sea levels rise. Mountain glaciers, ice caps, and snow cover have declined on average, contributing to further sea-level rise. Losses from the Greenland and Antarctica ice sheets have *very likely* contributed to sea level rise from 1993 to 2003. Dynamical ice loss explains most of the Antarctic net mass loss and about half of the Greenland net mass loss; the other half occurred because melting has exceeded snowfall accumulation (IPCC 2007c).

Global average sea level rose at an average rate of 0.07 plus or minus 0.02 inch per year from 1961 to 2003 with the rate increasing to about 0.12 plus or minus 0.03 inch per year from 1993 to 2003. Total 20th-Century rise is estimated at 0.56 plus or minus 0.16 foot (IPCC 2007c). However, since the IPCC Fourth Assessment Report was published, a recent study improved the historical estimates of upper-ocean (300 meters and 700 meters) warming from 1950 to 2003 (by correcting for expendable bathy-thermographs instrument bias). Domingues *et al.* (2008) found the improved estimates demonstrate clear agreement with the decadal variability of the climate models that included volcanic forcing. Further, this study estimated the globally averaged sea-level trend from 1961 to 2003 to be 0.063 plus or minus 0.01 inch per year with a rise of 0.094 inch per year evident from 1993 to 2003, consistent with the estimated trend of 0.091 inch per year from tide gauges after taking into account thermal expansion in the upper-ocean and deep ocean, variations in the Antarctica and Greenland ice sheets, glaciers and ice caps, and terrestrial storage.

Observed Impacts from the Changing Climate

The IPCC concludes that, "At continental, regional and ocean basin scales, numerous long-term changes in climate have been observed. These include changes in arctic temperatures and ice, widespread changes in precipitation amounts, ocean salinity, wind patterns and aspects of extreme weather including droughts, heavy precipitation, heat waves and the intensity of tropical cyclones" (IPCC 2007c).

Long-term trends in global precipitation amounts have been observed since 1900. Precipitation has substantially increased in eastern parts of North and South America, northern Europe, and northern and central Asia. Drying has been observed in the Sahel, the Mediterranean, southern Africa, and parts of southern Asia. Spatial and temporal variability for precipitation is high, and data are limited for some regions (IPCC 2007c).

Droughts that are more intense and longer have been observed since the 1970s, particularly in the tropics and subtropics, and have been caused by higher temperatures and decreased precipitation. Changes in sea-surface temperatures, wind patterns, and decreased snowpack and snow cover have also been linked to droughts (IPCC 2007c).

Long-term trends in tropical cyclone activity have been reported, but there is no clear trend in the number of tropical cyclones each year. There is observational evidence for an increase in intense tropical cyclone activity in the North Atlantic since about 1970, correlated with increases of tropical sea surface temperatures. However, concerns over data quality and multi-decadal variability persist (IPCC 2007c). The World Meteorological Organization (WMO) Sixth International Workshop on Tropical Cyclones in 2006 agreed that "no firm conclusion can be made" on anthropogenic influence on tropical cyclone activity because "there is evidence both for and against the existence of a detectable anthropogenic signal in the tropical cyclone climate record" (WMO 2006a).

Other characteristics of the global climate have not changed. The diurnal temperature range has not changed from 1979 to 2004; day- and night-time temperatures have risen at similar rates. Antarctic sea-ice extent shows no substantial average trends – despite inter-annual variability and localized changes – consistent with the lack of warming across the region from average atmospheric temperatures. There is also insufficient evidence to determine whether trends exist in large-scale phenomena such as the meridional overturning circulation (a mechanism for heat transport in the North Atlantic Ocean, where warm waters are carried north and cold waters are carried toward the equator) or in small-scale phenomena such as tornadoes, hail, lightning, and dust storms (IPCC 2007c).

3.4.3 Methodology

The methodology NHTSA used to characterize the effects of the alternatives on climate has two key elements:

1. Analyzing the effects of the alternatives on GHG emissions
2. Analyzing how the GHG emissions affect the climate system (climate effects)

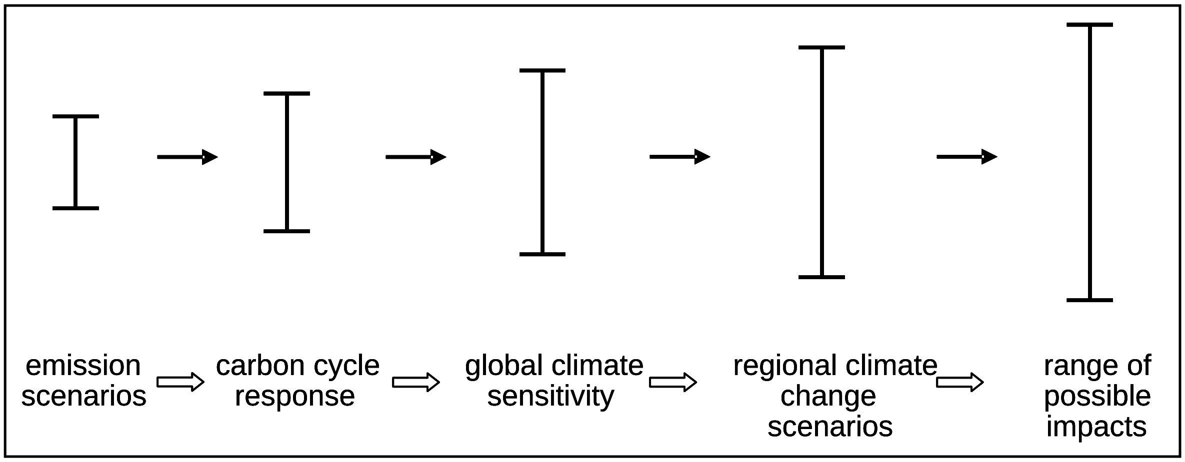
For both the effects on GHG emissions and the effects on the climate system, this FEIS expresses results – for each alternative – in terms of the environmental attribute being characterized (emissions, CO_2 concentrations, temperature, precipitation, and sea level). Comparisons between the No Action Alternative (Alternative 1) and each action alternative (Alternatives 2 through 7) are also presented to illustrate the differences in environmental effects among the alternative CAFE standards.

The methods used to characterize emissions and climate effects involve considerable uncertainty. Sources of uncertainty include the pace and effects of technology change in the transportation sector and other sectors that emit GHGs; changes in the future fuel supply that could affect emissions; sensitivity of climate to increased GHG concentrations; rate of change in the climate system in response to changing GHG concentrations; potential existence of thresholds in the climate system (which cannot be predicted or simulated); regional differences in the magnitude and rate of climate changes; and many other factors.

Moss and Schneider (2000) characterize the “cascade of uncertainty” in climate change simulations (Figure 3.4-3). As indicated in the figure, the emissions estimates used in this FEIS have narrower bands of uncertainty than the global climate effects, which are less uncertain than the regional climate change effects. The effects on climate are, in turn, less uncertain than the impacts of climate changes on affected resources (such as terrestrial and coastal ecosystems, human health, and other resources discussed in Section 4.5).

Where information in the analysis included in this FEIS is incomplete or unavailable, NHTSA has relied on the CEQ regulations regarding incomplete or unavailable information (*see* 40 CFR § 1502.22(b)). The understanding of the climate system is incomplete; like any analysis of complex, long-term changes to support decisionmaking, evaluating reasonably foreseeable significant adverse impacts on the human environment involves many assumptions and uncertainties. This FEIS uses methods and data that represent the best available information on this topic, and have been subjected to peer review and scrutiny. In fact, the information cited throughout this section that is extracted from the IPCC and USCCSP has endured a more thorough and systematic review process than information on virtually any other topic in environmental science and policy. The MAGICC (Model for the Assessment of Greenhouse-gas Induced Climate Change) model and the IPCC emissions scenarios described below are generally accepted in the scientific community.

Figure 3.4-3. Cascade of Uncertainty in Climate Change Simulations a/



a/ Source: Moss and Schneider (2000) – "Cascade of uncertainties typical in impact assessments showing the 'uncertainty explosion' as these ranges are multiplied to encompass a comprehensive range of future consequences, including physical, economic, social, and political impacts and policy responses."

NHTSA is aware of the USCCSP's recent release of the Final Report of Synthesis and Assessment Product (SAP) 3.1 regarding the strengths and limitations of climate models (CCSP 2008g). The reader might find the discussions in this draft Synthesis and Assessment Product useful to grasp a better understanding of the methodological limitations regarding modeling the environmental impacts of the proposed action and the range of alternatives on climate change.

3.4.3.1 Methodology for Modeling Greenhouse Gas Emissions

GHG emissions were estimated using the Volpe model, as described in Section 3.1.4. The emissions estimates include CO_2, CH_4, and N_2O emissions from both direct fuel combustion and upstream sources. The Volpe model also accounted for and estimated the following non-GHGs: SO_2, NO_x, CO, and VOCs.

The Volpe model assumes that major manufacturers will utilize all available technology before paying noncompliance civil penalties. In the more stringent alternatives, the Volpe model predicts that increasing numbers of manufacturers will run out of technology to apply and, theoretically, resort to penalty payment. Setting standards this high might not be technologically feasible, and doing so might not serve the need of the Nation to conserve fuel or reduce emissions.

Fuel savings from stricter CAFE standards also result in lower emissions of CO_2, the main GHG emitted as a result of refining, distribution, and use of transportation fuels.[12] There is a direct relationship between fuel economy and CO_2 emissions. Lower fuel consumption reduces CO_2 emissions directly because the primary source of transportation-related CO_2 emissions is fuel combustion in internal-combustion engines. NHTSA estimates reductions in CO_2 emissions resulting from fuel savings by assuming that the carbon content of gasoline, diesel, and other fuels is converted entirely to CO_2 during

[12] For this rulemaking, NHTSA estimated emissions of vehicular CO_2, CH_4, and N_2O emissions, but did not estimate vehicular emissions of HFCs. Methane and nitrous oxide account for less than 3 percent of the tailpipe GHG emissions from passenger cars and light trucks, and CO_2 emissions account for the remaining 97 percent. Of the total (including non-tailpipe) GHG emissions from passenger cars and light trucks, tailpipe CO_2 represents about 93.1 percent, tailpipe methane and nitrous oxide represent about 2.4 percent, and HFCs (from air conditioner leaks) represent about 4.5 percent. (Values calculated from EPA 2008a.)

the combustion process.[13] Reduced fuel consumption also reduces CO_2 emissions that result from the use of carbon-based energy sources during fuel production and distribution. NHTSA currently estimates the reductions in CO_2 emissions during each phase of fuel production and distribution using CO_2 emissions rates obtained from the GREET (Greenhouse Gases, Regulated Emissions, and Energy Use in Transportation) model, using the previous assumptions about how fuel savings are reflected in reductions in each phase (NHTSA 2008b). The total reduction in CO_2 emissions from improving fuel economy under each alternative CAFE standard is the sum of the reductions in emissions from reduced fuel use and from lower fuel production and distribution.

3.4.3.2 Methodology for Estimating Climate Effects

This FEIS estimates and reports on four direct and indirect effects of climate change, driven by alternative scenarios of GHG emissions, including:

1. Changes in CO_2 concentrations
2. Changes in global mean surface temperature
3. Changes in regional temperature and precipitation
4. Changes in sea level

The change in CO_2 concentration is a direct effect of the changes in GHG emissions and influences each of the other factors.

This FEIS uses a climate model to estimate the changes in CO_2 concentrations, global mean surface temperature, and changes in sea level for each alternate CAFE standard and uses increases in global mean surface temperature combined with an approach and coefficients from the IPCC Fourth Assessment Report (IPCC 2007a) to estimate changes in global precipitation. NHTSA used MAGICC version 5.3 (Wigley 2003 to 2008) to estimate changes in key direct and indirect effects. The application of MAGICC version 5.3 uses the emissions estimates for CO_2, CH_4, and N_2O from the Volpe model. Sensitivity analyses were completed to examine the relationship among various CAFE alternatives, climate sensitivities, and scenarios of global emissions paths and the associated direct and indirect effects for each combination. These relationships can be used to infer the effect of emissions associated with the regulatory alternatives on direct and indirect climate effects.

Sections 3.4.3.2.1 through 3.4.3.2.4 describe MAGICC, the climate sensitivity analyses, and the emissions scenarios used in the analysis.

3.4.3.2.1 MAGICC Version 5.3

The selection of MAGICC for this analysis was driven by a number of factors, as follows:

- MAGICC has been used in the peer-reviewed literature to evaluate changes in global mean surface temperature and sea-level rise, including the IPCC Fourth Assessment Report for WGI (IPCC 2007a) in which it was used to scale the results from the atmospheric-ocean general circulation models (AOGCMs)[14] to estimate the global mean surface temperature and the sea-level rise for global emissions scenarios that the AOGCMs did not run.

[13] This assumption results in a slight overestimate of CO_2 emissions, because a small fraction of the carbon content of gasoline is emitted as carbon monoxide and unburned hydrocarbons. However, the magnitude of this overestimate is likely to be extremely small. This approach is consistent with the recommendation of the IPCC for "Tier 1" national GHG emissions inventories (IPCC 2006).
[14] For a discussion of AOGCMs, *see* WGI, Chapter 8 in IPCC (2007a).

- MAGICC is publicly available and is already populated with the Special Report on Emission Scenarios (SRES) scenarios. The SRES scenarios are long-term emissions scenarios representing different assumptions about key drivers of GHG emissions. They are described in more detail below.

- MAGICC was designed for the type of analysis performed in this FEIS.

- More complex AOGCMs are not designed for the type of sensitivity analysis performed here and are best used to provide results for groups of scenarios with much greater differences in emissions such as the B1 (low), A1B (medium), and A2 (high) scenarios.[15]

- MAGICC has been updated to version 5.3 to incorporate the science from the IPCC Fourth Assessment Report (Wigley 2003 to 2008).

For the analysis using MAGICC, we have assumed that global emissions consistent with the No Action Alternative (Alternative 1) follow the trajectory provided by the SRES A1B (medium) scenario.

3.4.3.2.2 Modeling Runs and Sensitivity Analyses

The modeling runs and climate sensitivity analyses are designed to use information on CAFE alternatives, climate sensitivities, and SRES emissions scenarios provided by the IPCC (IPCC 2007a)[16] to model relative changes in atmospheric concentrations, global mean surface temperature, precipitation, and sea-level rise.

The modeling runs are based on the results provided for the seven CAFE alternatives using the Reference Case Volpe model assumptions, a climate sensitivity of 3 °C for a doubling of CO_2 concentrations in the atmosphere, and the SRES A1B (medium) scenario.

The approach uses the following steps to estimate these changes:

1. NHTSA assumed that global emissions consistent with the No Action Alternative follow the trajectories provided by the SRES A1B scenario, providing results illustrating the uncertainty due to factors influencing future global emissions of GHGs.

2. NHTSA assumed that global emissions for the CAFE alternatives are equal to the global emissions from the No Action Alternative minus the emissions reductions from the Volpe model for CO_2, CH_4, N_2O, SO_2, NO_x, CO, and VOCs. All SO_2 reductions were applied to the Aerosol region 1 of MAGICC, which includes North America.

3. NHTSA used MAGICC 5.3 to estimate the changes in CO_2 concentrations, global mean surface temperature, and sea-level rise through 2100 using the No Action Alternative and CAFE alternatives developed in Steps 1 and 2 above.

---

[15] The IPCC SRES scenarios were developed in the late 1990s and published in 2000 (Nakicenovic *et al.* 2000). The SRES scenarios were developed around four storylines. The A1 storyline included a strong commitment to market based solutions, high savings, high economic growth, and globalization. The A2 storyline differs from A1 with lower trade flows and slower rates of technological improvement. The B1 storyline includes a global integrated approach to sustainable development. The B2 storyline includes increased local awareness of environmental issues with strong efforts at the local level and less reliance on international institutions.

[16] The use of different emissions scenarios provides insight into the impact of alternative global emissions scenarios on the effect of the CAFE alternatives.

4. For the core results, NHTSA used the increase in global mean surface temperature, along with factors relating increase in global average precipitation to this increase in global mean surface temperature, to estimate the increase in global averaged precipitation for each CAFE alternative for the A1B (medium) scenario.

The approach uses the following steps to estimate the climate sensitivity of the results to the selection of the SRES global emissions scenario:

1. NHTSA assumed that global emissions consistent with the No Action Alternative follow four potential trajectories represented by the SRES A2, B1, B2, and A1FI scenarios. The results of these simulations illustrate the uncertainty due to factors influencing future global emissions of GHGs (that is, factors other than the CAFE rulemaking).

2. For each SRES scenario from Step 1, NHTSA assumed that global emissions for the CAFE alternatives are equal to the global emissions from the No Action Alternative minus the emissions reductions from the Volpe model for CO_2, CH_4, N_2O, SO_2, NO_x, CO, and VOCs. All SO_2 reductions were applied to the Aerosol region 1 of MAGICC, which includes North America.

3. NHTSA used MAGICC 5.3 to estimate the changes in CO_2 concentrations, global mean surface temperature, and sea-level rise through 2100 using the No Action Alternative and CAFE alternatives developed in Steps 1 and 2.

Section 3.4.4 presents the results of the model runs for the alternatives. Section 3.4.5 presents the results from similar runs in which the CAFE alternatives use the high- and mid-level Volpe model assumptions (for this analysis, called the High, Mid-1, and Mid-2 Scenarios), in effect providing a “CAFE assumption sensitivity analysis.”

3.4.3.2.3 Emissions Scenarios

As described above, MAGICC uses long-term emissions scenarios representing different assumptions about key drivers of GHG emissions. All scenarios used are based on the IPCC effort to develop a set of long-term (1990 to 2100) emissions scenarios to provide some standardization in climate-change modeling. The most widely used scenarios are those from the SRES (Nakicenovic *et al.* 2000).

The results rely primarily on the SRES scenario referred to as “A1B” to represent a Reference Case emissions scenario; that is, emissions for the No Action Alternative. NHTSA selected this scenario because it is regarded as a moderate emissions case and has been widely used in AOGCMs, including several AOGCM runs developed for the IPCC Fourth Assessment Report (IPCC 2007a).

NHTSA chose the A1B scenario based on the following factors:

- IPCC Working Group I evaluated the climate effects from A1B extensively in the Fourth Assessment Report (IPCC 2007a) and provides a basis for comparing the results from the analysis using MAGICC to those in the IPCC Fourth Assessment Report.

- The A1B and B2 scenarios are “middle-of-the-road” scenarios and provide the best comparison (see below) to the Energy Information Administration (EIA) Annual Energy Outlook (AEO) 2008 and International Energy Outlook (IEO) 2008 forecasts of liquid energy use, and the AEO 2008/IEO 2008 provide the base assumptions for key parameters in the Volpe model scenarios.

The A1B (medium) scenario provides a global context for emissions of a full suite of GHGs and ozone precursors. There are some inconsistencies between the overall assumptions IPCC used in its SRES (Nakicenovic *et al.* 2000) to develop global emissions scenarios and the assumptions used in the Volpe model in terms of economic growth, energy prices, energy supply, and energy demand. However, these inconsistencies affect the characterization of each CAFE alternative in equal proportion, so the relative estimates provide a reasonable approximation of the differences in environmental impacts among the alternatives. NHTSA used the A1B scenario as the primary scenario for the evaluation of climate effects, but used the A2, B1, B2, and the A1FI scenarios to provide an evaluation of the sensitivity of the results to alternative emissions scenarios.[17]

Each of the alternatives was simulated by calculating the difference in annual GHG emissions in relation to the No Action Alternative and subtracting this change from the A1B (medium) scenario to generate modified global-scale emissions scenarios, which each show the effect of the various regulatory alternatives on the global emissions path. For example, emissions from U.S. autos and light trucks in 2020 under Alternative 1, No Action, are 1,651 $MMTCO_2$; the emissions in 2020 under the Optimized Alternative (Alternative 3) are 1,622 $MMTCO_2$. The difference is 29 $MMTCO_2$. Global emissions for the A1B (medium) scenario in 2020 are 46,339 $MMTCO_2$, and represent the No Action Alternative. Global emissions for the Optimized Alternative are 29 $MMTCO_2$ less, or 46,310 $MMTCO_2$.

NHTSA based its assumptions in the Volpe model for growth in the number of vehicles and miles driven for cars and light trucks in the United States on those in the AEO because the IPCC SRES results are reported for four global regions, including the OECD, and not for the United States separately. The EIA also published the IEO for 2008 (EIA 2008c), which provides a global forecast of energy use and CO_2 from energy use through 2030, and which is consistent with assumptions in the 2008 IEO.[18]

Figures 3.4-4 to 3.4-7 provide the forecast of gross domestic product (GDP), CO_2 emissions from energy use, primary energy use from the IEO 2008, and the five SRES scenarios for the world and OECD 90 region.[19] The GDP growth assumptions for A1B for the OECD are close to those of the IEO 2008, but the A1B scenario has much higher GDP growth outside the OECD. This leads to higher global primary energy use by 2030, as shown in Figure 3.4-6, with much of the increase in natural gas use and higher emissions of CO_2 as shown in Figure 3.4-5. The global primary liquids energy use in A1B and the IEO 2008 compare well considering that the IEO forecast for liquid fuels includes about 10 percent of the total in unconventional sources, which are accounted for elsewhere in the SRES scenarios.

The forecast estimates for the OECD 90 region vary differently than the global numbers. The EIA shows a similar increase in primary energy use in the OECD 90 region but much greater increase in the use of primary liquid fuels, even considering the reporting differences between the IEO and SRES.

---

[17] From SRES, NHTSA used the A1B-AIM scenario to represent the A1B storyline, the A2-ASF scenario to represent the A2 storyline, the B1-IMAGE scenario to represent the B1 storyline, the B2-MESSAGE scenario to represent the B2 storyline, and the A1G-MINICAM scenario to represent the A1FI storyline.

[18] The IEO 2008 uses energy supply and consumption from the AEO 2008 for the United States and the same forecast for world oil prices.

[19] The IEO nuclear primary energy forecast numbers were adjusted to account for differences in reporting primary energy use for nuclear energy and all IEO energy-use estimates were converted to exajoules (EJ).

Figure 3.4-4. Average GDP Growth Rates (1990 to 2030)

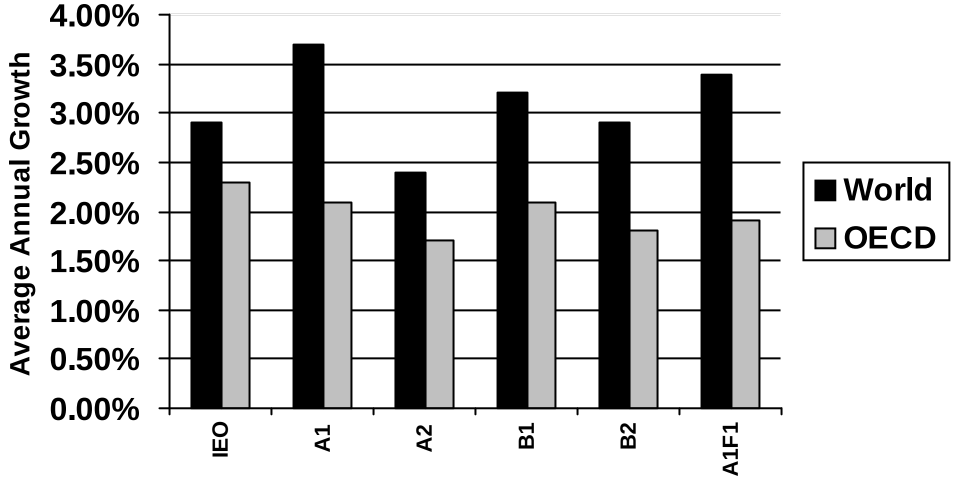


Figure 3.4-5. Global CO2 Emissions from Fossil Fuel Use

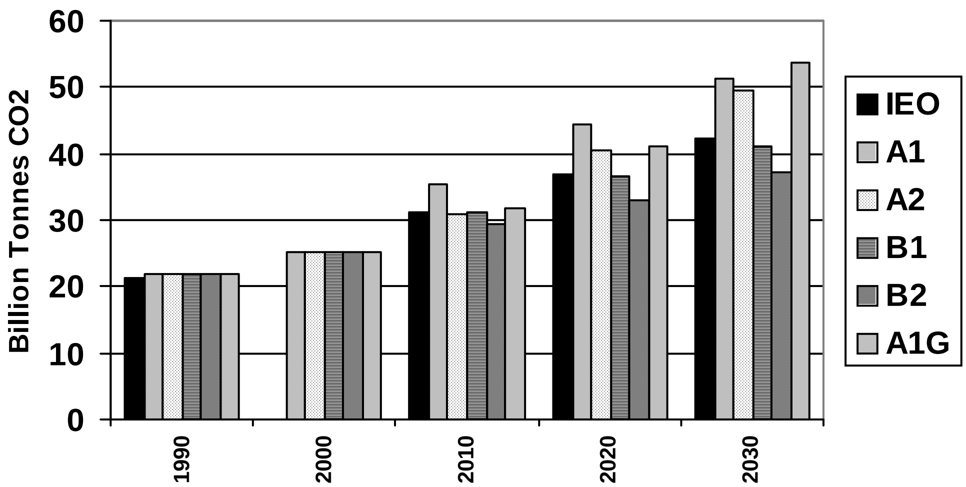

Figure 3.4-6. World Primary Energy Use Forecast

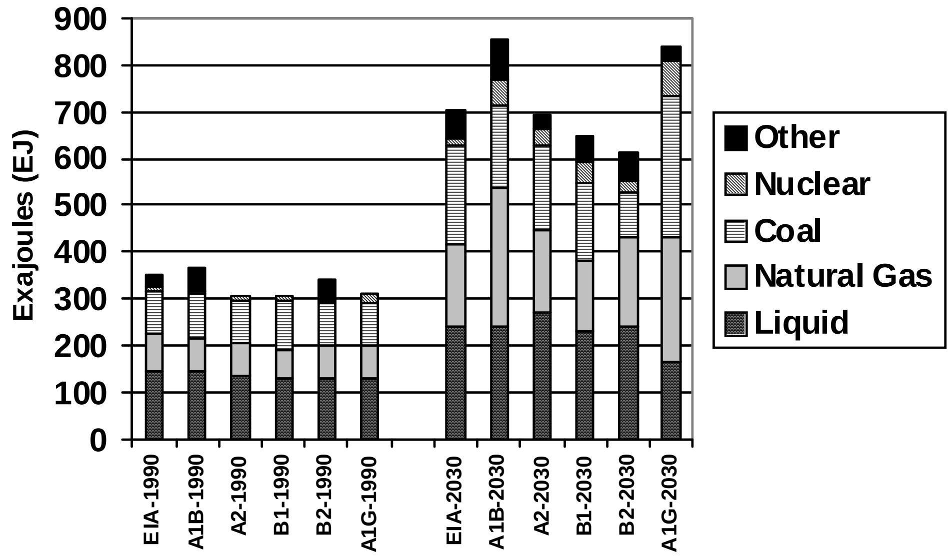

Figure 3.4-7. OECD90 Primary Energy Use Forecast[20]

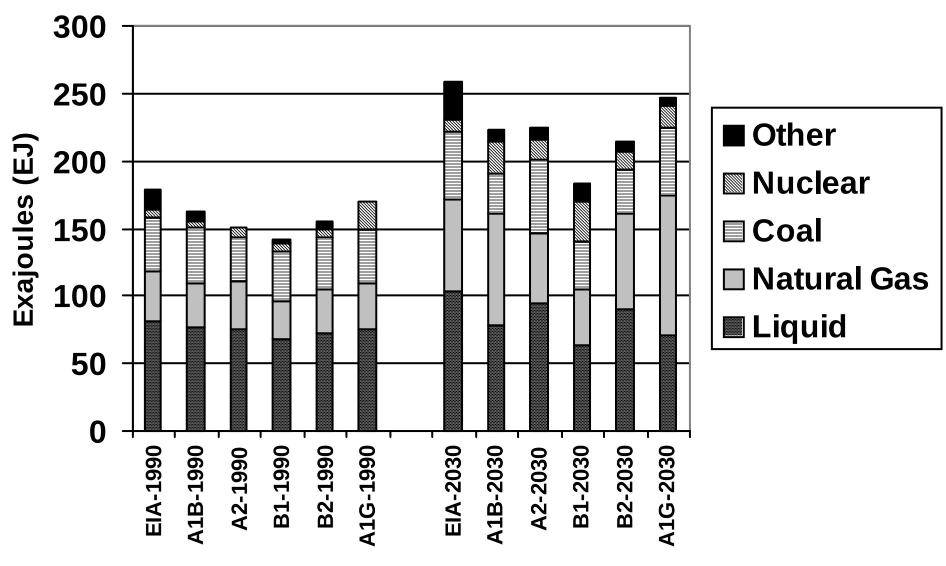


Where information in the analysis included in this FEIS is incomplete or unavailable, NHTSA has relied on the CEQ regulations regarding incomplete or unavailable information (*see* 40 CFR § 1502.22(b)). In this case, despite the inconsistencies between the IPCC assumptions on global trends

[20] The SRES results provide forecasts for countries that were members of the OECD in 1990 only. The IEO 1990 and 2030 estimates are scaled to reflect only countries in the OECD in 1990.

across all GHG-emitting sectors (and the drivers that affect them) and the particularities of the Volpe model on the U.S. transportation sector, the approach used is valid for this analysis. These inconsistencies affect all alternatives equally; therefore, they do not hinder a comparison of the alternatives in terms of their relative effects on climate.

The approaches focus on marginal changes in emissions that affect climate. Thus, the approaches result in a reasonable characterization of climate change for a given set of emissions reductions, regardless of the underlying details associated with those emissions reductions. The discussion that follows characterizes projected climate change under the No Action Alternative (Alternative 1) and the action alternatives (Alternatives 2 through 7).

The climate sensitivity analysis also uses the B1 (low), B2, A2 (high), and A1F1 emissions scenarios (Nakicenovic *et al.* 2000) as "reference" scenarios. This provides a basis for determining climate responses to varying levels of global emissions and climate sensitivities under for the Optimized Alternative (Alternative 3). Some responses of the climate system are believed to be non-linear; by using a range of emissions cases and climate sensitivities, the effects of the alternatives in relation to different reference cases can be estimated.

3.4.3.2.4 Tipping Points and Abrupt Climate Change

The phrase "tipping point" is most typically used, in the context of climate change and its consequences, to describe situations in which the climate system (the atmosphere, oceans, land, cryosphere,[21] and biosphere) reaches a point at which there is a disproportionately large or singular response in a climate-affected system as a result of only a moderate additional change in the inputs to that system (such as an increase in the CO_2 concentration). Exceeding one or more tipping points, which "occur when the climate system is forced to cross some threshold, triggering a translation to a new state at a rate determined by the climate system itself and faster than the cause" (Committee on Abrupt Climate Change 2002), could result in abrupt changes in the climate or any part of the climate system. These changes would likely produce impacts at a rate and intensity far greater than the slower, steady changes currently being observed (and in some cases, planned for) in the climate system.

The phrase tipping point is also used outside the climate modeling community. In addition to climate scientists, many others – including biologists, marine chemists, engineers, and policymakers – are concerned about tipping points, because it is not just the climate that can change abruptly. The same type of non-linear responses exists in the physical, environmental, and societal systems that climate affects. For example, ocean acidity resulting from an elevated atmospheric concentration of CO_2 might reach a point at which there would be a dramatic decline in coral ecosystems. Consideration of possible tipping points could therefore encompass sharp changes in climate-affected resources and not be restricted to climate change alone.

Using the broad definition of the term tipping point to include both climate change and its consequences, the scale of spatial responses can range from global (*e.g.*, a "supergreenhouse" atmosphere with higher temperatures worldwide), to continental or subcontinental changes (such as dramatically altering the Asian monsoon), to regional (*e.g.*, drying in the southwestern United States leading to increases in the frequency of fires, to local (such as loss of the Sierra Nevada snowpack). The definition of tipping point used by Lenton *et al.* (2008) (discussed below) specifically applies only to subcontinental or larger features, whereas public policy is concerned with a wider range of scales, as the IPCC analysis (discussed below) suggests.

[21] The cryosphere describes the portion of Earth's surface that is frozen water, such as snow, permafrost, floating ice, and glaciers.

The temporal scales considered are also important. On crossing a tipping point, the evolution of the climate-affected system is no longer controlled by the time scale of the climate forcing (such as the heat absorption by GHGs), but rather is determined by its internal dynamics, which can either be much faster than the forcing, or substantially slower. The much faster case – abrupt climate change – might be said to occur when the:

- Rate of change is sharply greater than (or a different sign than) what has been prevailing over previous decades;
- State of the system exceeds the range of variations experienced in the past; or
- Rate has accelerated to a pace that exceeds the resources and ability of nations to respond to it.

Climate changes could occur in many ways as tipping points are reached. These mechanisms range from the appearance or unusual strengthening of positive feedbacks – self-reinforcing cycles – and reversible-phase transitions in climate-affected systems to irreversible-phase transitions – where a threshold has been crossed that could lead to either abrupt or unexpected changes in the rate or direction of change in climate-affected systems. Although climate models incorporate many positive (and negative, or dampening) feedback mechanisms, the magnitude of these effects and the threshold at which the feedback-related tipping points are reached are only roughly known, especially regarding global impacts. In addition, models of climate and climate-affected systems do not contain all feedback processes. Although substantial progress has been made in understanding the qualitative processes associated with tipping points, there are limits to the quantitative understanding of many of these systems.

In recent years, the concept of a tipping point – or a set of tipping points – in Earth's climate system has been attracting increased attention among climate scientists and policy makers. The following sections draw on perspectives from four key analyses of the issue and other relevant research: the IPCC, the USCCSP, paleoclimate[22] evidence, and Lenton *et al.* (2008). The section concludes with a brief comparative evaluation.

IPCC Perspectives on Tipping Points

In its Fourth Assessment Report, the IPCC addresses the issue of tipping points in the discussion of "major or abrupt climate changes" and highlights three large systems: the meridional overturning circulation (MOC) system that drives Atlantic Ocean circulation, the collapse of the West Antarctic ice sheet, and the loss of the Greenland ice sheet (Meehl *et al.* 2007). The IPCC states that there is uncertainty in the understanding of these systems but concludes that these systems are unlikely to reach their tipping points within the 21st Century (Meehl *et al.* 2007). The IPCC also mentions additional systems, as noted below, that might have tipping points, but does not include estimates for them.

The IPCC WGI report (Meehl *et al.* 2007) describes various climate and climate-affected systems that might undergo abrupt change, contribute to "climate surprises," or experience irreversible impacts. The systems that the IPCC described include:

- Atlantic MOC (AMOC) and other ocean circulation changes
- Arctic sea ice

[22] Paleoclimatology is the study of climate change through the physical evidence left on earth of historical global climate change (prior to the widespread availability of records to temperature, precipitation, and other data). *See generally* http://www.giss.nasa.gov/research/paleo/.

- Glaciers and ice caps
- Greenland and West Antarctic ice sheets
- Vegetation cover
- Atmospheric and ocean-atmosphere regimes

The IPCC Working Group II (WGII) report provides insight on the uncertainties surrounding tipping points, their systemic and impact thresholds, and the value judgments required to select a critical level of warming (Carter *et al.* 2007). The presence of these thresholds can also present their own physical and ecological limits and informational and cognitive barriers to adaptation (Adger *et al.* 2007). In the case of this FEIS, uncertainty prevents NHTSA from being able to quantify the impacts of the alternatives under consideration on specific tipping-point thresholds.

In the IPCC WG II report, certain thresholds are assumed and then used with analyses of emissions scenarios and stabilization targets to assess how certain impacts might be avoided (Schneider *et al.* 2007). For example, several authors hypothesize that a large-scale climatic event or other impacts (for example, widespread coral-reef bleaching; deglaciation of West Antarctica) would be likely if atmospheric CO_2 concentrations stabilize at levels exceeding 450 ppm, although the location of the tipping points and thresholds is uncertain (O'Neill and Oppenheimer 2002, Lowe *et al.* 2006, and Corfee-Morlot and Höhne 2003, all as cited in Schneider *et al.* 2007).

USCCSP Perspectives on Tipping Points

The USCCSP reaches similar conclusions in its report *Scientific Assessment of the Effects of Global Change on the United States* (National Science and Technology Council 2008). The USCCSP report summarizes scientific studies that suggest that there are several "triggers" of abrupt climate change and that "anthropogenic forcing *could* increase the risk of abrupt climate change;" however, "future abrupt changes cannot be predicted with confidence" because of the insufficiencies of current climate models, which reflect the limits of current understanding.[23] However, the USCCSP report does reiterate the conclusion that if it occurs, an abrupt climate change event would likely transpire over the course of many hundreds of years and that it is *"very unlikely"* that any abrupt climate change will occur "during the 21st century."

The USCCSP analysis considers the susceptibility of the same three systems to abrupt change as IPCC highlighted: the AMOC system that drives Atlantic Ocean circulation, the collapse of the West Antarctic ice sheet, and the loss of the Greenland ice sheet (National Science and Technology Council 2008). The USCCSP analysis also suggests that there are thresholds in non-climate systems influenced by CO_2 emissions, such as ocean acidification, where there could be a threshold beyond which existing coral reef ecosystems cannot survive (CCSP 2008e). The USCCSP report concludes that these impacts, including climate-related thresholds, could occur in groups as thresholds are crossed, but, due to the uncertainty, more research is needed to quantify the impacts of crossing particular thresholds and to determine when these thresholds would be reached (CCSP 2008e). A forthcoming USCCSP report, Synthesis and Assessment Product 3.4, "Abrupt Climate Change," will provide additional information on this topic, focusing on glaciers and ice sheets, hydrological change, the MOC, and methane releases.

[23] *See* U.S. Climate Change Science Program, Synthesis and Assessment Product 3.1 (Climate Models: An Assessment of Strengths and Limitations), Final Report (July 2008), *available at* http://www.climatescience.gov/Library/default.htm#sap.

Paleoclimate Evidence on Tipping Points

The paleoclimate record cited by IPCC, USCCSP, and others gives an indication of sea-level rise from previous ice-sheet melt, and the corresponding temperature for these periods. For example, geological evidence showing the presence of elevated beaches suggests that global sea level was 4 to 6 meters higher during the most recent interglacial period about 125,000 years ago (Jansen *et al.* 2007). Paleoclimatic reconstructions suggest that global average temperature then was about 1 °C (1.8 °F) warmer than during the present interglacial period (Hansen *et al.* 2007b). Corings from the ice sheets to determine their ages, supplemented by simulations of ice-sheet extent, suggest that large-scale retreat of the southern half of the Greenland ice sheet and other Arctic ice fields likely contributed roughly 2 to 4 meters of sea-level rise during the last interglacial, with most of any remainder likely coming from the Antarctic ice sheet (Jansen *et al.* 2007).

Paleoclimatic reconstructions also indicate occurrences of abrupt changes in the terrestrial, ice, and oceanic climatic records. For example, ice-core records suggest that temperatures atop the Greenland ice sheet warmed by 8 to 16 °C (14 to 29 °F) within a few decades during Dansgaard-Oeschger events,[24] which were likely caused by the North Atlantic Ocean being covered by catastrophic outflows of glacial meltwater from the North American ice sheet that was present during glacial times (Jansen *et al.* 2007). A more recent study (Steffensen *et al.* 2008) provides more detail, indicating that a there was a sharp warming over 1 to 3 years (that is, "abrupt climate change happens in [a] few years"), followed by a more gradual warming over 50 years.

Based on the IPCC estimates of temperature increases of approximately 2 to 4 °C in the next 100 years, MacCracken (2008) notes that paleoclimatic research indicates that corresponding sea-level rise could be 10 to 20 meters or more from the melting of the West Antarctic and Greenland ice sheets. The time required to melt the ice sheets is uncertain, ranging from decades to centuries or longer. MacCracken (2008) suggests that "significant sea level rise [over 1 meter] could happen relatively quickly," meaning less than a century. For example, the average rate of rise from 20 kiloannum[25] (ka) to 8 ka was about 1 meter per century, so there have been periods with high rates of rise, although the melting North American ice sheet was an order of magnitude larger than Greenland is today (MacCracken, personal communication, 2008). For the future, Hansen *et al.* (2007b) asserts that positive feedback mechanisms in the climate system have the potential to cause large and rapid shifts in climate and in factors like glacial melt and sea-level rise that are closely dependent on the climate; Rahmstorf (2007) presents a projected sea-level rise in 2100 of 0.5 to 1.4 meters above the 1990 level.

In a study utilizing model runs and paleoclimatic data,[26] Hansen *et al.* (2007b) conclude that "…a CO_2 level exceeding about 450 ppm is 'dangerous,'" where "dangerous" is defined by the authors to be global warming of more than 1 ºC (1.8 ºF) above the level in 2000, potentially leading to highly disruptive effects. Although this 450-ppm estimate has limitations and uncertainties, Hansen actually considers this estimate of dangerous CO_2 concentration to be an upper limit because it depends on several simplifying assumptions (Hansen 2008b). He warns that the limit might be lower and that a "safe" level

[24] Dansgaard-Oeschger events are very rapid climate changes—up to 7 °C in some 50 years—during the Quaternary geologic period, and especially during the most recent glacial cycle. (A Dictionary of Geography. Oxford University Press, 1992, 1997, 2004.)
[25] Kiloannum means "one thousand years ago."
[26] The authors compare the corresponding GHG concentrations and associated temperature increases to paleoclimatology research to demonstrate that abrupt changes have occurred in Earth's past, resulting from a similar range in increased temperature as those being predicted, and to argue the existence of a CO_2 concentration equivalent level (in atmospheric GHG concentration) at which the probability of abrupt, irreversible changes in climate-affected systems might occur.

of CO_2 could be 350 ppm – lower than the CO_2-equivalent concentration, including the offsetting effects of aerosols, is today (Hansen 2008b).

The range of views linking past and future sea-level rise is clearly broad, with uncertainty attributable to each view. Therefore, the forthcoming USCCSP report – Synthesis and Assessment Product 3.4, "Abrupt Climate Change" – should provide additional, more complete information on the issue.

Perspectives on Tipping Points from a Critical Review of the Literature and an Expert Elicitation as Presented by Lenton *et al.* (2008)

Building on the IPCC and USCCSP research, during a workshop titled "Tipping Points in the Earth System," experts identified several climate systems that have tipping points and conducted an expert elicitation involving 52 members of the international scientific community, many of whom participated in the IPCC. This study identified nine systems facing separate tipping points due to increased CO_2 and temperature levels that met four scientifically based criteria to be considered "policy-relevant potential future tipping elements in the climate system" (Lenton *et al.* 2008). Additional systems were identified but insufficient information precluded these systems from meeting the definition of policy relevant. The systems at risk that the researchers identified are:

- Arctic sea ice
- Greenland ice sheet
- West Antarctic ice sheet
- Atlantic thermohaline circulation (a component of the AMOC)
- El-Niño-Southern oscillation
- Indian summer monsoon
- Sahara/Sahel and West African monsoon
- Amazon rainforest
- Boreal forest

The discussion that follows is drawn primarily from the Lenton *et al.* (2008) study, including the citations therein.

Arctic sea ice. The surface of Arctic sea ice has a higher reflectivity (albedo) than the darker ocean surface. As sea ice melts from higher air and ocean temperatures, more of the ocean is exposed, which allows more radiation to be absorbed, amplifying the sea-ice melt. In summer, Arctic sea-ice loss could lead to the ice cap melting beyond a certain size/thickness, making it unstable and leading to an ice-free Arctic. Recent record ice losses and modeling studies have led some researchers to suggest that the summer Arctic will be ice free within a decade or less, that there is a critical threshold for summer Arctic sea-ice loss, and that this threshold has already been crossed (Borenstein and Joling 2008).

Greenland ice sheet. The Greenland ice sheet is also susceptible to positive feedbacks. Melting at the glacial margins lowers the edge of the ice sheet to elevations that are warmer and where more melting will occur. The IPCC estimated the Greenland ice sheet threshold for negative surface mass at 1.9 to 4.6 °C (3.4 to 8.3 °F) above pre-industrial temperature, well within the predicted temperature range for this century. Dynamic ice-melting processes, regional temperatures, warming surrounding oceans, and recent observations indicating that both Greenland and Antarctica are now losing mass have led researchers to conclude that the timescale for Greenland ice-shelf collapse is conceivably on a scale of hundreds rather than thousands of years.

West Antarctic ice sheet. The West Antarctic ice sheet is grounded below sea level and positive feedbacks could result from the loss of buttressing sea-ice shelves and the ingress of warmer ocean water. While centuries or millennia could to pass before a collapse, the thresholds for ocean and surface atmospheric warming temperature are likely to be crossed this century. A recent study of ice-core records suggests strong links between past West Antarctic climate, and potentially its ice sheet, to large-scale changes in global climate, particularly major El Niño events (Schneider and Steig 2008). It should be noted that ice-sheet loss, even over millennia, could cause the sea level to rise at a rate greater than 1 meter per century – more than five times the rate of rise during the 20^{th} Century. The level reached would be higher than has been the case during at least the past few thousand years when coastal cities were established.

Atlantic thermohaline circulation. The term thermohaline circulation (THC) refers to the physical driving mechanism of ocean circulation, resulting from fluxes of heat and freshwater across the sea surface, subsequent interior mixing of heat and salt, and geothermal heat sources. The MOC, discussed in the IPCC and USCCSP reports, is the observed response in an ocean basin to this type of ocean circulation coupled with wind-driven currents. The Lenton *et al.* (2008) paper refers to risk to the Atlantic THC instead of the AMOC because they are discussing the influence of climate change on the underlying cooling or freshwater forcing of the Atlantic Ocean circulation, even though this in turn dramatically affects the AMOC.

If enough freshwater enters the North Atlantic (such as from melting sea ice or the Greenland ice sheet), the density-driven sinking of North Atlantic waters might be reduced or even stopped, as evidence indicated occurred happened during the last glacial cycle. This would likely reduce the northward flow of energy in the Gulf Stream and result in less heat transport to the North Atlantic. At the same time, reduced formation of very cold water would likely slow the global ocean THC, leading to impacts on global climate and ocean currents. The IPCC review of the results of model simulations suggests that an abrupt transition of the Atlantic Ocean's component of the global THC is *very unlikely* this century. However, more recent modeling that includes increased freshwater inputs suggests there could be initial changes this century, with larger and more intense reductions in the overturning circulation persisting for many centuries (Mikolajewicz *et al.* 2007).

El-Niño-Southern oscillation (ENSO). The changes that might lead to increasingly persistent (and frequent) El Niño (or La Niña) conditions are particularly uncertain. Increases in ocean heat content could have an effect on ENSO conditions, but predictive and paleoclimate modeling studies do not agree on the magnitude, frequency, and direction of these effects. However, ENSO has substantial and large-scale effects on the global climate system.

Indian summer monsoon. The Indian summer monsoon is the result of land-to-ocean pressure gradients and advection of moisture from ocean to land. By warming the land more than the ocean, climate change generally strengthens the monsoon. However, reductions in the amount of solar radiation that is absorbed by the land surface, such as land-use change, generally weaken it. An albedo greater than roughly 50 percent is necessary to simulate the collapse of the Indian summer monsoon in a simple model (Zickfield *et al.* 2005). IPCC projections do not project passing a threshold this century, although paleoclimatic reconstructions do indicate that the monsoon has changed substantially in the past.

West African monsoon. Sahara/Sahel rainfall depends on the West African monsoon circulation, which is affected by sea-surface temperature. By warming the land more than the ocean and therefore causing greater upward movement of the air, GHG forcing is expected to draw more moist oceanic air inland and thereby increase rainfall in the region, which has been shown by some models. Other models, however, project a less productive monsoon. The reasons for this inconsistency are not clear.

Amazon rainforest. The recycling of precipitation in the Amazon rainforest means that deforestation, reductions in precipitation, a longer dry season, and increased summer temperature could cause forest dieback. These conditions are thought to be linked to a more persistent El Niño and an increase of global average temperature by 3 to 4 °C (5.4 to 6.8 °F). Important additional stressors also present include forest fires and human activity (such as land clearing). A critical threshold might exist in canopy cover, which could be reached through changes in land use or regional precipitation, ENSO variability, and global forcing.

Boreal Forest. The dieback of boreal forest could result from a combination of increased heat stress and water stress, leading to decreased reproduction rates, increased disease vulnerability, and subsequent fire. Although highly uncertain, studies suggest a global warming of 3 °C (5.4 °F) could be the threshold for loss of the boreal forest.

Comparative Evaluation

The Lenton *et al.* (2008) group's list differs slightly from that of the IPCC because of differences in definition and criteria, an attempt to be more explicit than the IPCC, and the inclusion of more recent studies. The scientists defined these tipping points as "tipping elements" and attempted to estimate when the tipping element of the various systems might be reached, ranging from about 1 year (rapid) to more than 300 years (slow). As with the IPCC and USCCSP conclusions, this group also concluded that the loss of the Greenland ice sheet, the collapse of the West Antarctic ice sheet, and the disruption of the Atlantic THC systems are not expected to cross their estimated tipping elements in this century (though actions this century could create enough momentum in the climate system to cross the threshold in future centuries[27]). However, this group determined that several other systems could reach a tipping threshold within the century: loss of Arctic sea ice, Indian summer monsoon disruption, Sahara/Sahel and West African monsoon changes, drying of the Amazon rainforest, and warming of the boreal forest.

Another factor that might accelerate climate change at rates faster than those currently observed is the possible shift of soil and vegetation-carbon feedbacks, causing the soil and vegetation to become carbon sources rather than carbon sinks. Currently, soil and vegetation act as sinks, absorbing carbon from the atmosphere as plant material and storing carbon in the soil when the plants die. However, by mid-century (about the time the IPCC predicts the global average temperature reaches 2 ºC (3.6 ºF) above pre-industrial levels), increasing temperatures and precipitation could cause increased rates of transpiration, resulting in soil and vegetation becoming a potential source of carbon emissions (Cox *et al.* 2000 as cited in Meehl *et al.* 2007). Warming could also thaw frozen Arctic soils (permafrost), causing the wet soils to emit more methane, a GHG. There is evidence that this process is already taking place (Walter *et al.* 2007). This additional research clarifies the concept of tipping points by further revealing that several climate systems might have tipping points that could occur within the century, and in some systems changes are currently being observed. However, uncertainties exist, especially for timing estimates, and the uncertainties are at least partly responsible for the broad spectrum of views regarding the tipping point. Exactly where these tipping points exist, and the levels at which they occur, are still a matter in need of further scientific investigation before precise quantitative conclusions can be made.

Where information in this FEIS analysis is incomplete or unavailable, as here due to current climate modeling limitations, NHTSA has relied on the CEQ regulations regarding incomplete or unavailable information. 40 CFR § 1502.22(b). CEQ regulations state, in part, that when an agency is evaluating "reasonably foreseeable significant adverse impacts on the human environment and …information relevant to…[the] impacts cannot be obtained because the overall costs of obtaining it are exorbitant or the means to obtain it are not known, the agency shall include within the [EIS]:

[27] *See* Lenton *et al.* (2008).

(1) a statement that such information is incomplete or unavailable;

(2) a statement of the relevance of the incomplete or unavailable information to evaluating reasonably foreseeable significant adverse impacts on the human environment;

(3) a summary of existing credible scientific evidence which is relevant to evaluating the reasonably foreseeable significant adverse impacts on the human environment; and

(4) The agency's evaluation of such impacts based upon theoretical approaches or research methods generally accepted in the scientific community. For the purposes of this section, "reasonably foreseeable" includes impacts which have catastrophic consequences, even if their probability of occurrence is low, provided that the analysis of the impacts is supported by credible scientific evidence, is not based on pure conjecture, and is within the rule of reason."

40 CFR § 1502.22 (b)

This FEIS addresses the requirements of 40 CFR § 1502.22 appropriately. The above survey of the current state of climate science tipping points provides a "summary of existing credible scientific evidence which is relevant to evaluating the…adverse impacts of the CAFE standards." In *Colorado Environmental Coalition v. Dombeck,* the Tenth Circuit found that the ultimate goal of the agency is to ensure that the EIS's "form, content, and preparation foster both informed decision making and informed public participation" (185 F.3d 1162, 1172 [10th Cir. 1999] [quoting *Oregon Envtl. Council v. Kunzman*, 817 F.2d 484, 492 (9th Cir. 1987)]). The Tenth Circuit held that 40 CFR § 1502.22 could not be read as imposing a "data gathering requirement under circumstances where no such data exists." *Id.*

In this case, this FEIS acknowledges that information on tipping points or abrupt climate change is incomplete, and the state of the science does not allow for a characterization of how the CAFE alternatives influence these risks. This action alone, even as analyzed for the most stringent alternative, does not produce sufficient CO_2 emissions reductions to avert levels of abrupt and severe climate change. To the degree that the action in this rulemaking reduces the rate of CO_2 emissions, the rule contributes to the general reduction or delay of reaching these tipping-point thresholds. These conclusions are not meant to be read as expressing NHTSA's view that tipping points in climate-related systems are not areas of concern for policymakers. Under NEPA, the agency is obligated to discuss "the environmental impact[s] *of the proposed action*" (42 U.S.C. § 4332(2)(C)(i) [emphasis added]). The above discussion fulfills NHTSA's NEPA obligations regarding this issue.

3.4.4 Environmental Consequences

This section describes the consequences of the MY 2011-2015 CAFE standards in relation to GHG emissions and climate effects.

3.4.4.1 Greenhouse Gas Emissions

To estimate the emissions resulting from changes in passenger-car and light-truck CAFE standards, NHTSA uses the Volpe model (*see* Section 3.1.4 for a description of the model). The change in fuel use projected to result from each alternative CAFE standard determines the resulting impacts on total and petroleum energy use, which in turn affects the amount of CO_2 emissions. Reducing fuel use also lowers CO_2 emissions from the use of fossil carbon-based energy during crude oil extraction, transportation, and refining, and in the transportation, storage, and distribution of refined fuel. Because CO_2 accounts for such a large fraction of total GHGs emitted during fuel production and use – more than 95 percent, even after accounting for the higher global warming potentials of other GHGs – NHTSA's consideration of GHG impacts focuses on reductions in CO_2 emissions resulting from the savings in fuel use that accompany higher fuel economy.[28]

NHTSA estimated GHG emissions for each alternative using the Reference Case assumptions. In the discussion and table that follows, emissions reductions represent the differences in total annual emissions by all cars or light trucks in use between their estimated future levels under the No Action Alternative (Alternative 1) and each action alternative (Alternatives 2 through 7). Emissions reductions resulting from the CAFE standard for MY 2011-2015 cars and light trucks were estimated from 2010 to 2100. Reductions would begin in 2010, the first year that MY 2011 vehicles would be on the road. For each alternative, all vehicles after MY 2015 were assumed to meet the MY 2015 CAFE standards. Emissions were estimated for all alternatives through 2100, and these emissions were compared against the NPRM baseline (which assumes all vehicles after MY 2010 meet MY 2010 standards) to estimate emissions reductions. The Volpe model estimates emissions through the year 2060.[29] Annual emissions reductions from 2061-2100 were held constant at 2060 levels.

Table 3.4-1 and Figure 3.4-8 show total emissions and emissions reductions resulting from applying the seven alternatives to new passenger cars and light trucks from 2010 to 2100. Emissions for the period range from 193,212 $MMTCO_2$ for the Technology Exhaustion Alternative (Alternative 7) to 221,258 $MMTCO_2$ for the No Action Alternative. Compared to the No Action Alternative, projections of emissions reductions over the period 2010 to 2100 due to the MY 2011-2015 CAFE standards ranged from 5,922 to 28,047 $MMTCO_2$.[30] Compared to global emissions of 4,850,000 $MMTCO_2$ over this period (projected by the A1B-medium scenario), this rulemaking is expected to reduce global CO_2 emissions by about 0.1 to 0.6 percent.

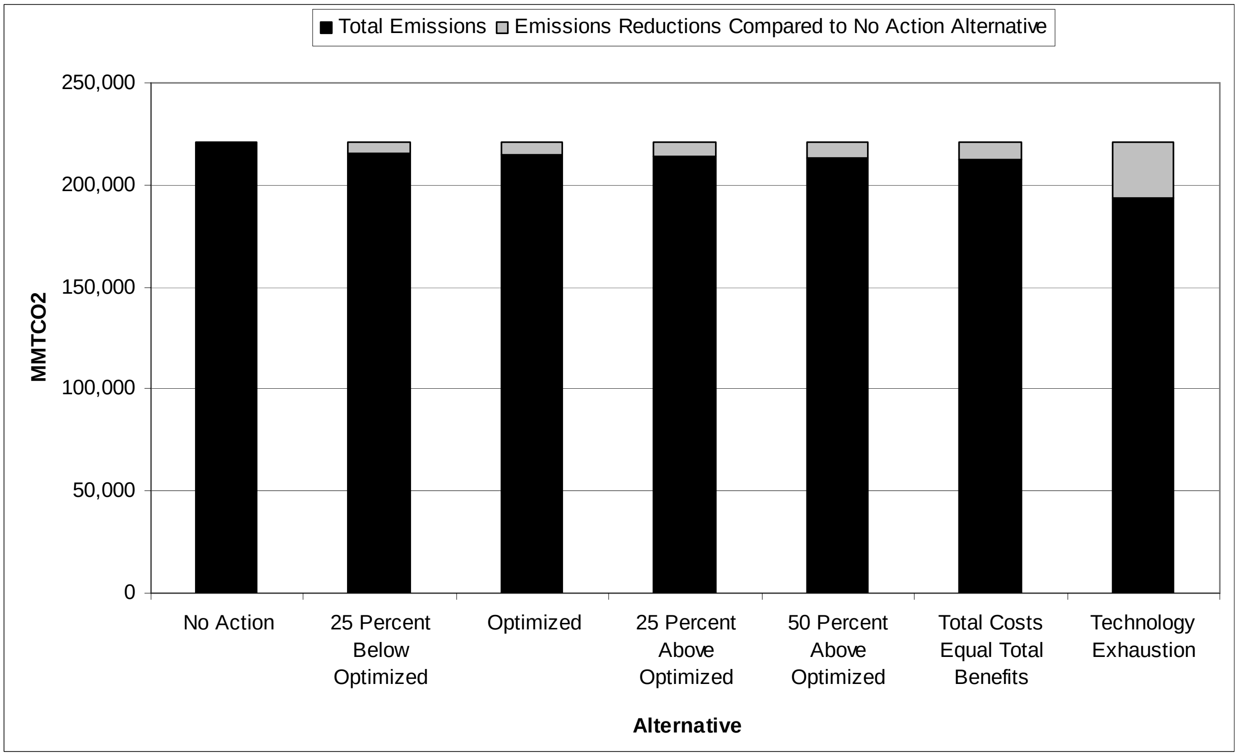
Table 3.4-1

Reference Case Emissions and Emissions Reductions Due to the MY 2011-2015 CAFE Standards from 2010-2100 ($MMTCO_2$)

Alternative	Emissions	Emissions Reductions Compared to No Action Alternative
1 No Action	221,258	0
2 25 Percent Below Optimized	215,337	5,922
3 Optimized	214,643	6,616
4 25 Percent Above Optimized	214,144	7,114
5 50 Percent Above Optimized	213,254	8,004
6 Total Costs Equal Total Benefits	212,345	8,913
7 Technology Exhaustion	193,212	28,047

[28] Although this section includes a discussion of CO_2 emissions only, the climate modeling discussion in Section 3.4.4.4 assesses the direct and indirect effects associated with emissions reductions of multiple gases, including CO_2, CH_4, N_2O, SO_2, CO, NO_x, and VOCs.
[29] *See* Section 3.1.3 for a summary of the scope and parameters of the Volpe model.
[30] The values here are summed from 2010 through 2100, and are thus considerably higher than the value of 520 $MMTCO_2$ cited in the NPRM for the Optimized Alternative (Alternative 3). The latter value is the reduction in CO_2 emissions by only MY 2011-2015 cars and light trucks over their lifetimes resulting from the optimized CAFE standards, measured as a reduction from the NPRM baseline of extending the CAFE standards for MY 2010 to apply to MY 2011-2015.

Figure 3.4-8. Reference Case Emissions and Emissions Reductions Due to the MY 2011-2015 CAFE Standards from 2010 to 2100 (MMTCO$_2$)



To get a sense of the relative impact of these reductions, it can be helpful to consider the relative importance of emissions from cars and light trucks as a whole and to compare them against emissions projections from the transportation sector, and expected or stated goals from existing programs designed to reduce CO_2 emissions.

As mentioned earlier, U.S. cars and light trucks account for 19.2 percent of CO_2 emissions in the United States. Thus, with the action alternatives reducing U.S. car and light truck CO_2 emissions by 2.7 to 12.7 percent, this would represent a reduction of 0.5 to 2.4 percent of total U.S. CO_2 emissions (assuming the relative contribution of cars and light trucks stays the same). Figure 3.4-9 shows projected annual emissions from cars and light trucks under the MY 2011-2015 alternative CAFE standards.

As Table 3.4-2 shows, total CO_2 emissions accounted for by the U.S. car and light-truck fleets are projected to increase substantially from their level in 2010 under the No Action Alternative, which would extend passenger car and light truck CAFE standards for MY 2010 to apply to all future model years. The table also shows that each of the action alternatives would reduce total car and light-truck CO_2 emissions in future years from their projected levels under the No Action Alternative. Progressively larger reductions in CO_2 emissions from their levels under the No Action Alternative are projected to occur during each future year as the action alternatives require successively higher fuel economy levels for MY 2011-2015 and later passenger cars and light-trucks.

However, Table 3.4-2 also shows that none of the action alternatives would reduce total CO_2 emissions accounted for by passenger cars and light trucks below the levels that are projected to occur in calendar year 2010. This is because forecasted growth in the number of cars and light trucks in use throughout the United States, combined with assumed increases in their average use, is projected to result in sufficiently rapid growth in total car and light truck travel to more than offset the increases in fuel economy that would result even under the Technology Exhaustion Alternative (Alternative 7). As a consequence, total fuel consumption by U.S. passenger cars and light trucks is projected to increase over the period shown in the table under each of the action alternatives. Because CO_2 emissions are a direct consequence of total fuel consumption, the same result is projected for total CO_2 emissions from passenger cars and light trucks.

Emissions of CO_2, the primary gas that drives climate effects, from the U.S. car and light-truck fleet represented about 2.5 percent of total global emissions of all GHGs in 2000 (EPA 2008a; WRI 2008). Although substantial, this source contributes a small percentage of global emissions, and the relative contribution of CO_2 emissions from the U.S. light-vehicle fleet is expected to decline in the future. This expected decline is due primarily to rapid growth of emissions from developing economies (which result in part from growth in global transportation sector emissions). In the SRES A1B (medium) scenario (Nakicenovic *et al.* 2000), the share of liquid fuel use – mostly petroleum and biofuels – from Organization for Economic Cooperation and Development (OECD) countries (including the United States) declines from 60 percent in 2000 to 17 percent in 2100.

In its Annual Energy Outlook, EIA projects U.S. transportation CO_2 emissions to increase from 2,037 $MMTCO_2$ in 2010 to 2,682 $MMTCO_2$ in 2030,[31] with total U.S. emissions from transportation over this period at 49,287 $MMTCO_2$. Over this same period, the emissions reductions over the range of the new standards are projected to be 527 to 2,656 $MMTCO_2$, which would yield a 1- to 5-percent reduction from the transportation sector. The environmental impact from increasing fuel economy standards grows as new vehicles enter the fleet and older vehicles are retired. For example, in 2030, projected emissions reductions are 50 to 239 $MMTCO_2$, a 2- to 9-percent decrease from projected U.S. transportation emissions of 2,682 $MMTCO_2$ in 2030. It is important to note that the EIA did not take into account the

[31] AEO provides projections through 2030, not through 2100 (the relevant period for climate modeling).

expected effects of this rulemaking in their forecast (EIA 2007a), thus enabling a comparison of the impact of this rulemaking to U.S. transportation emissions under the No Action Alternative.

As another measure of the relative environmental impact of this rulemaking, these emissions reductions can be compared to existing programs designed to reduce GHG emissions in the United States. In 2007, Arizona, California, New Mexico, Oregon, and Washington formed the Western Climate Initiative (WCI) to develop regional strategies to address climate change. The WCI has a stated goal of reducing 350 $MMTCO_2$ equivalent over the period from 2009 to 2020 (WCI 2007a). Emissions levels in 2020 would represent a 33-percent reduction from the No Action Alternative and a 15-percent reduction from the beginning of the action (WCI 2007b). By comparison, this rulemaking is expected to reduce CO_2 emissions by 116 to 660 $MMTCO_2$ over the same period, with emissions levels in 2020 representing a 1- to 5-percent reduction from the future baseline emissions for cars and light trucks. Nine northeast and mid-Atlantic states have formed the Regional Greenhouse Gas Initiative (RGGI) to reduce CO_2 emissions from power plants in the northeast. Emissions reductions from 2006 to 2024 are estimated at 268 $MMTCO_2$ (RGGI 2006).[32] This represents a 23-percent reduction from the future baseline, and a 10-percent reduction from the beginning of the action (RGGI 2006). By comparison, NHTSA forecasts that this rulemaking would reduce CO_2 emissions by 252 to 1,334 $MMTCO_2$ over this period, with emissions levels in 2024 representing a 3- to 9-percent reduction from the future baseline emissions for cars and light trucks.

Two points are important to emphasize. First, emissions from sources addressed in the WCI and RGGI decrease compared to the beginning of the action, while emissions from cars and trucks continue to increase under this rulemaking due to increases in VMT. Second, these projections are only estimates, and the scope of these climate programs differs from that in this rulemaking in terms of geography, sector, and purpose.

The approach, goals, and methods of reductions vary between the NHTSA action and these regional GHG reduction initiatives. However, the expected end result – reduction of tons of CO_2 – of all of these initiatives are similar. The Stabilization Wedge Theory promulgated by Pacala and Socolow (2004) for climate change mitigation includes a graphical representation of the contributions of many GHG reduction initiatives and the ability for all of these "wedges," over time, to add up to a climate-change solution. The reductions from this rulemaking could be viewed in this context as one of many actions needed to reduce U.S. transportation emissions.

Where information in the analysis included in this FEIS is incomplete or unavailable, NHTSA has relied on the CEQ regulations regarding incomplete or unavailable information. *See* 40 CFR § 1502.22(b). In this case, the comparison of emissions reductions from the alternative CAFE standards to emissions reductions associated with other programs is intended to benefit decisionmakers by providing relative benchmarks, rather than absolute metrics, for selecting among alternatives. In summary, the alternatives analyzed here deliver GHG emissions reductions that are on the same scale as many of the most progressive and ambitious GHG emissions reduction programs underway in the United States.

3.4.4.2 Sensitivity Analysis

NTHSA performed sensitivity analyses to examine how changes in key economic assumptions affect the CAFE standards under the Optimized Alternative, and the resulting fuel savings and environmental impacts. Although the sensitivity analysis did not examine the effect of variations in economic assumptions on CAFE standards and their impacts under other action alternatives, three of the

[32] Emissions reductions were estimated by determining the difference between the RGGI Cap and the Phase III RGGI reference case. These estimates do not include offsets.

remaining five action alternatives would establish fuel economy standards that are based directly on those under the Optimized Alternative. In addition, CAFE standards under the alternative equating total costs and total benefits would also vary in response to changes in CAFE standards under the Optimized Alternative. Thus, it is reasonable to assume that fuel economy levels under each of those alternatives, and the resulting fuel savings and reductions in CO_2 emissions, will vary similarly to those under the Optimized Alternative in response to changes in economic assumptions.

The specific economic assumptions NHTSA varied in these sensitivity analyses were:

- The value of economic damages caused by CO_2 emissions (the "social cost of carbon")
- The discount rate applied to future benefits
- The level of military security outlays associated with variation in U.S. petroleum imports
- The magnitude of the fuel economy rebound effect

NHTSA performed sensitivity analyses of variations in CAFE standards, fuel savings, and reductions in CO_2 emissions in response to changes in these economic variables using the Optimized CAFE standards from both the Reference Case and the Mid-2 Scenario as bases. The primary difference between the Reference Case and the Mid-2 Scenario is that the former uses the AEO 2008 reference case forecast of fuel prices, while the latter uses fuel prices from the AEO 2008 high price case. All other economic assumptions were held constant in these analyses.

Sections 3.4.4.2.1 and 3.4.4.2.2 summarize how these changes in economic assumptions would affect CAFE standards and realized fuel economy levels under the Optimized Alternative, fuel savings compared to the No Action Alternative, and reductions in CO_2 emissions from those under the No Action Alternative for passenger cars and light trucks over the period 2010-2100.

3.4.4.2.1 Range of Input Values in Sensitivity Analysis

The sensitivity analyses first examined the effect of raising the value of reducing CO_2 emissions to $80 per metric ton CO_2. This figure corresponds to an increase of one standard deviation from the mean estimate of the social cost of carbon reported in a 2008 survey of more than 200 estimates of the SCC conducted by Tol.[33] Its derivation is described in detail in Section 10.2.2.3 of this FEIS.

Like the reference values of $2 per ton for the U.S. domestic benefit and $33 per ton for the global value of reducing CO_2 emissions, the alternative value of $80 per ton is assumed to increase at 2.4 percent annually beginning in 2007. Thus, over the lifetimes of MY 2011-15 passenger cars and light trucks, the value of reducing CO_2 emissions would average nearly $160 per ton.

The sensitivity analyses also examined the effect of discounting benefits other than those from reducing CO_2 emissions at an annual rate of 3 percent, rather than at the 7-percent rate used in the Reference Case and the Mid-2 Scenario. (In all cases, future benefits from reducing CO_2 emissions were discounted at the lower 3-percent rate, because these benefits will be experienced by future generations.) The 3-percent rate is more appropriate if manufacturers are assumed to recover costs for complying with higher CAFE standards from buyers in the form of higher prices for new vehicles (OMB 2003).

[33] Richard S.J. Tol (2008), The social cost of carbon: trends, outliers, and catastrophes, *Economics -- the Open-Access, Open-Assessment E-Journal*, **2** (25), 1-24.

Recognizing the uncertainty surrounding the effect of variations in U.S. oil imports on military activities in oil-producing regions, the sensitivity analyses also tested the effect of assuming that U.S. military spending would decline by $0.05 for each gallon by which CAFE standards reduce U.S. imports of crude petroleum or refined fuel. This estimate reflects the assumption that approximately one-third of expenses to support U.S. military activities in major oil-producing regions of the world are likely to vary in proportion to the scale of those activities. It contrasts with the assumption employed in the Reference Case and the Mid-2 Scenario that U.S. military outlays would be unaffected by the level of U.S. imports of crude petroleum or refined petroleum products.

Finally, the sensitivity analyses examined the consequences for fuel economy levels, fuel savings, and reductions in CO_2 emissions of rebound effects of 10 percent and 20 percent. These compare to the 15-percent value for the rebound effect used in the Reference Case and the Mid-2 Scenario. NHTSA's detailed analysis of 66 published estimates of the long-run rebound effect concluded that nearly two-thirds of those estimates fell within the range of 10 to 20 percent.

3.4.4.2.2 Sensitivity Analysis Results

Tables 3.4-3 and 3.4-4 illustrate the effects of these alternative assumptions on fuel economy levels under the Optimized Alternative, fuel savings compared to the No Action Alternative, and the resulting reductions in CO_2 emissions. Table 3.4-3 shows the effects of alternative economic assumptions on fuel economy, fuel savings, and reductions in CO_2 emissions in the Reference Case; Table 3.4-4 reports the effects of the same changes in economic assumptions for the Mid-2 Scenario.

Table 3.4-3

Sensitivity of Reference Case Results to Changes in Economic Assumptions

Economic Assumptions	Combined Car and Light Truck MPG (2015) a/	Fuel Savings 2010-2100 (billion gallons)	Reduction in CO_2 Emissions 2010-2100 (MMt)
Reference Case	29.6	634	6,616
CO_2 Reductions Valued @ $80/ton	33.3	1,570	15,716
3% Discount Rate	30.3	898	8,954
Military Security Savings @ $0.05/gal	29.6	643	6,715
10% Rebound Effect	29.6	630	6,571
20% Rebound Effect	29.1	494	5,105

a/ Industry-wide combined MPG required by passenger car and light truck CAFE standards for MY 2015.

Table 3.4-4

Sensitivity of Mid-2 Scenario Results to Changes in Economic Assumptions

Economic Assumptions	Combined Car and Light Truck MPG (2015) a/	Fuel Savings 2010-2100 (billion gallons)	Reduction in CO_2 Emissions 2010-2100 (MMt)
Mid-2 Scenario	31.8	1,588	16,467
CO_2 Reductions Valued @ $80/ton	33.5	1,887	19,532
3% Discount Rate	33.5	1,891	19,569
Military Security Savings @ $0.05/gal	31.8	1,591	16,496
10% Rebound Effect	31.7	1,570	16,264
20% Rebound Effect	30.3	1,286	13,449

a/ Industry-wide combined MPG required by passenger car and light truck CAFE standards for MY 2015.

As these tables illustrate, increasing the benefits from of reducing CO_2 emissions to $80 per ton would substantially increase fuel economy, fuel savings, and reductions in CO_2 emissions in both the Reference Case and the Mid-2 Scenario.

Table 3.4-3 shows that reducing the discount rate applied to future benefits (other than those from reducing CO_2 emissions, which are already discounted at 3 percent) from the 7 percent used in the Reference Case to 3 percent would result in modest increases in required fuel economy, fuel savings, and reductions in CO_2 emissions in the Reference Case. In the Mid-2 Scenario, however, Table 3.4-4 shows that lowering the discount rate to 3 percent would lead to a pronounced increase in required car and light truck fuel economy, and in the resulting fuel savings and reductions in CO_2 emissions.

In contrast, assuming that U.S. military outlays would decline by $0.05 for each gallon that CAFE standards reduce U.S. petroleum imports has almost no effect on fuel economy, fuel savings, or reductions in CO_2 emissions under either the Reference Case or the Mid-2 Scenario. Although the effects of this change on required fuel economy, fuel savings, and emissions reductions do have the expected direction, they are extremely small, and certainly well within the range of uncertainty in estimating them.

Finally, the tables show that reducing the rebound effect from the 15 percent assumed in both the Reference Case and the Mid-2 Scenario to 10 percent would have only a slight effect on fuel savings and reductions in CO_2 emissions. Although the reported effects of reducing the rebound effect to 10% are in the opposite direction from those expected, they are so small as to be well within the range of uncertainty in estimating these effects. In contrast, increasing the rebound effect from the 15 percent value used in the Reference Case and the Mid-2 Scenario to 20 percent would lower fuel savings and emissions reductions somewhat in both cases, as Tables 3.4-3 and 3.4-4 report.

3.4.4.3 Effect of Credit Flexibility on Emissions

Consistent with the Energy Independence and Security Act (EISA), NHTSA's NPRM not only proposed new CAFE standards for passenger cars and light trucks, but also revised provisions regarding the creation and application of CAFE credits. In this context, CAFE credits refer to flexibilities allowed under the Energy Policy and Conservation Act (EPCA) provisions governing use of Alternative Motor Fuels Act (AMFA) credits, allowable banked credits, and transfers of credits between the car and truck fleets allowed under EISA. The additional flexibility to transfer credits between manufacturing companies is addressed separately below. Because EPCA prohibits NHTSA from considering these flexibilities when determining the stringency of CAFE standards, NHTSA did not attempt to do so when it developed standards by using the Volpe model to estimate the stringency at which net benefits to society would be maximized.

Under the EISA, AMFA credits are being phased out. The allowable credits are reduced so that by 2020 such credits will no longer be allowed under law.

However, responding to the *Federal Register* notice regarding the scope of analysis required by NEPA, EPA and the California Attorney General have indicated that, notwithstanding EPCA's constraints regarding the context for the establishment of CAFE standards, NHTSA should attempt to account for the creation and application of CAFE credits when evaluating the effects of new CAFE standards.

As we explained in the NPRM, NHTSA believes that manufacturers are likely to take advantage of these flexibility mechanisms, thereby reducing benefits and costs. Regarding AMFA credits, for example, manufacturer product plans identify the models and quantities of flex-fuel vehicles they intend to build. While individual product plans are protected as confidential commercial information, in the aggregate they reveal that manufacturers could use AMFA credits to assist in compliance with the standards. Manufacturers building dual-fuel vehicles are entitled to a CAFE benefit of up to 1.2 mpg in 2011 to 2014 and 1.0 mpg in 2015 for each fleet. NHTSA tentatively estimates that the impact of the use of AMFA credits could result in an average reduction of approximately 0.9 mpg in each year for model years 2011 through 2015, and a related increase in CO_2 emissions. Regarding other than AMFA credits (*e.g.*, CAFE credits earned through over-compliance, credits transferred between fleets, and credits acquired from other manufacturers), we do not have a sound basis to predict the extent to which manufacturers might use them, particularly since the credit transfer and credit trading programs have been only recently authorized.

3.4.4.3.1 Difficulties in Quantifying Emissions Implications of Credits

Questions NHTSA might need to address in performing an analysis of potential credit use and the resulting emissions include the following:

- Would manufacturers that have never used CAFE flexibilities do so in the future?
- Would flexibility-induced increases in the sale of flexible-fuel vehicles (FFVs) lead to increases in the use of alternative fuels?
- Having earned CAFE credits in a given model year, in what model year would a given manufacturer most likely apply those credits?
- Having earned CAFE credits in one fleet (*i.e.*, passenger or nonpassenger), to which fleet would a given manufacturer most likely apply those credits?

Such questions are similar to, though possibly less tractable than the behavioral and strategic questions that would be entailed in attempting to represent manufacturers' ability to "pull ahead" the implementation of some technologies, and in attempting to estimate CAFE-induced changes in market shares. As discussed on pp. 24393 to 24394 of the NPRM, data and approaches are lacking on how to analyze manufacturers' ability to develop and strategically time the application of new technologies. Substantial concerns remain about how to develop a credible market share model for integration into the modeling system NHTSA has used to analyze the costs and effects of CAFE standards.

3.4.4.3.2 Market Behavior

Some manufacturers make substantial use of current flexibilities. Other manufacturers regularly exceed CAFE standards applicable to one or both fleets, and allow the corresponding excess CAFE credits to expire. Some manufacturers transfer earned CAFE credits to future (or past) model years, but do not produce FFVs and create corresponding CAFE credits. Finally, still other manufacturers regularly pay civil penalties for noncompliance, even when producing FFVs would substantially reduce the magnitude of those penalties.

Notwithstanding these uncertainties, NHTSA anticipates that manufacturers would make varied use of the flexibilities provided by EPCA, as amended by EISA. These flexibilities could result in somewhat lower benefits (that is, CO_2 emissions reductions) than estimated here, as manufacturers' actions would cause VMT levels, fuel consumption, and emissions to be higher than reported here. We expect that all of the seven alternatives reported here—including the No Action Alternative in relation to which the effects of the six action alternatives are measured—would be affected. Insofar as the No Action Alternative would be affected, it is even less certain how the net effects of each of the six action alternatives would change.

NHTSA expects that use of flexibilities would tend to be greater under more stringent standards. As stringency increases, the potential for manufacturers to face greater cost increases, and for some, depending on its level of technological implementation, costs could rise substantially. The economic advantage of employing allowed flexibilities increases and could affect manufacturer behavior in this regard. A critical factor in addressing the fuel and emissions impacts of such flexibilities is that the likely extent of utilization cannot be assumed constant across the alternatives.

3.4.4.3.3 Trading Between Companies

The allowable trading between manufacturers is categorically different from the case discussed above. The provisions in Section 104 of Title I of the EISA require that fuel savings, and thus, GHG emissions, be conserved in any trades between manufacturers. Therefore, there would not be an environmental impact of any such trades because any increases in fuel use or emissions would have to be offset by the manufacturer buying the credits.

3.4.4.4 Direct and Indirect Effects on Climate Change

Sections 3.4.4.3.1 through 3.4.4.3.4 describe the direct and indirect effects of the alternatives on climate change in relation to atmospheric CO_2 concentrations, temperature, precipitation, and sea-level rise.

3.4.4.4.1 Atmospheric CO_2 Concentrations

MAGICC is a simple climate model that is well calibrated to the mean of the multi-model ensemble results for three of the most commonly used emissions scenarios – B1 (low), A1B (medium), and A2 (high) from the IPCC SRES series – as shown in Table 3.4-5.[34] As the table indicates, the results of the model runs developed for this analysis agree relatively well with IPCC estimates for both CO_2 concentrations and surface temperature.

Table 3.4-5

Comparison of MAGICC Modeling Results and Reported IPCC Results (IPCC 2007a)

	CO_2 Concentration (ppm)		Global Mean Increase in Surface Temperature (°C)		Sea-level Rise (cm)	
Scenario	**IPCC WGI (2100)**	**MAGICC (2100)**	**IPCC WGI (2080-2099)**	**MAGICC (2090)**	**IPCC WGI (2090-2099) a/**	**MAGICC (2095)**
B1 (low)	550	538.3	1.79	1.81	28	26
A1B (medium)	715	717.2	2.65	2.76	35	35
A2 (high)	836	866.8	3.13	3.31	37	38

a/ The IPCC values represent the average of the 5- to 95-percent range of the rise of sea level between 1980 to 1989 and 2090 to 2099.

A comparison of sea-level rise from MAGICC 5.3 and the IPCC Fourth Assessment Report is presented in the release documentation for MAGICC 5.3 (Wigley 2003 to 2008). In Table 3 of the documentation, Wigley (2008) presents the results for six SRES scenarios, which show that the

[34] NHTSA used the default climate sensitivity in MAGICC of 3.0 °C.

comparable value for sea-level rise from MAGICC 5.3 (total sea-level rise minus estimates for contributions from non-melt sources such as warming of the permafrost) within 0.01 centimeter in 2095.

As discussed in Section 3.4.2, NHTSA used the SRES A1B (medium) scenario to represent the No Action Alternative in the MAGICC modeling runs. Table 3.4-6 and Figures 3.4-10 through 3.4.13 present the results of MAGICC simulations for the No Action Alternative and the six action alternatives, in terms of CO_2 concentrations and increases in global mean surface temperature in 2030, 2060, and 2100. As Figures 3.4-10 and 3.4-11 show, the reduction in the amount of increases in CO_2 concentrations and temperature from each of the action alternatives is just a fraction of the total increases in CO_2 concentrations and global mean surface temperature. However, the relative impact of the action alternatives is shown by the reduction in increase of both CO_2 concentrations and temperature under Alternative 7. As shown in Figures 3.3-12 and 3.4-13, the reduction in increase of CO_2 concentrations under Alternative 7 is nearly four times that of Alternative 2. Similarly, the reduction in increase of temperature under Alternative 7 is more than five times that of Alternative 2.

As shown in the table and figures, estimated CO_2 concentrations for 2100 range from 714.6 ppm under the most stringent alternative (Technology Exhaustion) to 717.2 ppm under the No Action Alternative. For 2030 and 2060, the range is even smaller. Because CO_2 concentrations are the key driver of other climate effects (which in turn act as drivers on the resource impacts discussed in Chapter 4), this leads to small differences in these effects.

Table 3.4-6

Reference Case MY 2011-2015 Standards Impact on CO_2 Concentrations, Global Mean Surface Temperature Increase, and Sea-level Rise in 2100 Using MAGICC (A1B a/)

Totals by Alternative	CO_2 Concentration (ppm)			Global Mean Surface Temperature Increase (°C)			Sea-level Rise (cm)		
	2030	2060	2100	2030	2060	2100	2030	2060	2100
1 No Action (A1B-AIM)	455.5	573.7	717.2	0.874	1.944	2.959	7.99	19.30	37.10

3.4.4.4.2 Temperature

The MAGICC model simulations of mean global surface air temperature increases are shown in Table 3.4-6. For all alternatives, the temperature increase is about 0.87 °C for 2030, 1.94 °C for 2060, and 2.95 °C for 2100. The differences among alternatives are small. For 2100, the reduction in temperature increase, in relation to the No Action Alternative, ranges from 0.002 °C to 0.013 °C.

Table 3.4-7 summarizes the regional changes in warming and seasonal temperatures presented in the IPCC Fourth Assessment Report. At this time, quantifying the changes to regional climate from the CAFE alternatives is not possible, but the alternatives would be expected to reduce the impacts in proportion to the amount of reduction in global mean surface temperature.

Table 3.4-7

Summary of Regional Changes to Warming and Seasonal Temperatures Extracted from the IPCC Fourth Assessment Report (Christensen *et al.* 2007)

Land Area	Sub-region	Mean Warming	Maximum Summer Temperatures
Africa	Mediterranean area and northern Sahara	*Likely* larger than global mean throughout continent and in all seasons	
	Southern Africa and western margins		
	East Africa		
Mediterranean and Europe	Northern Europe	*Likely* to increase more than the global mean with largest warming in winter	Maximum summer temperatures *likely* to increase more than the average
	Southern and Central Europe		
	Mediterranean area		
Asia	Central Asia	*Likely* to be well above the global mean	
	Tibetan Plateau	*Likely* to be well above the global mean	
	Northern Asia	*Likely* to be well above the global mean	
	Eastern Asia	*Likely* to be above the global mean	*Very likely* that heat waves/hot spells in summer will be longer, more intense, and more frequent *Very likely* fewer very cold days
	South Asia	*Likely* to be above the global mean	*Very likely* fewer very cold days
	Southeast Asia	*Likely* to be similar to the global mean	
North America	Northern regions/Northern North America	*Likely* to exceed the global mean warming	Warming is *likely* to be greatest in winter. Minimum winter temperatures are *likely* to increase more than the average
	Southwest		Warming is *likely* to be greatest in summer Maximum summer temperatures are *likely* to increase more than the average
	Northeast USA		
	Southern Canada		
	Canada		

Table 3.4-7 (cont'd)

Summary of Regional Changes to Warming and Seasonal Temperatures Extracted from the IPCC Fourth Assessment Report (Christensen *et al.* 2007)

Land Area	Sub-region	Mean Warming	Maximum Summer Temperatures
	Northernmost part of Canada		
Central and South America	Southern South America	*Likely* to be similar to the global mean warming	
	Central America	*Likely* to be larger than global mean warming	
	Southern Andes		
	Tierra del Fuego		
	Southeastern South America		
	Northern South America		
Australia and New Zealand	Southern Australia	*Likely* comparable to the global mean but less than in the rest of Australia	Increased frequency of extreme high daily temperatures and decreased frequency of cold extremes are *very likely*
	Southwestern Australia	*Likely* comparable to the global mean	
	Rest of Australia	*Likely* comparable to the global mean	
	New Zealand, South Island	*Likely* less than the global mean	
	Rest of New Zealand	*Likely* comparable to the global mean	
Polar Regions	Arctic	*Very likely* to warm during this century more than the global mean	Warming greatest in winter and smallest in summer
	Antarctic	*Likely* to warm	
Small Islands		*Likely* to be smaller than the global annual mean	

MAGICC 5.3 estimates radiative forcing from black carbon, a primary aerosol emitted through the incomplete combustion of fossil fuel and biomass burning. However, emissions trends for black carbon are "hard-wired" in the model to follow emissions of SO_2 and cannot be specified as separate inputs to the model.[35] The radiative forcing of black carbon is difficult to accurately quantify because it is a function of microphysical properties of the geographic and vertical placement, and lifetime of the aerosol; however, that black carbon contributes substantially to global warming is clear (Jacobson 2001). Total global black carbon emissions are estimated to be approximately 8 teragrams of carbon per year (Tg C/yr) (Bond *et al.* 2004 as cited in Forster *et al.* 2007) with estimates of fossil fuel contributions

[35] Accurately determining the magnitude of mobile source emissions of black carbon is difficult because the emissions vary with fuel properties and fluctuations in the combustion environment. MOBILE6.2 outputs particulate matter mass that is then incorporated in the Volpe model. This particulate matter is based on tailpipe emissions and thus includes carbon emissions from the combustion process. Because the carbon emissions are included as part of the particular matter and are not treated independently, the Volpe model does not provide direct results of the impact of the carbon emissions.

ranging from 2.8 Tg C/yr (Ito and Penner 2005 as cited in Forster *et al.* 2007) to 8.0 Tg C/yr (Haywood and Boucher as cited in Forster *et al.* 2007). The United States contributes an estimated 6.1 percent of the global soot emissions, with major sources including off-road vehicles, on-road vehicles, stack emissions, and fugitive sources (Jacobson Testimony 2007). In summary, the climate modeling accounts for the effects of black carbon on climate variables.

3.4.4.4.3 Precipitation

According to IPCC (Meehl *et al.* 2007), global mean precipitation is expected to increase under all scenarios. Generally, precipitation increases occur in the tropical regions and high latitudes, with decreases in the sub-tropics. The results from the AOGCMs suggest considerable uncertainty in future precipitation for the five SRES scenarios.

Where information in the analysis included in this FEIS is incomplete or unavailable, NHTSA has relied on the CEQ regulations regarding incomplete or unavailable information. *See* 40 CFR § 1502.22(b). In this case, the IPCC (Meehl *et al.* 2007) summary of precipitation represents the most thoroughly reviewed, credible assessment of this highly uncertain factor. NHTSA expects that the alternative CAFE standards would reduce the changes in proportion to their effects on temperature.

The global mean change in precipitation provided by the IPCC for the A2 (high), A1B (medium), and B1 (low) scenarios (Meehl *et al.* 2007) is given as the scaled change in precipitation (as a percentage change from 1980 to 1999 averages) divided by the increase in global mean surface warming for the same period (per °C) as shown in Table 3.4-8. The IPCC provides scaling factors in the year ranges of 2011 to 2030, 2046 to 2065, 2080 to 2099, and 2180 to 2199. NHTSA used the scaling factors for the A1B (medium) scenario in our analysis because MAGICC does not directly estimate changes in global mean precipitation.

Table 3.4-8

Global Mean Precipitation Change (scaled, % per °C) (Meehl *et al.* 2007)

Scenario	2011-2030	2046-2065	2080-2099	2180-2199
A2 (high)	1.38	1.33	1.45	NA
A1B (medium	1.45	1.51	1.63	1.68
B1 (low)	1.62	1.65	1.88	1.89

Applying these scaling factors to the reductions in global mean surface warming provides estimates of changes in global mean precipitation. Given that the CAFE standards action alternatives reduce temperature increases slightly in relation to the No Action Alternative, they also slightly reduce predicted increases in precipitation, as shown in Table 3.4-9 (again based on the A1B [medium] scenario).

In addition to changes in mean annual precipitation, climate change is anticipated to affect the intensity of precipitation, as described below (Meehl *et al.* 2007):

> Intensity of precipitation events is projected to increase, particularly in tropical and high latitude areas that experience increases in mean precipitation. Even in areas where mean precipitation decreases (most subtropical and mid-latitude regions), precipitation intensity is projected to increase but there would be longer periods between rainfall events. There is a tendency for drying of the mid-continental areas during summer, indicating a greater risk of droughts in those regions. Precipitation extremes increase more than does the mean in most tropical and mid- and high-latitude areas.

Table 3.4-9

Reference Case MY 2011-2015 Alternative CAFE Standards: Impact on Reductions in Global Mean Precipitation Based on A1B a/ SRES Scenario (percent change), Using Increases in Global Mean Surface Temperature Simulated by MAGICC

Scenario	2020	2055	2090
Global Mean Precipitation Change (scaled, % K-1)	1.45	1.51	1.63

5 50 Percent Above Optimized	0.00	0.00	0.00
6 Total Costs Equal Total Benefits	0.00	0.00	0.00
7 Technology Exhaustion	0.00	0.01	0.02

a/ The A1B scenario is the SRES marker scenario used by the IPCC WGI to represent the SRES A1B (medium) storyline.

Regional variations and changes in the intensity of precipitation events cannot be quantified further, primarily due to the unavailability of AOGCMs required to estimate these changes. These models are typically used to provide results among scenarios with very large changes in emissions such as the SRES B1 (low), A1B (medium), and A2 (high) scenarios; very small changes in emissions profiles would produce results that would be difficult to resolve among scenarios with small changes in emissions. Also, the multiple AOGCMs produce results that are regionally consistent in some cases but inconsistent for other areas.

Table 3.4-10 summarizes the regional changes in precipitation from the IPCC Fourth Assessment Report. Quantifying the changes in regional climate from the alternative CAFE standards is not possible at present, but they would be expected to reduce the changes in relation to the reduction in global mean surface temperature.

Table 3.4-10

Summary of Regional Changes to Precipitation Extracted from the IPCC Fourth Assessment Report (Christensen *et al.* 2007)

Land Area	Sub-region	Precipitation	Snow Season and Snow Depth
Africa	Mediterranean area and northern Sahara	*Very likely* to decrease	
	Southern Africa and western margins	Winter rainfall *likely* to decrease in southern parts	
	East Africa	*Likely* to be an increase in annual mean rainfall	
Mediterranean and Europe	Northern Europe	*Very likely* to increase and extremes are *likely* to increase	*Likely* to decrease.
	Southern and Central Europe		
	Mediterranean area	*Very likely* to decrease and precipitation days are *very likely* to decrease	
Asia	Central Asia	Precipitation in summer is *likely* to decrease	
	Tibetan Plateau	Precipitation in boreal winter is *very likely* to increase	
	Northern Asia	Precipitation in boreal winter is *very likely* to increase Precipitation in summer is *likely* to increase	
	Eastern Asia	Precipitation in boreal winter is *likely* to increase Precipitation in summer is *likely* to increase *Very likely* to be an increase in the frequency of intense precipitation Extreme rainfall and winds associated with tropical cyclones are *likely* to increase	
	South Asia	Precipitation in summer is *likely* to increase *Very likely* to be an increase in the frequency of intense precipitation Extreme rainfall and winds associated with tropical cyclones are *likely* to increase	
	Southeast Asia	Precipitation in boreal winter is *likely* to increase in southern parts Precipitation in summer is *likely* to increase in most parts Extreme rainfall and winds associated with tropical cyclones are *likely* to increase	
North America	Northern regions/Northern North America		Snow season length and snow depth are *very likely* to decrease
	Southwest	Annual mean precipitation is *likely* to decrease	
	Northeast USA	Annual mean precipitation is *very likely* to increase	
	Southern Canada		
	Canada	Annual mean precipitation is *very likely* to increase	

Table 3.4-10 (cont'd)

Summary of Regional Changes to Precipitation Extracted from the IPCC Fourth Assessment Report (Christensen *et al.* 2007)

Land Area	Sub-region	Precipitation	Snow Season and Snow Depth
North America (cont'd)	Northernmost part of Canada		Snow season length and snow depth are *likely* to increase
Central and South America	Southern South America		
	Central America	Annual precipitation is *likely* to decrease	
	Southern Andes	Annual precipitation is *likely* to decrease	
	Tierra del Fuego	Winter precipitation is *likely* to increase	
	Southeastern South America	Summer precipitation is *likely* to increase	
	Northern South America	Uncertain how rainfall would change	
Australia and New Zealand	Southern Australia	Precipitation is *likely* to decrease in winter and spring	
	Southwestern Australia	Precipitation is *very likely* to decrease in winter	
	Rest of Australia		
	New Zealand, South Island	Precipitation is *likely* to increase in the west	
	Rest of New Zealand		
Polar Regions	Arctic	Annual precipitation is *very likely* to increase. *Very likely* that the relative precipitation increase would be largest in winter and smallest in summer	
	Antarctic	Precipitation *likely* to increase	
Small Islands		Mixed, depending on the region	

3.4.4.4.4 Sea-level Rise

IPCC identifies four primary components to sea-level rise: (1) thermal expansion of ocean water, (2) melting of glaciers and ice caps, (3) loss of land-based ice in Antarctica, (4) and loss of land-based ice in Greenland (IPCC 2007c). Ice-sheet discharge is an additional factor that could influence sea level over the long term. MAGICC calculates the oceanic thermal expansion component of global-mean sea level rise using a nonlinear temperature- and pressure-dependent expansion coefficient (Wigley 2003 to 2008). It also addresses the other three primary components through ice-melt models for small glaciers and the Greenland and Antarctic ice sheets, and excludes non-melt sources, which the IPCC Fourth Assessment Report also excluded. Neither MAGICC 5.3 nor the IPCC Fourth Assessment Report includes more recent information, suggesting that ice flow from Greenland and Antarctica will be accelerated. The Fourth Assessment Report estimates the ice flow to be between 9 and 17 centimeters by 2100 (Wigley 2003 to 2008).

The state of the science reflected as of the publication of the IPCC Fourth Assessment Report projects a sea-level rise of 18 to 59 centimeters by 2090 to 2099 (Parry *et al.* 2007 as cited by National Science and Technology Council 2008). This projection does not include all changes in ice-sheet flow or the potential for rapid acceleration in ice loss (Alley *et al.* 2005, Gregory and Huybrechts 2006, and Hansen 2005, all as cited by Pew Center on Global Climate Change 2007). Several recent studies have found the IPCC estimates of potential sea-level rise might be underestimated regarding ice loss from the Greenland and Antarctic ice sheets (Shepherd and Wignham 2007, Csatho *et al.* 2008) and ice loss from mountain glaciers (Meier *et al.* 2007). Further, IPCC results for sea-level projections might underestimate sea level rise due to changes in global precipitation (Wentz *et al.* 2007 and Zhang *et al.* 2007). Rahmstorf (2007) used a semi-empirical approach to project future sea-level rise. The approach yielded a proportionality coefficient of 3.4 millimeters per year per degree Centigrade of warming, and a projected sea-level rise of 0.5 to 1.4 meters above 1990 levels in 2100 when applying IPCC Third Assessment Report warming scenarios. Rahmstorf (2007) concludes that "[a] rise over 1 meter by 2100 for strong warming scenarios cannot be ruled out." Section 3.5.5, Coastal Ecosystems, discusses sea-level rise in more detail.

Table 3.4-6 lists the impacts on sea-level rise under the scenarios and shows sea-level rise in 2100 ranging from 37.10 centimeters under the No Action Alternative to 36.99 centimeters under the Technology Exhaustion Alternative, for a maximum reduction of 0.11 centimeter by 2100 from the CAFE alternatives.

In summary, the impacts of the MY 2011-2015 alternative CAFE alternatives on global mean surface temperature, precipitation, or sea-level rise are small in relation to the expected changes associated with the emissions trajectories in the SRES scenarios. This is due primarily to the global and multi-sectoral nature of the climate problem.

3.4.5 Input Scenarios

In response to public comments, and to test how different economic assumptions might affect estimates of emissions reductions and resulting climate effects, NHTSA modeled three additional scenarios—High, Mid-1, and Mid-2—and compared the results to the results for the Reference Case described in Section 3.4.4. Variables NHTSA altered include fuel price, SCC, oil import externalities, and the discount rate for other benefits.

For the High Scenario, NHTSA used the AEO 2008 high fuel prices, an SCC of $33 per ton (2007 dollars), and a 3-percent discount rate for other benefits. Table 3.4-11 shows the emissions and emissions reductions resulting from the High Scenario.

Table 3.4-11

High Scenario Emissions and Emissions Reductions Due to the MY 2011-2015 CAFE Standards from 2010-2100 (MMTCO$_2$)

Alternative	Emissions	Emissions Reductions Compared to No Action Alternative
1 No Action	195,501	0
2 25 Percent Below Optimized	182,890	12,611
3 Optimized	180,591	14,910
4 25 Percent Above Optimized	179,079	16,422
5 50 Percent Above Optimized	177,669	17,832
6 Total Costs Equal Total Benefits	176,736	18,765
7 Technology Exhaustion	170,829	24,672

Compared to the Reference Case, total emissions under the High Scenario were lower for all alternatives (*see* Figure 3.4-13). The primary reason for this difference is the lower VMT forecast under the High Scenario. Emissions reductions for all alternatives compared to the No Action Alternative were higher under the High Scenario than under the Reference Case, except for the emissions reduction resulting from the Technology Exhaustion Alternative (*see* Figure 3.4-14). Emissions reductions would be greater for the Technology Exhaustion Alternative under the Reference Case than under the High Scenario.

Table 3.4-12 shows the resulting effects on CO_2 concentration, global mean surface temperature, and sea-level rise. Under the High Scenario, the resulting CO_2 concentration, global mean surface temperature, and sea-level rise were lower than under the Reference Case for all action alternatives except the Technology Exhaustion Alternative. Thus, the differences between the action alternatives and the No Action Alternative are greater under the High Scenario than under the Reference Case, except for the Technology Exhaustion Alternative.[36]

To further assess how different economic assumptions could affect estimates of fuel consumption, NHTSA ran two additional scenarios in the Volpe model: the Mid-1 Scenario and the Mid-2 Scenario. For the Mid-1 Scenario, NHTSA used the AEO 2008 high fuel prices, an SCC of $33 per ton (2007 dollars), and a 7-percent discount rate for other benefits. Compared to the Reference Case, total emissions under the Mid-1 Scenario were lower for all alternatives. Emissions reductions compared to the No Action Alternative were higher for all alternatives under the Mid-1 Scenario, except for the Technology Exhaustion Alternative. The primary reason for this difference is the lower VMT forecasted under the Mid-1 Scenario. The resulting CO_2 concentrations, global mean surface temperature, and sea-level rise were lower for all alternatives under the Mid-1 Scenario, except for the Technology Exhaustion Alternative. Thus, the differences between the action alternatives and the No Action Alternative are greater under the Mid-1 Scenario than under the Reference Case except for the Technology Exhaustion Alternative.

For the Mid-2 Scenario, NHTSA used the AEO 2008 high fuel prices, an SCC of $2 per ton (2007 dollars), and a 7-percent discount rate for other benefits. Compared to the Reference Case, total emissions under the Mid-2 Scenario were lower for all alternatives. Emissions reductions compared to the No Action Alternative were higher for all alternatives under the Mid-2 Scenario, except the Technology Exhaustion Alternative. The primary reason for this difference is the lower VMT forecast under the Mid-2 Scenario. The resulting CO_2 concentrations, global mean surface temperature, and sea-level rise were lower for all alternatives under the Mid-2 Scenario, except for the Technology Exhaustion Alternative. Thus, the differences between the action alternatives and the No Action Alternative are greater under the Mid-2 Scenario than under the Reference Case, except for the Technology Exhaustion Alternative.

Tables in Appendix B list the results for the Mid-1 and Mid-2 Scenarios.

[36] Note that in both the Reference Case and the High Scenario, the No Action Alternative is modeled to have the same emissions, *viz.* emissions set to the A1B scenario. This is the case even though, in absolute terms, U.S. passenger-vehicle and light-truck emissions are lower under the High Scenario than the Reference Case. In other words, the MAGICC model runs are intended to show relative differences in relation to a no action case; they are not intended to show absolute differences between Volpe model assumptions.

Figure 3.4-14. Comparison of Emissions under the Reference Case and High Scenario Due to the MY 2011-2015 CAFE Standards from 2010-2100 ($MMTCO_2$)

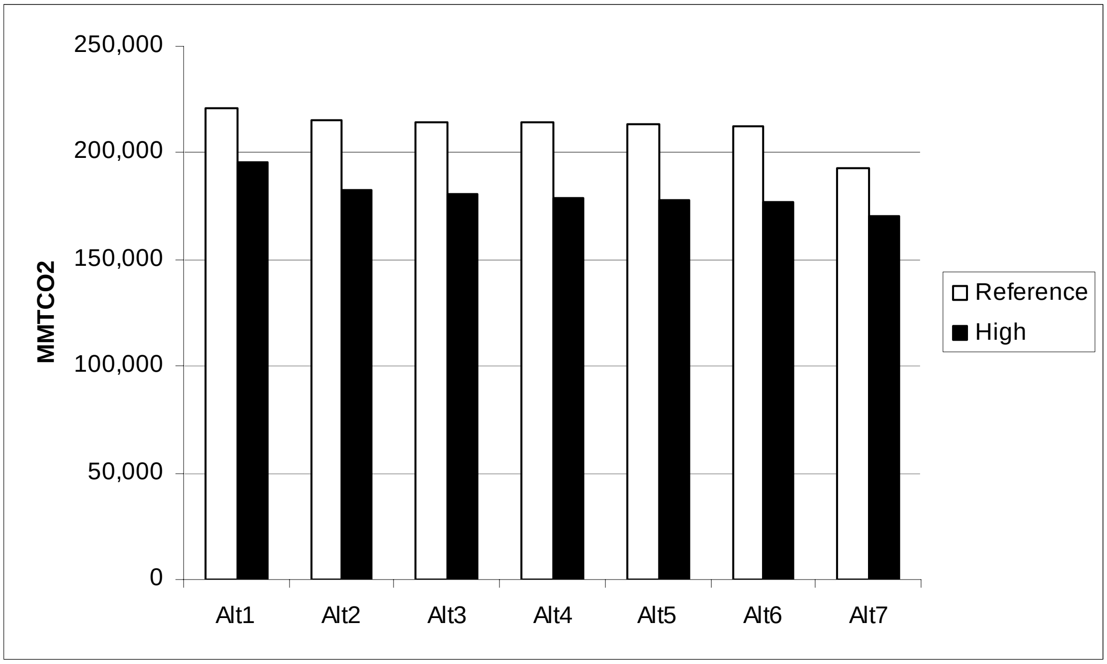

Figure 3.4-15. Comparison of Emissions Reductions under the Reference Case and High Scenario Due to the MY 2011-2015 CAFE Standards from 2010-2100 ($MMTCO_2$)

a/ The A1B scenario is the SRES marker scenario used by the IPCC WGI to represent the SRES A1B (medium) storyline.

3.5 OTHER POTENTIALLY AFFECTED RESOURCE AREAS

This section describes the affected environment and environmental consequences of the alternative CAFE standards on water resources (3.5.1), biological resources (3.5.2), land use and development (3.5.3), safety (3.5.4), hazardous materials and regulated wastes (3.5.5), land uses protected under Section 4(f) (3.5.6), historic and cultural resources (3.5.7), noise (3.5.8), and environmental justice (3.5.9). These sections describe the current and projected future threats to these resources from non-global climate change impacts relevant to the alternatives and provide primarily qualitative assessments of any potential consequences of the alternatives—either positive or negative—on these resources.

This section does not describe the affected environment in relation to, or address potential environmental consequences resulting from, global climate change. For a description of potential impacts of global climate change, *see* Chapter 4.

3.5.1 Water Resources

3.5.1.1 Affected Environment

Water resources include surface water and groundwater. Surface waters are water bodies open to the atmosphere, such as rivers, streams, lakes, oceans, and wetlands; surface waters can contain either fresh or salt water. Groundwater is found in natural reservoirs or aquifers below Earth's surface. Sources of groundwater include rainfall and surface water, which penetrate the ground and recharge the water table. Sections 3.5.1.1.1 through 3.5.1.1.3 describe the current and projected future threats to these resources from non-global climate change impacts related to the proposed action. The production and combustion of fossil fuels, the production of biofuels, and shifts in the location of mining activities are the identified relevant sources of impact. Section 3.5.2 describes relevant aspects of surface water resources from a habitat perspective. For a discussion of the effects of global climate change on freshwater and coastal systems, see Sections 4.5.3 and 4.5.5.

Impacts to water resources during recent decades have come from a number of different sources. These impacts include increased water demand for human and agricultural use, pollution from point and non-point sources, and climatic changes. One of the major human-caused impacts on water quality has been the extraction, refining, and combustion of petroleum products, or oil.

3.5.1.1.1 Oil Extraction and Refining

Oil refineries, which produce gasoline and diesel fuel, and the motor vehicles that combust petroleum-based fuels, are major sources of VOCs, SO_2, NO_x, CO, and other air pollutants (EPA 1995a, EPA 1997b). In the atmosphere, SO_2 and NO_x contribute to the formation of acid rain (the wet, dry, or fog deposition of SO_2 and NO_x), which enters water bodies either directly or as runoff from terrestrial systems (*see* Section 3.3 for more information on air quality). Once in surface waters, these pollutants can cause acidification of the water body, changing the acidity or alkalinity (commonly called pH) of the system and affecting the function of freshwater ecosystems (Van Dam 1996, Baum 2001, EPA 2007b). An EPA survey of sensitive freshwater lakes and streams (those with a low capacity to neutralize or buffer against decreases in pH) found that 75 percent of the lakes and 50 percent of the streams had experienced acidification as a result of acid rain (EPA 2007b). EPA has identified the areas of the United States most sensitive to acid rain as the Adirondacks and Catskill Mountains in New York State, the mid-Appalachian highlands along the east coast, the upper Midwest, and mountainous areas of the western United States (EPA 2007b).

Water quality might also be affected by petroleum products released during the refining and distribution process. Oil spills can lead to contamination of surface and groundwater and can result in impacts to drinking water and marine and freshwater ecosystems (*see* Section 3.5.2.1.1). EPA estimates that, of the volume of oil spilled in "harmful quantities," as defined under the Clean Water Act, 83.8 percent was deposited in internal/headland waters and within 3 miles of shore, with 17.5 percent spilled from pipelines, often in inland areas (EPA 2004a). The environmental impacts on and recovery time for individual waterbodies vary based on several factors (*e.g.*, salinity, water movement, wind, temperature), with faster-moving and warm water locations recovering more quickly (EPA 2008f).

During oil extraction, the primary waste product is highly saline liquid called "produced water," which can contain metals and other potentially toxic components (*see* Section 3.5.5.1.1 for more on produced water). Produced water and other oil extraction wastes are most commonly disposed of by reinjecting them to the well, which increases pressure and can force out more oil. Potential impacts from these wastes generally occur when large amounts are spilled and they enter surface waters, when decommissioned wells are improperly sealed, or when saline water from the wells intrudes into fresh surface water or groundwater (Kharaka and Otton 2005).

Water quality impacts also occur as a result of contamination by VOCs. A nationwide study of groundwater aquifers conducted by United States Geological Survey (USGS) found VOCs in 90 of 98 major aquifers sampled (Zogorski *et al.* 2006). The study concluded that "…[t]he widespread occurrence of VOCs indicates the ubiquitous nature of VOC sources and the vulnerability of many of the Nation's aquifers to low-level VOC contamination." Several of the most commonly identified VOCs were a gasoline additive (gasoline oxygenate – methyl tertiary butyl ether [MTBE]) and a gasoline hydrocarbon (toluene). USGS notes, however, that only 1 to 2 percent of the well samples had concentrations of VOCs at levels that would be of potential concern to human health; none of the VOCs found in potentially hazardous quantities were primarily used in the manufacture of fuels or as fuel additives (Zogorski *et al.* 2006). Section 3.5.5 describes toxic chemicals released during fuel production and combustion.

3.5.1.1.2 CO_2 Emissions

Oceanic concentrations of CO_2 from anthropogenic (human-made) sources, primarily the combustion of fossil fuels, have increased since the Industrial Revolution and likely will continue to increase. In addition to its role as a GHG, atmospheric CO_2 plays a key role in the biogeochemical cycle of carbon. Atmospheric CO_2 concentrations influence the chemistry of natural waters.

Atmospheric concentrations of CO_2 are in equilibrium with aqueous (dissolved in water) carbonic acid (H_2CO_3), which in turn influences the aqueous concentrations of bicarbonate ion (HCO_3^-) and carbonate ion (CO_3^{2}). In natural waters, the carbonate system controls pH, which in turn controls the availability of some nutrients and toxic materials in freshwater and marine systems.

One of the large-scale non-climatic effects of an increase in CO_2 emissions is the potential for ocean acidification. The ocean exchanges huge quantities of CO_2 with the atmosphere, and when atmospheric concentrations rise (due to anthropogenic emissions), there is a net flux from the atmosphere into the oceans. This decreases the pH of the oceans, reducing the availability of calcium. According to Richardson and Poloczanska (2008), "declines in ocean pH may impact calcifying organisms, from corals in the tropics to pteropods (winged snails) in polar ecosystems, and will take tens of thousands of years to reequilibrate to preindustrial conditions." Section 4.7 provides more information on the non-climate effects of CO_2 on plant and animal communities.

3.5.1.1.3 Biofuel Cultivation and Mining Activity

The need to supply agricultural products for a growing population will continue to affect water resources; future irrigation needs are likely to include increased production of both food and biofuel crops (Simpson 2008). Global demand for water is increasing as a result of population growth and economic development and irrigation currently accounts for around 70 percent of global water withdrawals (Shiklomanov and Rodda 2003 as cited in Kundzewicz *et al.* 2007). EPA states that "[d]emand for biofuels is also likely to have impacts on water including increasing land in agricultural production, resulting in increased risk of runoff of sediments, nutrients, and pesticides … [p]roduction of biofuels also uses significant amounts of water" (EPA 2008d). Runoff from agricultural sources often contains nitrogen, phosphorus, and other fertilizers and chemicals that harm water quality and can lead to euthrophication (the enrichment of a water body with plant-essential nutrients that can ultimately lead to oxygen depletion) (Vitousek *et al.* 1997, as cited in Fischlin *et al.* 2007). If biofuel production in the United States continues to be based on input-intensive crops like corn and soybeans, projected expansions to meet demand likely will result in significantly increased runoff of fertilizer and sediment (Simpson 2008).

Shifts toward fuel-saving lighter vehicles, either as a result of consumer preference for fuel-efficient vehicles or down-weighting design decisions by manufacturers, might result in changes in mining land use patterns with resulting impacts to water quality (*see* Section 3.5.3.1.1). Metal mining results in impacts to water resources via run-off sedimentation from cleared mining sites and degradation of groundwater quality or quantity due to excavation and extraction activities (EPA 1995a). Shifts in demand for lighter vehicles could mean that areas with iron deposits would experience less mining activity, while areas where commonly used light weight metals (such as aluminum or magnesium) might experience an increase in mining and related water impacts.

3.5.1.2 Environmental Consequences

As discussed in Section 3.3, each action alternative is generally expected to decrease the amount of VOCs, SO_2, NO_x, and other air pollutants in relation to No Action Alternative (Alternative 1) levels. Reductions in these pollutant levels would be the result of lower petroleum fuel consumption by cars and light trucks, and a potential for reduced extraction, transportation, and refining of crude oil. NHTSA expects that lower pollutant emissions would decrease the formation of acid rain in the atmosphere as compared to the No Action Alternative, which in turn would have a beneficial impact on the quality of freshwater standards by decreasing eutrophication and acidification. As discussed in Section 3.4, the impact of the alternative CAFE standards on CO_2 is relatively small compared to global emissions of CO_2. The U.S. car and light-truck fleet represents less than 4 percent of the global emissions of CO_2 from cars and light trucks, and this contribution is projected to decline in the future, due primarily to rapid growth of emissions from developing countries.

Each alternative could lead to an indirect increase in the production of biofuels and the use of more lightweight materials in vehicles, depending on the mix of tools manufacturers use to meet the increased CAFE standards, economic demand, and technological capabilities. If biofuel production were to increase, agricultural runoff could increase. If manufacturers opted for increased production of down-weighted vehicles, shifts in the location of metal extraction could alternatively benefit water quality in locations of decreased activity, while negatively affecting it in areas of increased activity. However, due to uncertainty about how manufacturers would meet the new requirements, and the fact that none of the alternative CAFE standards prescribe increased biofuel use or vehicle down-weighting, these potential impacts are not quantifiable. Section 3.5.4 provides additional information on vehicle down-weighting.

3.5.2 Biological Resources

3.5.2.1 Affected Environment

Biological resources include vegetation, wildlife, and special status species (those classified as "threatened" or "endangered" under the Endangered Species Act). The U.S. Fish and Wildlife Service has jurisdiction over terrestrial and freshwater special status species and the National Marine Fisheries Service has jurisdiction over marine special status species. States and other federal agencies, such as the Department of the Interior's Bureau of Land Management, also have species of concern to which they have assigned additional protections. Sections 3.5.2.1.1 through 3.5.2.1.3 describe the current and projected future threats to these biological resources from non-global climate change impacts related to the proposed action. As discussed below, the production and combustion of fossil fuels, the cultivation and production of biofuels from agricultural crops, and shifts in the location of mining activities are the identified relevant sources of impacts on biological resources. Section 4.5 describes the effects of global climate change on ecosystems.

3.5.2.1.1 Petroleum Extraction and Refining

Oil extraction activities could impact biological resources through habitat destruction and encroachment, raising concerns about their effects on the preservation of animal and plant populations and their habitats. Oil exploration and extraction result in intrusions into onshore and offshore natural habitats and can involve construction within natural habitats. "The general environmental effects of encroachment into natural habitats and the chronic effects of drilling and generating mud and discharge water on benthic (bottom-dwelling) populations, migratory bird populations, and marine mammals constitute serious environmental concerns for these ecosystems" (Borasin *et al.* 2002 as cited in O'Rourke and Connolly 2003).

Oil extraction and transportation can also result in spills of oil and hazardous materials. Oil contamination of aquatic and coastal habitats can directly smother small species and is dangerous to animals and fish if ingested or coated on their fur, skin, or scales. Oil refining and related activities result in chemical and thermal pollution of water, both of which can be harmful to animal and plant populations (Borasin *et al.* 2002). Offshore and onshore drilling and oil transport can lead to spills, vessel or pipeline breakage, and other accidents that release petroleum, toxic chemicals, and highly saline water into the environment and affect plant and animal communities.

Oil extraction, refining and transport activities, and the combustion of fuel during motor-vehicle operation, result in air emissions that affect air quality and can contribute to the production of acid rain; these effects can have negative impacts on plants and animals. Once present in surface waters, air pollutants can cause acidification of waterbodies, changing the pH of the system and affecting the function of freshwater ecosystems. EPA states:

> …plants and animals living within an ecosystem are highly interdependent…Because of the connections between the many fish, plants, and other organisms living in an aquatic ecosystem, changes in pH or aluminum levels affect biodiversity as well. Thus, as lakes and streams become more acidic, the numbers and types of fish and other aquatic plants and animals that live in these waters decrease (EPA 2008b).

Acid rain has also been shown to affect forest ecosystems negatively, both directly and indirectly. These impacts include stunted tree growth and increased mortality, primarily as a result of the leaching of calcium and other soil nutrients (Driscoll *et al.* 2001, DeHayes *et al.* 1999, Baum 2001). Declines in biodiversity of aquatic species and changes in terrestrial habitats likely have ripple effects on other wildlife that depend on these resources.

The combustion of fossil fuels and certain agricultural practices have lead to a disruption in the nitrogen cycle (the process by which gaseous nitrogen from the atmosphere is used and recycled by organisms) with serious repercussions for biological resources. Nitrogen-cycle disruption has occurred through the introduction of large amounts of anthropogenic nitrogen in the form of ammonium and nitrogen oxides to aquatic and terrestrial systems (Vitousek 1994). Increased availability of nitrogen in these systems is a major cause of eutrophication in freshwater and marine waterbodies. Eutrophic systems typically contain communities dominated by phytoplankton (free-floating microscopic plants). Eutrophication can ultimately result in fish and other aquatic animal kills and harmful algal blooms. Acid rain enhances eutrophication of aquatic systems through the deposition of additional nitrogen (Lindberg n.d.). Introduction of large quantities of nitrogen to certain terrestrial systems has also been predicted to lead to an increase in decomposing soil bacteria and subsequent increase in the release of CO_2 into the atmosphere as these bacteria consume organic matter (Black 2008).

3.5.2.1.2 CO_2 Emissions

Ocean acidification as a result of increasing concentrations of atmospheric CO_2, primarily from the combustion of fossil fuels, is expected to affect calciferous marine organisms. In conjunction with rapid climate change, ocean acidification could pose severe threats to coral reef ecosystems. Hoegh-Guldberg *et al.* (2007) state that "[u]nder conditions expected in the 21st century, global warming and ocean acidification will compromise carbonate accretion, with corals becoming increasingly rare on reef systems. The result will be less diverse reef communities and carbonate reef structures that fail to be maintained."

In contrast to its potential adverse effect on the productivity of marine ecosystems, higher CO_2 concentrations in the atmosphere could increase the productivity of terrestrial systems, because plants use CO_2 as an input to photosynthesis. The IPCC Fourth Assessment Report states that "[o]n physiological grounds, almost all models predict stimulation of carbon assimilation and sequestration in response to rising CO_2, called CO_2 fertilization" (Denman *et al.* 2007).

Under bench-scale and field-scale experimental conditions, several investigators have found that higher concentrations have a "fertilizer" effect on plant growth (*e.g.*, Long *et al.* 2006, Schimel *et al.* 2000). IPCC reviewed and synthesized field and chamber studies, finding that:

> There is a large range of responses, with woody plants consistently showing NPP [net primary productivity] increases of 23 to 25 percent (Norby *et al.*, 2005), but much smaller increases for grain crops (Ainsworth and Long 2005) … Overall, about two-thirds of the experiments show positive response to increased CO_2 (Ainsworth and Long 2005, Luo *et al.* 2005, as cited in Denman *et al.* 2007). Since saturation of CO_2 stimulation due to nutrient or other limitations is common (Dukes *et al.* 2005, Körner *et al.* 2005, both as cited in Denman *et al.* 2007), it is not yet clear how strong the CO_2 fertilization effect actually is.

The CO_2 fertilization effect could mitigate some of the increase in atmospheric CO_2 concentrations by resulting in more storage of carbon in vegetation.

Increased atmospheric CO_2, in conjunction with other environmental factors and changes in plant communities, could alter growth, abundance, and respiration rates of some soil microbes (Lipson *et al.* 2005, Chung *et al.* 2007, Lesaulnier *et al.* 2008).

3.5.2.1.3 Land Disturbances Due to Biofuel Production and Mining

Future demands for biofuel production are predicted to require increased commitments of land to agricultural production (EPA 2008d). Placing additional land into agricultural production or returning marginal agricultural land to production to grow perennial grass or trees for use in cellulosic ethanol production would decrease the area available as natural habitat. A decrease in habitat and potential habitat for plants and animal species would likely result in negative impacts to certain species. Increased agriculture production would also likely result in increased surface runoff of sediments and fertilizers. Additional fertilizer inputs to water could increase eutrophication and associated impacts. Sediment runoff can settle to the bottom of waterbodies and degrade essential habitat for some species of aquatic organisms, bury food sources and areas used for spawning, and kill benthic organisms (EPA 2000b).

As stated in section 3.5.1.1.3, a shift toward lighter vehicles would likely result in changes to mining land use patterns and impacts to water quality; such changes could affect aquatic and terrestrial ecosystems. EPA notes that mining activities could result in the destruction of terrestrial habitat, loss of fish populations due to water-quality impacts, and a loss of plants due to increased dust (EPA 1995a). As previously stated, such a shift would likely be beneficial in areas of decreased activity and detrimental in areas of increased activity.

3.5.2.1.4 Endangered Species

Off-shore drilling, on-shore oil and gas drilling, and roads created to access remote extraction sites through habitats used by threatened or endangered species might also affect these plants and animals both directly, through loss of individual animals or habitat, and indirectly, through water-quality degradation or cumulative impacts with other projects. Loss of potential habitat to the production of biofuels could also result in negative impacts to some species (*e.g.*, diminished potential for habitat expansion, increased runoff-related impacts).

Increased anthropogenic inputs of nitrogen to terrestrial, aquatic, and microbial communities containing rare plants and animals could also affect threatened and endangered species. In ecosystems with certain vegetation and soil types, this increased nitrogen availability can result in reduced biodiversity or the exclusion of certain endemic species in favor of those adapted to make use of these nutrients to their competitive advantage (Bobbink *et al.* 1998, Fenn *et al.* 2003, Weiss 1999). For example, the decline of certain nutrient-poor native grasslands in California, which serve as critical habitat for the Bay checkerspot butterfly, is likely partially due to an increase in invasive grass species made possible by such nutrient inputs (Weiss 1999).

3.5.2.2 Environmental Consequences

The decrease in overall fuel consumption by cars and light trucks, anticipated under all of the alternatives except the No Action Alternative, could lead to reductions in oil exploration, extraction, transportation, and refining. NHTSA expects that a reduction in these activities would result in decreased impacts to on- and off-shore habitat and plant and animal species. This decrease could have a small overall benefit to plants and animals primarily through decreased levels of direct ground disturbance and releases of oil and hazardous materials. Reductions in the rate of fuel consumption increase under all of the alternatives compared to the No Action Alternative would lead to overall decreases in the release of SO_2 and NOx. Reductions in acid rain and anthropogenic nutrient deposition could lower levels of eutrophication in surface waters and could slow direct impacts to ecosystems and to soil leaching.

Reductions in the rate of fuel consumption increase would also lead to a decrease in the release of CO_2 compared to the No Action Alternative. Lower levels of atmospheric CO_2 could slow projected effects to terrestrial plant growth, calciferous marine organisms, and microorganisms. However, as discussed in Section 3.5.1.2, the reduction in CO_2 as a result of the proposed action would be relatively small compared to current and projected global CO_2 releases (*see* Chapter 2 and Section 3.3).

The alternatives could lead to an increase in the production of biofuels and mining for lightweight raw materials, depending on the mix of tools manufacturers use to meet the new CAFE standards, economic demands from consumers and manufacturers, and technological developments. Depending on these factors, increased production of biofuels could result in the conversion of existing food-agricultural lands and non-agricultural areas to biofuel crop production. This change in land use would have implications for environmental issues associated with fertilizer runoff, water body eutrophication, and sediment runoff effects to aquatic organism food and spawning habitat. Similarly, increased mining land-disturbance activities could affect aquatic health due to increased sedimentation. However, due to the uncertainty surrounding how manufacturers would meet the new requirements and the fact that none of the analyzed standards prescribe increased biofuel use or vehicle downweighting, these potential effects are not quantifiable.

NHTSA has not been able to identify or quantify the impacts to endangered or threatened species or critical habitat as a result of this rulemaking. Therefore, NHTSA will not perform a Section 7 Consultation.

3.5.3 Land Use and Development

3.5.3.1 Affected Environment

Land use and development refers to human activities that alter land (*e.g.*, industrial and residential construction in urban and rural settings, clearing of natural habitat for agricultural or industrial use) and may affect the amount of carbon or biomass in existing forest or soil stocks in the affected areas. For the purposes of this analysis, shifts in agricultural and mining production and changes to manufacturing plants that produce cars and light trucks are the identified relevant sources of impact.

3.5.3.1.1 Changes in Agricultural Production and Mining

Biofuel production is predicted to require increased devotion of land to agricultural production (EPA 2008d, Keeney and Hertel 2008). Converting areas into cropland would decrease the overall land area kept in a natural state as well as the potential area available for other uses (such as commercial development or pastureland) (Keeney and Hertel 2008). Uncertainty exists regarding how much additional land could be required to meet projected biofuel needs in the United States, as well as how an increase in biofuel production could affect other land uses (Keeney and Hertel 2008).

Shifts toward fuel-saving lighter vehicles, either as a result of consumer preference for fuel-efficient vehicles or downweighting design decisions by manufacturers, might result in changes in mining land use patterns. Mining for the minerals needed to construct these lighter vehicles (primarily aluminum and magnesium) could shift some metal extraction activities to areas rich in these resources. Schexnayder *et al.* (2001) noted that such a shift in materials "could reduce mining for iron ore in the United States, but increase the mining of bauxite for aluminum, magnesium, titanium, and other materials in such major countries as Canada, China, and Russia and in many small, developing countries, such as Guinea, Jamaica, and Sierra Leone."

3.5.3.1.2 Manufacturing Changes

Recent shifts in consumer demand in the United States away from less fuel-efficient vehicles have begun to change the types of vehicles produced and the manufacturing plants where they are made. Sharp decreases in demand for trucks and SUVs have recently resulted in plant closures and production shifts to plants where small cars and gas-electric hybrid vehicles are made (WWJ News Radio 2008, Keenan and Mckenna 2008, Bunkley 2008).

3.5.3.2 Environmental Consequences

The alternatives could lead to an increase in the production of biofuels and the use of more lightweight materials in vehicles, depending on the mix of tools manufacturers use to meet the new CAFE standards, economic demands from consumers and manufacturers, and technological developments. Depending on these factors, increased production of biofuels could result in the conversion of existing food-agricultural lands and natural areas to the production of these fuel crops. Downweighted vehicles could result in shifts in mining from areas containing iron to those containing aluminum and magnesium. These changes would have implications for environmental issues associated with land use and development. However, due to the uncertainty surrounding how manufacturers would meet the new requirements and the fact that none of the analyzed standards prescribe increased biofuel use or vehicle downweighting, these potential impacts are not quantifiable. *See* Section 3.5.4 for more information on vehicle downweighting.

Major changes to manufacturing facilities, such as those occurring with the apparent shift in consumer demand toward more fuel-efficient vehicles, might have implications for environmental issues associated with land use and development. However, NHTSA's review of existing and available technologies and capabilities shows that the CAFE standards under all the alternatives can be met by existing and planned manufacturing facilities. Because of the availability of sufficient existing and planned capacity, and because none of the alternatives prescribe particular technologies for meeting these standards, the various alternatives are not projected to force changes in product mixes that would result in plant changes.

3.5.4 Safety and Other Impacts to Human Health

This section addresses how future improvements in fuel economy might affect human health and welfare through vehicle safety performance, particularly crashworthiness and the rate of traffic fatalities. It also addresses how the new standards might affect energy concerns, which could have ramifications for family health and welfare.

3.5.4.1 Affected Environment

Multiple factors influence traffic fatality rates, including driver demographics (age, gender, etc); driver behavior (*e.g.*, driving under the influence, seat belt use, observance of speed limits and other traffic laws, miles driven); and vehicle characteristics such as size, weight, and various technologies designed to increase vehicle safety performance (*e.g.*, air bags, anti-lock braking systems, structural reinforcement, impact crumple zones). Several studies have attempted to define the relationship between vehicle crashworthiness (specifically as it relates to traffic fatalities) and fuel economy standards; however, different methodologies have yielded different conclusions. Although much of the research identifies a link between vehicle downsizing and decreased crashworthiness, studies have reached various conclusions.

The 2002 National Academy of Sciences report (NAS 2002) made explicit links between weight and vehicle safety. The NAS study conclusions were divided, with 11 of 13 committee members representing the majority view and 2 of 13 the minority view. The findings of the majority state, "the majority of the committee finds that the downsizing and weight reduction that occurred in the late 1970s and early 1980s most likely produced between 1,300 and 2,600 crash fatalities and between 13,000 and 26,000 serious injuries in 1993. The proportion of these casualties attributable to CAFE standards is uncertain." Two members provided a minority view: "The relationships between vehicle weight and safety are complex and not measurable with any reasonable degree of certainty at present. The relationship of fuel economy to safety is even more tenuous. … it appears that in certain kinds of accidents, reducing weight will increase safety risk, while in others it may reduce it. Reducing the weights of light-duty vehicles will neither benefit nor harm all highway users, there will be winners and losers…"

The Kahane study (2003) estimates the effect of 100-pound reductions in heavy (more than 3,900 pounds curb weight) light trucks and vans (LTVs), light LTVs, heavy passenger cars, and light passenger cars. It compares the fatality rates of LTVs and cars to quantify differences among vehicle types, given drivers of the same age, gender, etc. The study found that annual fatalities increased with a reduction in weight in all groups of passenger vehicles except light trucks with a curb weight greater than 3,900 pounds. The net safety effect of removing 100 pounds from a light truck is close to zero for the group of all light trucks with a curb weight greater than 3,900 pounds.

Honda has cited several reports, which it asserts demonstrate that limited weight reductions would not reduce safety and could possibly decrease overall fatalities. Honda stated that the 2003 study by Dynamic Research Inc. (DRI) found that reducing weight without reducing size slightly decreased fatalities, and that this was confirmed in a 2004 study by DRI[37] that assessed new data and methodology changes in the 2003 Kahane study. DRI submitted an additional study, *Supplemental Results on the Independent Effects of Curb Weight, Wheelbase, and Track Width on Fatality Risk in 1985-1998 Model Year Passenger Cars and 1985-1997 Model Year LTVs* (van Auken and Zellner 2005). This DRI study concluded that reductions in "footprint" (the product of multiplying a vehicle's wheelbase by its track width) are harmful to safety, whereas reductions in mass while holding footprint constant would benefit safety.

NHTSA analyses of the relationships between fatality risk and mass, track width, and wheelbase in four-door 1991 to 1999 passenger cars (Docket No. 2003-16318-0016) found a strong relationship between track width and the rollover fatality rate, but only a modest (although substantial) relationship between track width and fatality rate in non-rollover crashes. Even controlling for track width and wheelbase – for example, by holding footprint constant – weight reduction in the lighter cars is strongly associated with higher non-rollover fatality rates in the NHTSA analysis.

While further scientific examination continues, EISA included an important reform that requires NHTSA to issue attribute-based standards, which eliminates or reduces the incentive to decrease the size (weight) of the vehicle to comply with the fuel economy standards because smaller-footprint (size) vehicles have to achieve higher fuel economy targets. The attribute-based approach was originally recommended by the NAS to remove the apparent incentive to reduce size and/or the weight of vehicles as a means of meeting the standards.

NHTSA adopted an attribute-based approach for light trucks in 2006. NHTSA continues to examine this important safety issue and has tentatively concluded in its current NPRM that use of the

[37] *See* Docket Nos. 2003-16318-2, 2003-16318-3, and 2003-16318-7.

footprint-attribute will achieve greater fuel economy/emissions reductions without creating an incentive to downsize vehicles.

Another way that the new standards could affect human health and welfare is by increasing the amount of VMT. NHTSA tracks very closely the rate of traffic fatalities as a function of VMT, even while recognizing that many other factors are critical in determining fatality risks. In February 2008, NHTSA reported that the fatality rate in 2006 was 1.41 per million VMT, a decline from 2005 rates (Subramanian 2008). These effects are not limited to vehicle occupants (bicyclists and pedestrians could also have an increased risk as a result of increased VMT). However, as with vehicle occupant fatalities, many other factors are important in determining the overall risk associated with vehicle, pedestrian, and bicycle fatalities.

Finally, there is scientific literature that posits a relationship between petroleum scarcity and human health. Frumkin *et al.* (2007) argues that increased oil prices could result in increased use of other fuels for power generation and increase costs to hospitals for providing back-up power via diesel generators. Petroleum scarcity could also result in more expensive food (due to transportation and agricultural costs), which could be intensified by several factors, including climate change, market demand for biofuels (which would inflate some food prices), and degradation of agricultural land. These effects could threaten the health of low-income people and others who do not have secure access to food. Other effects of peak petroleum prices on health are more speculative, but concerns remain for issues such as (1) higher petroleum prices triggering a persistent economic downturn, which could increase the ranks of the uninsured, (2) social disruptions that could create a substantial burden of anxiety, depression, and other psychological ailments, and (3) resource scarcity, including petroleum scarcity, that could trigger armed conflict, which poses multiple risks to public health. To the extent that the CAFE standards affect petroleum supply or price, they might have an effect on human welfare.

3.5.4.2 Environmental Consequences

Because of the attribute-based approach recommended by NAS and adopted by NHTSA, the incentive to meet the new standards by making more smaller vehicles and fewer larger vehicles should be reduced or eliminated. Further, NHTSA chose fuel-economy levels that could be achieved without reductions in weight for vehicles less than 5,000 pounds. Because the alternatives do not mandate the methods by which the CAFE standards are achieved, vehicle manufacturers could achieve increased fleet fuel economy by reducing vehicle weight. To the extent that manufacturers choose this approach, there could be some additional traffic fatalities and more serious injuries resulting from vehicle accidents. The extent of these effects cannot be estimated without knowing the extent to which manufacturers choose to meet the new CAFE standards by making lighter vehicles with similar footprints.

The PRIA for the CAFE standards of MY 2011-2015 passenger cars and light trucks concluded that increases in fleet fuel economy are likely to lead to more miles being driven by the U.S. population (NHTSA 2008a). Known as the rebound effect, higher CAFE standards would lead to the perception of a lower cost of driving, which is typically the largest component of the cost of operating a vehicle. In response to the perception of lowered costs, consumers would increase the number of miles they drive. By one estimate, a 10-percent increase in fuel economy would ultimately result in a 2.4-percent increase in total miles traveled (Small and Dender 2005a). The recent and unprecedented decline in miles driven – a 4.3 percent drop in the total miles driven in March of 2008 as compared to March of 2007, equating to a decrease of 11 billion miles (FHWA 2008) – in response to recent surges in the price of gasoline, underscores the relationship between the cost of operating a passenger vehicle and driver behavior as it relates to miles driven. Because increased average fuel economy would lead to vehicles that cost less to operate, it can be expected that individuals would drive more miles, and traffic accidents and fatalities of vehicle occupants, bicyclists, and pedestrians would increase on the whole. However, an estimate of increased fatalities based on miles driven is influenced, in part, by unpredictable market forces, and is uncertain to predict.

The alternatives would reduce petroleum use. To the extent that petroleum scarcity would be reduced by higher fuel economy standards, any adverse health impacts as described by Frumkin *et al.* (2007) would also be reduced.

3.5.5 Hazardous Materials and Regulated Wastes

3.5.5.1 Affected Environment

Hazardous wastes are defined here as solid wastes, which also include certain liquid or gaseous materials, that because of their quantity and concentration, or their physical, chemical, or infectious characteristics could cause or contribute to an increase in mortality or an increase in serious irreversible or incapacitating reversible illness or could pose a substantial hazard to human health or the environment when improperly treated, stored, used, transported, disposed of, or otherwise managed. Hazardous wastes are generally designated as such by individual states or EPA under the Resource Conservation and Recovery Act of 1976. Additional federal and state legislation and regulations, such as the Federal Insecticide, Fungicide, and Rodenticide Act, determine handling and notification standards for other potentially toxic substances. For the purposes of this analysis, hazardous materials and wastes generated during the oil extraction and refining processes and by agricultural production and mining activities are the identified relevant sources of impact.

3.5.5.1.1 Wastes Produced during the Extraction Phase of Oil Production

The primary waste created during the extraction of oil is “produced water,” highly saline water pumped from oil and gas wells during mining (American Petroleum Institute 2000, EPA 2000c). In 1995, the onshore oil and gas industry produced approximately 15 billion barrels of produced water (American Petroleum Institute 2000). Produced waters are generally “highly saline (total dissolved solids may exceed 350,000 milligrams per liter [mg/L]), may contain toxic metals, organic and inorganic components, and radium-226/228 and other naturally occurring radioactive materials” (Kharaka and Otton 2005). Drilling wastes, primarily mud and rock cuttings, account for 149 million barrels of extraction wastes. “Associated wastes,” generally the most hazardous wastes produced during extraction (often containing benzenes, arsenic, and toxic metals), account for another 22 million barrels (The American Petroleum Institute 2000, EPA 2000c).

Wastes produced during oil and gas extraction have been known to have serious environmental effects on soil, water, and ecosystems (Kharaka and Otton 2005, O’Rourke and Connolly 2003). Onshore environmental effects result “primarily from the improper disposal of large volumes of saline water produced with oil and gas, from accidental hydrocarbon and produced water releases, and from abandoned oil wells that were not correctly sealed” (Kharaka and Otton 2005). Offshore effects result from improperly treated produced water released into the waters surrounding the oil platform (EPA 2000c).

3.5.5.1.2 Wastes Produced during the Refining Phase of Oil Production

Wastes produced during the petroleum-refining process are primarily released to the air and water, accounting for 75 percent (air emissions) and 24 percent (wastewater discharges) of the total (EPA 1995a). EPA defines a release as the “on-site discharge of a toxic chemical to the environment…emissions to the air, discharges to bodies of water, releases at the facility to land, as well as contained disposal into underground injection wells” (EPA 1995a). EPA reports that 9 of the 10 most common toxic substances released by the petroleum-refining industry are volatile chemicals, highly reactive substances prone to state changes or combustion, that include benzene, toluene, ethylbenzene, xylene, cyclohexane, 1,2,4-trimethylbenzene and ethylbenze (EPA 1995a). These substances are present in crude oil and in finished petroleum products. Other potentially dangerous substances commonly released during the refining process include ammonia, asoline additives (methanol, ethanol, and MTBE), and chemical feedstocks (propylene, ethylene, and napthalene) (EPA 1995a). Spent sulfuric acid is by far the most commonly produced toxic substance; however, it is generally reclaimed instead of released or transferred for disposal (EPA 1995a).

Wastes released during the oil-refining process can cause environmental impacts to water quality, air quality, and human health. The volatile chemicals released during the refining process are known to react in the atmosphere and contribute to ground-level ozone and smog (EPA 1995a). Several of the produced volatile chemicals are also known or suspected carcinogens, and many others are known to cause respiratory problems and impair internal-organ functions, particularly in the liver and kidneys (EPA 1995a). Ammonia is a form of nitrogen and can contribute to eutrophication in surface waters.

3.5.5.1.3 Agricultural Materials

Agricultural production, especially of the type required to grow the corn and soy beans most commonly used to produce biofuels in the United States, also results in the release of potentially hazardous materials and wastes. Wastes from agricultural production can include pesticide (insecticides, rodenticides, fungicides, and herbicides) and fertilizer runoff and leaching, wastes used in the maintenance and operation of agricultural machinery (used oil, fuel spills, organic solvents, metal machining wastes, spent batteries), and other assorted process wastes (EPA 2000d).

Agricultural wastes in the form of runoff from agricultural fields can cause environmental impacts to water and human health. Fertilizers can run off into surface waters and cause eutrophication, while pesticides can directly affect beneficial insects and wildlife (EPA 2000d). A National Renewable Energy Lab report concludes that the negative environmental impacts on soil and water due to impacts of increased biofuel production are likely to occur disproportionately in the Midwest, where most of these crops are grown (Powers 2005). Human health can also be affected by improperly handled or applied pesticides, with potential effects ranging from minor respiratory or skin inflammation to death (EPA 2000d). Nitrogen fertilizer runoff to drinking-water sources can lead to methemogloanemia, the potentially fatal binding of a form of nitrogen to hemoglobin in infants (Powers 2005).

Ethanol, as a biofuel additive to gasoline, is suspected of enhancing the plume size after a gasoline-blended ethanol spill and might decrease degradation of the spilled hydrocarbon and related compounds, such as benzene (Powers *et al.* 2001, Deeb *et al.* 2002, Williams *et al.* 2003).

3.5.5.1.4 Automobile Production and Assembly

Hazardous materials and toxic substances are produced by motor vehicles and the motor vehicle equipment industry, businesses engaged in the manufacture and assembly of cars, trucks, and busses. EPA reports that solvents (xylene, methyl ethyl ketone, acetone, etc.) are the most commonly released toxic substances it tracks for this industry (EPA 1995a). These solvents are used to clean metal and in the vehicle-finishing process during assembly and painting (EPA 1995a). Other industry wastes include metal paint and component-part scrap.

In addition, studies have suggested that the substitution of lighter weight materials (such as aluminum, magnesium, titanium, or plastic) for steel and iron to increase fuel efficiency could increase the total waste stream resulting from automobile manufacturing (Schexnayder *et al.* 2001). Mining wastes generated during the extraction of these lighter raw materials would likely increase substantially, primarily due to aluminum mining, and other production wastes (e.g., from refining of aluminum and plastic manufacturing) could also increase (Schexnayder *et al.* 2001, Dhingra 1999). The extraction and processing of these metals and the production of manmade fibers and plastics also generate various hazardous wastes (EPA 1995b, EPA 1997c). An assessment of the solid and hazardous wastes generated during the production of three lightweight concept cars concluded the net generation of waste would increase versus conventional vehicles; however, the study also noted that the generation of most hazardous materials of particular concern to human health (*e.g.*, cadmium, chlorine, lead) emitted during the production of vehicles appeared to decrease in the vehicle models analyzed (Schexnayder *et al.* 2001). Recycling of vehicles at the end of the vehicle life could help to offset some of the projected net increase in waste production versus primarily steel/iron construction vehicles.

3.5.5.1.5 CO_2 Emissions

CO_2 is not currently classified as a hazardous material or regulated waste. For a discussion of the release of CO_2 relevant to the proposed action and its impacts on climate change, *see* Section 3.4. For a discussion of the impacts of CO_2 on water resources, *see* Section 3.5.1.1.2. For a discussion of the impacts of CO_2 on biological resources, *see* Section 3.5.2.1.2.

3.5.5.2 Environmental Consequences

The projected reduction in fuel production and consumption as a result of the proposed action could lead to a reduction in the amount of hazardous materials and wastes created by the oil extraction and refining industries. NHTSA expects corresponding decreases in the associated environmental and health impacts of these substances. However, these effects would likely be small if they occurred because of the limited overall effect of the proposed action on these areas.

All of the alternatives could lead to an increase in the production of biofuels and the use of more lightweight materials in vehicles, depending on the mix of tools manufacturers use to meet the new CAFE standards, economic demands from consumers and manufacturers, and technological developments. If biofuel production increased, these could be additional runoff of agricultural fertilizers and pesticides; if manufacturers pursued vehicle downweighting, these could be a net increase in the waste stream. However, due to the uncertainty surrounding how manufacturers would meet the new requirements and the fact that none of the analyzed standards prescribes increased biofuel use or vehicle downweighting, these potential impacts are not quantifiable. *See* Section 3.5.4 for additional information on vehicle downweighting.

3.5.6 Land Uses Protected under Section 4(f)

3.5.6.1 Affected Environment

Section 4(f) resources are publicly owned parks, recreational areas, wildlife and waterfowl refuges, or public and private historical sites, which are given special consideration by the DOT. Originally included as part of the Department of Transportation Act of 1966, Section 4(f) stipulates that DOT agencies cannot approve the use of land from publicly owned parks, recreational areas, wildlife and waterfowl refuges, or public and private historical sites unless: "(1) there is no feasible and prudent alternative to the use of such land, and (2) such program includes all possible planning to minimize harm to such park, recreational area, wildlife and waterfowl refuge, or historic site resulting from such use" (49 U.S.C. 303).

3.5.6.2 Environmental Consequences

"Section 4(f) only applies where land is permanently incorporated into a transportation facility and when the primary purpose of the activity on the 4(f) resource is for transportation" (FHWA 2005). Therefore, these resources are not affected by the types of environmental issues under consideration as part of the proposed action.

3.5.7 Historic and Cultural Resources

3.5.7.1 Affected Environment

The National Historic Preservation Act of 1966, Section 106 states that agencies of the Federal Government must take into account the impacts of their action to historic properties; the regulations to meet this requirement can be found at 36 CFR Part 800. This process, known as the "Section 106 process," is intended to support historic preservation and mitigate impacts to significant historical or archeological properties through the coordination of federal agencies, states, and other affected parties. Historic properties are generally identified through the *National Register of Historic Places*, which lists properties of significance to the United States or a particular locale because of their setting or location, contribution to or association with history, or unique craftsmanship or materials. National Register-eligible properties must also be sites: "A. That are associated with events that have made a significant contribution to the broad patterns of our history; or B. That are associated with the lives of persons significant in our past; or C. That embody the distinctive characteristics of a type, period, or method of construction, or that represent the work of a master, or that possess high artistic values, or that represent a significant and distinguishable entity whose components may lack individual distinction; or D. That have yielded, or may be likely to yield, information important in prehistory or history" (NPS n.d.). Acid rain as a result of the processing of petroleum products and the combustion of petroleum-based fuels is the identified relevant source of impact to historic and cultural resources for this analysis.

Acid rain, the primary source of which is the combustion of fossil fuels, is one cause of degradation to exposed cultural resources and historic sites. EPA states that "[a]cid rain and the dry deposition of acidic particles contribute to the corrosion of metals (such as bronze) and the deterioration of paint and stone (such as marble and limestone). These effects substantially reduce the societal value of buildings, bridges, cultural objects (such as statues, monuments, and tombstones), and cars" (EPA 2007b).

3.5.7.2 Environmental Consequences

The projected reduction in fuel production and combustion as a result of the proposed action could lead to a minor reduction in the amount of pollutants that cause acid rain. A decrease in the production of such pollutants could result in a corresponding decrease in the amount of damage to historic and other structures caused by acid rain. However, such effects are not quantifiable.

3.5.8 Noise

3.5.8.1 Affected Environment

Excessive amounts of noise, which is measured in decibels, can present a disturbance and a hazard to human health at certain levels. Potential health hazards from noise range from annoyance (sleep disturbance, lack of concentration, and stress) to hearing loss at high levels (Delucchi and Hsu 1998, Geary 1998, Fleming *et al.* 2005). Motor-vehicle noise also affects property value. A study of the impacts of roadway noise on property value estimated this cost to be roughly 3 billion dollars in 1991 dollars (Delucchi and Hsu 1998). The noise from motor vehicles has been shown to be one of the primary causes of noise disturbance in homes (OECD 1988, as cited in Delucchi and Hsu 1998 and Geary 1998). Noise generated by vehicles causes inconvenience, irritation, and potentially even discomfort to occupants of other vehicles, to pedestrians and other bystanders, and to residents or occupants of surrounding property.

3.5.8.2 Environmental Consequences

As a result of the rebound effect (the increase in VMT as the cost per mile for fuel decreases), NHTSA predicts that there will be increased vehicle use under all of the alternatives; higher overall VMTs would result in increases in vehicle road noise. However, determining if there will be noise impacts is not possible based on the available data. Noise levels are location specific, meaning factors such as the time of day at which increases in traffic occur, existing ambient noise levels, the presence or absence of noise abatement structures, and the location of school, residences, and other sensitive noise receptors all influence whether there will be noise impacts.

All of the alternatives could lead to an increase in use of hybrid vehicles, depending on the mix of tools manufacturers use to meet the new CAFE standards, economic demands from consumers and manufacturers, and technological developments. An increased percentage of hybrid vehicles could result in reduced road noise, potentially offsetting some of the increase in road noise predicted to result from increased VMT. However, due to the uncertainty surrounding how manufacturers would meet the new requirements, the fact that none of the alternatives prescribes increased production of hybrid vehicles, and the location-specific nature of noise impacts, these potential impacts are not quantifiable.

3.5.9 Environmental Justice

3.5.9.1 Affected Environment

Federal agencies must identify and address disproportionably high and adverse impacts to minority and low-income populations in the United States (Executive Order 12898, *Federal Actions to Address Environmental Justice in Minority Populations and Low-Income Populations*). DOT Order 5610.2 establishes the process the Department uses to “incorporate environmental justice principles (as embodied in the Executive Order) into existing programs, policies, and activities.” The production and use of fossil fuels and the production of biofuels are the identified relevant sources of impact to environmental populations for this analysis. For a discussion of the effects of changes in climate on environmental justice populations, *see* Section 4.6.

Numerous studies have noted that there appears to be a historic and ongoing relationship between the environmental impacts of petroleum extraction, processing, and use and environmental justice populations (Pastor *et al.* 2001, O’Rourke and Connolly 2003, Lynch *et al.* 2004, Hymel 2007, Srinivasan *et al.* 2003).

Potential impacts of the oil exploration and extraction process on environmental justice communities include “human health and safety risks for neighboring communities and oil industry workers, and displacement of indigenous communities” (O’Rourke and Connolly 2003). Subsistence-use activities (collecting plants or animals to fulfill basic needs for food, clothing, or shelter) can also be affected by extraction and exploration through the direct loss of subsistence-use areas or impacts to culturally/economically important plants and animals as a result of a spill or hazardous material release (O’Rourke and Connolly 2003, Kharaka and Otton 2005).

It has been shown that minority and low income populations often disproportionately reside near high-risk polluting facilities, such as oil refineries (Pastor *et al.* 2001, Graham *et al.* 1999, O'Rourke and Connolly 2003), and "mobile" sources of air toxins and pollutants, such as highways (Morello-Frosch 2002, Jerrett *et al.* 2001, O'Neill *et al.* 2003c). Populations near refineries could be disproportionately affected by exposure to potentially dangerous petroleum and by-products of the refining process, such as benzene (Borasin et. al 2002). Exposure to the toxic chemicals associated with refineries, primarily by refinery workers, has been shown to be related to increases in certain diseases and types of cancer (Pukkala 1998, Chan *et al.* 2005); the precise nature and severity of these health impacts are still under debate. Pollutants from transportation sources, such as NO_2 and CO from roadway traffic, are often unevenly distributed and tend to remain near their release locations (O'Neill *et al.* 2003c). A correlation between this uneven distribution of some pollutants and minority and low income populations has been documented, demonstrating the potential for a disproportionate allocation of the health impacts of these air pollutants to environmental justice populations (Jerret *et al.* 2001, Morello-Frosch 2002). Recent reviews by health and medical researchers indicate a general consensus that proximity to high-traffic roadways could result in health effects in the areas of cardiovascular health (Adar and Kaufman 2007), and asthma and respiratory health (Heinrich and Wichmann 2004, Salam *et al.* 2008). The exact nature of the relationship between these health impacts, traffic-related emissions, and the influence of confounding factors such as traffic noise are not known at this time (Samet 2007).

The production of biofuels could, depending on the mix of agricultural crops or crop residues used in its production, affect food prices. The International Food Policy Research Institute states, "An aggressive biofuel scenario that assumes that current plans for expansion of the sector in Africa, Asia, Europe, and North and South America are actually realized could lead to substantial price increases for some food crops by 2020 – about 80 percent for oilseeds and about 40 percent for maize – unless new technologies are developed that increase efficiency and productivity in both crop production and biofuel processing" (von Braun and Pachauri 2006). Such an increase in food prices would disproportionately affect low income and minority populations, because these groups are less likely to be capable of absorbing the impacts of higher prices.

3.5.9.2 Environmental Consequences

The projected reduction in fuel production and consumption as a result of the action alternatives could lead to a minor reduction in the amount of direct land disturbance as a result of oil exploration and extraction, and the amount of air pollution produced by the oil refineries. There could be corresponding decreases in impacts on environmental justice populations as a result of the alternatives, but the effects of any such decreases are not quantifiable and would likely be minor, if they occurred.

As discussed in Section 3.3, the overall decrease in emissions predicted to occur as a result of the new CAFE standards is not evenly distributed due to the increase in VMT from the rebound effect and regional changes in upstream emissions. As a result, some criteria and toxic air pollutants are predicted to increase in some air quality nonattainment areas. The large size of each nonattainment area, the uniform distribution of increases in VMT, and the minor emissions increases in affected nonattainment and other areas make it unlikely that there would be disproportionate effects to environmental justice populations.

All of the alternatives could lead to an increase in the production of biofuels, depending on the mix of tools manufacturers use to meet the increased CAFE standards, economic demands from consumers and manufacturers, and technological developments. If grain-based biofuel production increases, there could be effects on food prices. However, because of the uncertainty surrounding how manufacturers would meet the new requirements, and the fact that none of the alternatives prescribes increased biofuel use, these potential impacts are not quantifiable.

4 Cumulative Impacts

4.1 INTRODUCTION

The Council on Environmental Quality (CEQ) identifies the impacts that must be addressed and considered by federal agencies in satisfying the requirements of the National Environmental Policy Act (NEPA). This includes permanent, temporary, indirect, and cumulative impacts.

CEQ NEPA implementing regulations define “cumulative impact” as “the impact on the environment which results from the incremental impact of the action when added to other past, present, and reasonably foreseeable future actions regardless of what agency (Federal or non-Federal) or person undertakes such other actions.” 40 Code of Federal Regulations (CFR) § 1508.7. Cumulative impacts should be evaluated along with the overall impacts analysis of each alternative. The range of alternatives considered should include a No Action Alternative as a baseline against which to evaluate cumulative effects. The range of actions to be considered includes not only the proposed action but all connected and similar actions that could contribute to cumulative effects. Related actions should be addressed in the same analysis. CEQ recommends that an agency’s analysis accomplish the following:

- Focus on the effects and resources within the context of the proposed action.
- Present a concise list of issues that have relevance to the anticipated effects of the proposed action or eventual decision.
- Reach conclusions based on the best available data at the time of the analysis.
- Rely on information from other agencies and organizations on reasonably foreseeable projects or activities that are beyond the scope of the analyzing agency’s purview.
- Relate to the geographic scope of the proposed project.
- Relate to the temporal period of the proposed project.

A cumulative impacts analysis involves assumptions and uncertainties. Monitoring programs and research can be identified to supplement the available information and thus, enhance analyses for the future. The absence of an ideal database should not prevent the completion of a cumulative effects analysis.

This section addresses areas of the quantitative analyses presented in Chapter 3, with particular attention to energy, air, and climate. Chapter 4 describes the indirect cumulative effects of climate change on a global scale. This chapter is organized according to the conventions of the climate change literature rather than the conventions of an Environmental Impact Statement (EIS) format. To assist the reader, the chart on the following page maps topics found in U.S. Department of Transportation (DOT) NEPA documents (DOT Order 5610.1C) to the sections in this Final Environmental Impact Statement (FEIS).

4.1.1 Approach to Scientific Uncertainty and Incomplete Information

4.1.1.1 CEQ Regulations

CEQ regulations recognize that many federal agencies confront limited information and substantial uncertainties when analyzing the potential environmental impacts of their actions under NEPA

Typical NEPA Topics	EIS Subsections
Water	4.4 Climate; 4.5.3 Freshwater Resources; 4.5.5 Coastal Systems and Low-lying Areas
Ecosystems	4.5.3 Freshwater Resources; 4.5.4 Terrestrial Ecosystems; 4.5.5 Coastal Systems and Low-lying Areas; 4.5.6 Food, Fiber, and Forest Products; 4.7 Non-climate Cumulative Impacts of CO_2
Threatened and endangered species	4.5.4 Terrestrial Ecosystems; 4.5.5 Coastal Systems and Low-lying Areas; 4.7 Non-climate Cumulative Impacts of CO_2
Publicly owned parklands, recreational areas, wildlife and waterfowl refuges, and historic sites, Section 4(f) related issues	4.5.3 Freshwater Resources; 4.5.4 Terrestrial Ecosystems; 4.5.5 Coastal Systems and Low-lying Areas; 4.5.7 Industries, Settlements, and Society
Properties and sites of historic and cultural significance	4.5.7 Industries, Settlements, and Society
Considerations relating to pedestrians and bicyclists	4.5.7 Industries, Settlements, and Society
Social impacts	4.5.7 Industries, Settlements, and Society; 4.6 Environmental Justice
Noise	4.5.7 Industries, Settlements, and Society
Air	4.3 Air Quality
Energy supply and natural resource development	4.2 Energy; 4.5.4 Terrestrial Ecosystems; 4.5.6 Food, Fiber, and Forest Products; 4.5.7 Industries, Settlements, and Society
Floodplain management evaluation	4.5.3 Freshwater Resources; 4.5.5 Coastal Systems and Low-lying Areas
Wetlands or coastal zones	4.5.3 Freshwater Resources; 4.5.5 Coastal Systems and Low-lying Areas
Construction impacts	4.3 Air Quality; 4.4 Climate; 4.5.7 Industries, Settlements, and Society; 4.5.8 Human Health
Land use and urban growth	4.4 Climate; 4.5.6 Food, Fiber, and Forest Products; 4.5.7 Industries, Settlements, and Society
Human environment involving community disruption and relocation	4.3 Air Quality; 4.4 Climate; 4.5.5 Coastal Systems and Low-lying Areas; 4.6 Environmental Justice; 4.5.7 Industries, Settlements, and Society; 4.5.8 Human Health

(40 CFR § 1502.22). Accordingly, the regulations provide agencies with a means to formally acknowledge incomplete or unavailable information in NEPA documents. Where “information relevant to reasonably foreseeable significant adverse impacts cannot be obtained because the overall costs of obtaining it are exorbitant or the means to obtain it are not known,” the regulations require an agency to include in its NEPA document:

1. A statement that such information is incomplete or unavailable;

2. A statement of the relevance of the incomplete or unavailable information to evaluating reasonably foreseeable significant adverse impacts on the human environment;

3. A summary of existing credible scientific evidence that is relevant to evaluating the reasonably foreseeable significant adverse impacts on the human environment; and

4. The agency’s evaluation of such impacts based on theoretical approaches or research methods generally accepted in the scientific community.

Relying on these provisions is appropriate where an agency is performing a NEPA analysis that involves potential environmental impacts resulting from carbon dioxide (CO_2) emissions (***e.g., Mayo Found. v. Surface Transp. Bd.***, 472 F.3d 545, 555, 8th Cir. 2006). CEQ regulations also authorize agencies to incorporate material into a NEPA document by reference in order to “cut down on bulk without impeding agency and public review of the action” (40 CFR § 1502.21).

Throughout this EIS, the National Highway Transportation Safety Administration (NHTSA) uses these two mechanisms – acknowledging incomplete or unavailable information and incorporation by reference – to address areas where the agency cannot develop a credible estimate of the potential environmental impacts of the standards or reasonable alternatives. In particular, NHTSA recognizes that information about the potential environmental impacts of changes in emissions of CO_2 and other greenhouse gases (GHG) and associated changes in temperature, including those expected to result from the proposed rule, is incomplete. In this EIS, NHTSA often relies on the Intergovernmental Panel on Climate Change (IPCC) Fourth Assessment Report (2007) as a recent “summary of existing credible scientific evidence which is relevant to evaluating the reasonably foreseeable significant adverse impacts on the human environment” (40 CFR § 1502.22(b)(3)).

4.1.1.2 Uncertainty within the IPCC Framework

The IPCC Reports communicate uncertainty and confidence bounds using descriptive words in italics, such as *likely* and *very likely*, to represent levels of confidence in conclusions. This is briefly explained in the IPCC Fourth Assessment Synthesis Report and the IPCC Fourth Assessment Report Summary for Policy Makers (IPCC 2007d, IPCC 2007c). A more detailed discussion of the IPCC’s treatment of uncertainty can be found in the Guidance Notes for Lead Authors of the IPCC Fourth Assessment Report on Addressing Uncertainties (IPCC 2005).

This FEIS uses the IPCC uncertainty language (always noted in italics) throughout Chapters 3 and 4 when discussing qualitative environmental impacts on certain resources. The reader should refer to the documents referenced above to gain a full understanding of the meaning of those uncertainty terms, because they might be different from the meaning of language describing uncertainty in this FEIS as required by the CEQ regulations discussed above.

4.1.2 Temporal and Geographic Boundaries

When evaluating cumulative effects, the analyst must consider expanding the geographic study area beyond that of the proposed action, as well as expanding the temporal (time) limits to consider past, present, and reasonably foreseeable future actions that might affect the environmental resources of concern. The timeframe for this cumulative impacts analysis extends through year 2100 and considers potential cumulative impacts on a national, as well as global, basis.

4.2 ENERGY

A NEPA analysis must consider the cumulative impacts of the proposed action. For this EIS, such considerations involve evaluating the cumulative fuel consumption of the vehicle fleet from the onset of the new standards.

4.2.1 Affected Environment

According to the Energy Information Administration (EIA), net imports of total liquid fuels, including crude oil and refined products, will fall to 51 percent in 2022 and then increase to 54 percent in 2030. This change is attributed to changes in the Corporate Average Fuel Economy (CAFE) standards and in the increased use of biofuels. These imports will replace declining production in meeting the increasing demand for liquid fuels in the United States. The large volume of crude oil imports has a number of impacts on the domestic economy. Further decreases or increases in imports, likely under some of the CAFE alternatives, could affect the world price of crude oil. However, over time the U.S. share of global demand for liquid fuels will decline due to rapid increases in demand in developing economies, including China and India, reducing the relative impact of the CAFE standards on global markets.

Over time a larger share of liquid fuels is expected to be produced from unconventional sources such as biofuels, shale oil, coal-to-liquids, and gas-to-liquids. These alternate sources would affect CO_2 and other emission reductions from the CAFE alternatives. This shift would be driven by changes to the Renewable Fuels Standard (RFS) in the Energy Independence and Security Act (EISA), which forecasts that 36 billion gallons of renewable fuels will be required by 2022 for use primarily in the transportation sector. The EIA Annual Energy Outlook (AEO) 2008 forecasts that domestic production of non-hydro renewable energy will increase from less than 4 quadrillion British thermal units (BTUs) in 2006 to more than 10 quadrillion BTUs in 2030 (EIA 2008a). In the United States, liquid fuels from gas, coal, and biomass are projected to increase from 0.00 quadrillion BTUs in 2006 to 0.54 quadrillion BTUs. Overall, NHTSA expects in the short-term, the impact from these changes would net out. Over the long-term, the impact of these changes remains uncertain.

Changes to the CAFE standards are unlikely to affect domestic production, given the level of crude oil imports. The domestic environmental impacts over the life of the model year (MY) 2011-2020 vehicles are unlikely to change, regardless of the alternative elected. Impacts on production would occur outside of the United States, and would be determined by the balance between the decline in U.S. imports and the increase in demand from developing countries. Impacts on petroleum products would be mixed. U.S. imports of petroleum products are often targeted for specific product requirements, for logistical reasons, or to optimize the inputs and outputs from refineries. Petroleum imports depend on specific product demands and the mix of crudes processed in the refineries, which are projected to change considerably over time. Consequently, any decline in demand for petroleum products is likely to have some effect on both overseas and domestic refineries.

4.2.2 Environmental Consequences

Implementing alternative CAFE standards would result in different future levels of fuel use, total energy, and petroleum consumption, which in turn would have an impact on emissions of GHGs and criteria air pollutants. An important measure of the impact of alternative CAFE standards is the impact on the cumulative fuel consumption of the vehicle fleet from the onset of the new standards. Passenger cars and light trucks are considered separately; total fuel consumption encompasses gasoline and diesel. CAFE standards for MY 2011-2020 are assumed to apply to all subsequent additions to the vehicle fleet. The impact of alternative CAFE standards, by affecting petroleum consumption, total energy consumption, and emissions, would ultimately determine many of the indirect environmental impacts of adopting higher CAFE standards.

Table 4.2-1 shows the cumulative fuel consumption of passenger cars under the No Action Alternative (Alternative 1) and the six action alternative CAFE standards with the Reference Case inputs, as described in Table 2.2-1 (*see* Section 2.2 of this FEIS). By 2060, when MY 2011 or later cars are likely to comprise the entire fleet, cumulative fuel consumption (from 2010) reaches 4.43 trillion gallons under the No Action Alternative. Cumulative consumption falls across the alternatives, from 4.03 trillion gallons under the Optimized Alternative (Alternative 3) to 3.47 trillion gallons under the Technology Exhaustion Alternative (Alternative 7).

Table 4.2-2 shows the cumulative fuel consumption of light trucks/sport utility vehicles (SUVs) under the CAFE alternatives examined. Cumulative fuel consumption by 2060 reaches 5.31 trillion gallons under the No Action Alternative. Cumulative consumption declines across the alternatives, from 4.73 trillion gallons under the Optimized Alternative to 3.93 trillion gallons under the Technology Exhaustion Alternative, which represent a cumulative savings of 1.38 trillion gallons relative to the No Action Alternative.

4.2.3 Input Scenarios

In response to public comments, and to test how different economic assumptions might affect estimates of fuel consumption, NHTSA ran a scenario using high cost assumptions and compared the results to the Reference Case. Tables 4.2-3 and 4.2-4 list the results for the High Scenario. The High Scenario assumes higher fuel prices than are assumed in the Reference Case, which results in lower fuel consumption across all of the CAFE alternatives examined. This is true even for the No Action Alternative, because higher fuel prices in the High Scenario would reduce fuel consumption (relative to the Reference Case) even in the absence of any change in CAFE standards.

Table 4.2-3 shows the cumulative fuel consumption of passenger cars under the No Action Alternative and the six action alternative CAFE standards in the High Scenario. By 2060, when MY 2011 or later cars are likely to comprise the entire fleet, cumulative fuel consumption (from 2010) reaches 3.97 trillion gallons under the No Action Alternative. Cumulative consumption declines across the alternatives, from 3.32 trillion gallons under the Optimized Alternative to 3.12 trillion gallons under the Technology Exhaustion Alternative, which represents cumulative savings of 851.1 billion gallons relative to the No Action Alternative.

Table 4.2-4 shows the cumulative fuel consumption of light trucks/SUVs under the various CAFE alternatives in the High Scenario. Cumulative fuel consumption by 2060 reaches 4.76 trillion gallons under the No Action Alternative. Cumulative consumption falls across the alternatives, from 3.87 trillion gallons under the Optimized Alternative to 3.54 trillion gallons under the Technology Exhaustion Alternative, which represents cumulative savings of 1.22 trillion gallons relative to the No Action Alternative.

To further assess how different economic assumptions might affect estimates of fuel consumption, NHTSA ran two additional scenarios in the Volpe model: the Mid-1 Scenario and the Mid-2 Scenario. As the names of the scenarios suggest, results from the two additional scenarios fall between those of the Reference Case and the High Scenario. For a summary of Mid-1 and Mid-2 scenario results, *see* tables in Appendix B.

Table 4.2-1

Reference Case Passenger Car Cumulative Annual Fuel Consumption and Cumulative Fuel Savings (billion gallons)

4.3 AIR QUALITY

4.3.1 Affected Environment

Section 3.3.1 describes the air quality affected environment.

4.3.2 Methodology

4.3.2.1 Overview

The analysis methodology for air quality cumulative impacts and consequent health outcomes is the same as described in Section 3.3.2, except that NHTSA added the potential CAFE standards for MY 2016-2020 because the EISA requires that passenger cars and light trucks achieve an average of at least 35 miles per gallon (mpg) by 2020. The MY 2016-2020 standards are thus a reasonably foreseeable future action that must be considered.

NHTSA analyzed the cumulative air quality impacts of the action alternatives by calculating the emissions from passenger cars and light trucks that would occur under each alternative and including the potential CAFE standards for MY 2016-2020, and assessing the changes in emissions in relation to the No Action Alternative. Many of the factors that affect air quality at any given location, such as meteorology and atmospheric processes, cannot be accounted for when evaluating human health and environmental impacts because this analysis cannot be done without a full-scale photochemical air quality modeling analysis. Full-scale photochemical air quality modeling was not conducted for this cumulative analysis; therefore, the ambient air quality impacts associated with each alternative cannot be analyzed for this FEIS. Full-scale photochemical air quality modeling is necessary to accurately project levels of particulate matter 2.5 microns in diameter or less ($PM_{2.5}$), ozone, and air toxics. A national-scale air quality modeling analysis would analyze the combined impacts of each alternative on $PM_{2.5}$, ozone, and MSATs. The atmospheric chemistry related to ambient concentrations of $PM_{2.5}$, ozone, and air toxics is very complex, and making predictions based solely on emissions changes is extremely difficult. The analysis of the alternatives is predicated on the common sense proposition that assessing emissions is a valid approach to assessing air quality impacts because emissions, ambient concentrations, and health effects are connected. Lower emissions should result in lower ambient concentrations of pollutants on an overall average basis, which should lead to decreased health effects of those pollutants.

The cumulative impacts analysis consists of three components analyzed together:

- CAFE implementation through MY 2010
- The MY 2011-2015 CAFE standard rules
- Assumed MY 2016-2020 rules based on EISA requirements for at least 35 mpg by 2020

For comparison, the non-cumulative impacts analysis (Section 3.3.2) consists of only two components:

- CAFE implementation through MY 2010
- The MY 2011-2015 CAFE standard rules

Because EISA directs NHTSA to increase CAFE standards to reach a combined fleet average CAFE level of at least 35 mpg by model year 2020, MY 2016-2020 CAFE standards are reasonably foreseeable and must be accounted for when analyzing the cumulative impacts of the MY 2011-2015 CAFE standards. For each alternative, NHTSA assumed that passenger-car and light-truck CAFE standards would continue to increase over MY 2016-2020 at their average annual rate of increase over

MY 2011-2015. This assumption results in passenger-car and light-truck CAFE standards under each action alternative that meet or exceed the EISA requirement of a combined fleet average of at least 35 mpg by model year 2020. NHTSA assumed further that the fuel economy standards for model year 2020 would remain in effect through the end of the analysis period. Because the CAFE standards apply to new vehicles, this assumption results in emissions reductions and fuel savings that continue to grow as new vehicles meeting the CAFE standards for MY 2020 and beyond are added to the fleet in each subsequent year, reaching their maximum values when all passenger cars and light trucks in the U.S. fleet meet these standards. For calendar years 2016-2020, the non-cumulative impacts analysis (Section 3.3.2) assumes that MY 2016-2020 and later passenger cars and light trucks would continue to meet the MY 2015 standards. By contrast, the cumulative impacts analysis assumes that MY 2016-2020 passenger cars and light trucks would meet the potential MY 2016-2020 standards and that MY 2021 and later passenger cars and light trucks would meet the potential MY 2020 standard.

The results presented in Section 4.3.3, Environmental Consequences, are for the Reference Case inputs as shown in Table 2.2-1 (*see* Section 2.2). Section 4.3.4, Input Scenarios, discusses the alternatives with three other input scenarios – High, Mid-1, and Mid-2.

4.3.2.2 Treatment of Incomplete or Unavailable Information

As noted in Section 3.3.2, the estimates of emissions rely on models and forecasts that contain numerous assumptions and data that are uncertain. Examples of areas in which information is incomplete or unavailable include future emission rates, vehicle manufacturers' decisions on vehicle technology and design, the mix of vehicle types and model years, emissions from fuel refining and distribution, and economic factors. Where information in the analysis included in the FEIS is incomplete or unavailable, the agency has relied on CEQ regulations regarding incomplete or unavailable information (40 CFR § 1502.22(b)). NHTSA used the best available models and supporting data in preparing this FEIS. The models used have been scientifically reviewed and have been approved by the agencies that sponsored their development. NHTSA believes that the assumptions made in the FEIS regarding uncertain conditions reflect the best available information and are valid and sufficient for this analysis.

4.3.3 Environmental Consequences

4.3.3.1 Results of Emissions Analysis – Reference Case

The Clean Air Act (CAA) has been successful in reducing emissions from on-road mobile sources. As discussed in Section 3.3.1, pollutant emissions from vehicles have been declining since 1970, and the U.S. Environmental Protection Agency (EPA) projects the decline will continue. However, as future trends show, vehicle travel is having increasingly less impact on emissions as a result of stricter EPA standards for vehicle emissions and the chemical composition of fuels, even with additional increases in vehicle miles traveled (VMT) (Smith 2002). This general trend would continue, more or less, with implementation of any alternative CAFE standard. The cumulative impacts analysis shows that some of the alternative CAFE standards would lead to reductions and some would lead to increases in emissions from passenger cars and light trucks, compared to current trends without the alternative CAFE standards. The amounts of the reductions and increases would vary by pollutant, calendar year, and alternative. The more restrictive alternatives generally would result in greater emission reductions compared to the No Action Alternative. This trend is shown in the analysis of the MY 2011-2015 CAFE standards in Section 3.3.3.

This section analyzes the cumulative impacts of the standards and the assumed MY 2016-2020 standards. The analysis shows that the CAFE standards would lead to further reductions in emissions from passenger cars and light trucks, although the amount of the reductions would vary by the alternative

CAFE standards. Some exceptions, however, are: carbon monoxide (CO) emissions would increase with Alternative 2 (25 Percent Below Optimized), Alternative 3 (Optimized), and (in 2025 and 2035) Alternative 4 (25 Percent Above Optimized). VOC emissions would increase with Alternatives 2 and 3 in 2015. The more restrictive alternatives would result in greater emission reductions compared to Alternative 1 (No Action).

4.3.3.2 Alternative 1: No Action

4.3.3.2.1 Criteria Pollutants

With the No Action Alternative, the CAFE standards would remain at the MY 2010 level in future years. Emissions for this alternative would follow the same trends as shown in the environmental consequences analysis (*see* Section 3.3.3.2). Nationwide emissions changes would be uneven with respect to pollutant and alternative, reflecting projected changes in VMT, emission factors, and diesel share of the vehicle fleet. Cumulative emissions would be less than non-cumulative emissions for the same combination of pollutant, year, and alternative, with the exception of CO.

Table 4.3-1 summarizes the total national cumulative emissions from passenger cars and light trucks for Alternative 1 (No Action) for each criteria pollutant and analysis year. Alternatives 2 through 7 are presented from left to right in the table in order of increasing fuel economy requirements. Alternative 1 would generally have the highest emissions for all criteria pollutants. Emissions of CO under Alternatives 2 and 3 are exceptions, showing increases compared to the No Action Alternative. Appendix B-1 presents the cumulative emissions of criteria pollutants for each nonattainment area.

Table 4.3-1

Nationwide Criteria Pollutant Emissions from Passenger Cars and Light Trucks (tons/year)
Cumulative Effects with MY 2011-2015 Standards and Potential MY 2016-2020 Standards

Pollutant and Year	Alt. 1 No Action	Alt. 2 25% Below Optimized	Alt. 3 Optimized	Alt. 4 25% Above Optimized	Alt. 5 50% Above Optimized	Alt. 6 Total Costs Equal Total Benefits	Alt. 7 Technology Exhaustion
VOCs							
2015	2,261,550	2,259,712	2,259,680	2,257,453	2,256,856	2,253,598	2,185,838
2020	1,896,683	1,882,585	1,882,513	1,875,117	1,872,667	1,864,598	1,666,245
2025	1,817,495	1,787,653	1,787,778	1,773,541	1,769,015	1,755,492	1,407,415
2035	1,906,119	1,861,129	1,862,621	1,832,904	1,825,138	1,803,935	1,196,950

Table 4.3-2 lists the net changes in nationwide cumulative emissions from passenger cars and light trucks for the No Action Alternative for each criteria pollutant and analysis year. Alternatives 2 through 7 are presented in the table from left to right in order of increasing fuel economy requirements. The reductions in nationwide cumulative emissions generally increase from left to right, except as noted above for CO emissions. This reflects the increasing fuel economy requirements that are assumed under successive alternatives.

a/ Negative emissions changes indicate reductions; positive emissions changes are increases.
b/ Emissions changes for the No Action Alternative are shown as zero because the No Action Alternative is the baseline to which the emissions for the other alternatives are compared.

4.3.3.2.2 Air Toxics

As with the criteria pollutants, current trends in the levels of air toxics emissions from vehicles would continue, with emissions of most air toxics continuing to decline, despite a growth in total VMT, as a result of the EPA emission standards. Exceptions to this trend are emissions of benzene and formaldehyde, which increase in 2035 over 2025 levels with the No Action Alternative. Further, with current trends, emissions of diesel particulate matter (DPM) increase in every analysis year with the No Action Alternative. Alternative 1 (No Action) would result in no other increase or decrease in toxic air pollutant emissions in nonattainment and maintenance areas throughout the United States.

Table 4.3-3 summarizes the cumulative national toxic air pollutant emissions from passenger cars and light trucks for Alternative 1 (No Action) for each toxic air pollutant and analysis year. Alternatives 2 through 7 are presented in order of increasing fuel economy requirements from left to right. Unlike criteria pollutants, emissions of many toxic air pollutants would increase in several alternatives. The changes in air toxic emissions, whether positive or negative, would generally be small relative to Alternative 1 emissions levels. An exception is Alternative 7, which would result in changes in emissions of some toxic air pollutants that would be large relative to Alternative 1 emissions levels.

Changes in cumulative emissions for toxic air pollutants reflect decreases with reductions in upstream emissions, and increases due to the rebound effect and changes in the proportion of diesel vehicles. Cumulative emissions of acetaldehyde would increase under Alternatives 4 and 5 for all analysis years, and under Alternatives 2, 3, 6, and 7 for some analysis years. Cumulative emissions of acrolein would increase with all the action alternatives because data on upstream emissions reductions were not available. Cumulative emissions of benzene would decrease under all the action alternatives compared to the No Action Alternative. Cumulative emissions of 1,3-butadiene would generally decrease slightly from Alternative 1 under successive alternatives. Cumulative emissions of DPM would decline under all alternatives relative to the No Action Alternative. Cumulative emissions of formaldehyde would decrease with Alternatives 2 and 3 but increase with Alternative 7; changes in formaldehyde emissions under Alternatives 4, 5, and 6 vary depending on analysis year.

Cumulative emissions would generally be less than non-cumulative emissions for the same combination of pollutant, year, and alternative, for acetaldehyde (except in 2035 and with Alternative 7 in all years), benzene (except Alternative 7 in 2035), DPM, and formaldehyde (except Alternative 7). Cumulative emissions would generally be greater than non-cumulative emissions for the same combination of pollutant, year, and alternative, for acrolein and 1,3-butadiene (in 2020-2035). Appendix B-1 presents the cumulative emissions of toxic air pollutants for each nonattainment area for the No Action Alternative.

Table 4.3-4 lists the net changes in nationwide cumulative emissions from passenger cars and light trucks compared to Alternative 1 (No Action) for each air toxic and analysis year. Alternatives 2 through 7 are presented from left to right in order of increasing fuel economy requirements. In Table 4.3-4 the nationwide emissions changes are uneven with respect to pollutant and alternative, reflecting the changes in VMT and emissions by cars versus trucks and gasoline versus diesel engines that are projected to occur with the increasing fuel economy requirements assumed under successive alternatives.

Table 4.3-3

a/ Negative emissions changes indicate reductions; positive emissions changes are increases.

b/ Emissions changes for the No Action Alternative are shown as zero because the No Action Alternative is the baseline to which the emissions for the other alternatives are compared.

c/ Data on upstream emissions reductions were not available for acrolein. Thus, the emissions for acrolein reflect only the change in tailpipe emissions.

4.3.3.2.3 Health Outcomes and Costs

With Alternative 1 (No Action), the CAFE standards would remain at the MY 2010 level in future years. Emissions of criteria pollutants and air toxics would change as described above. Human health effects of emissions are tied to specific pollutants, and will vary as emissions of these pollutants vary. The No Action Alternative would result in no other increase or decrease in human health effects throughout the United States, compared to current trends.

Table 4.3-5 lists the net changes in health outcomes due to nationwide cumulative emissions in each analysis year. Alternatives 1 through 7 are presented from left to right in order of increasing fuel economy requirements. The health impacts of vehicle emissions decrease for all alternatives compared to the No Action Alternative, and decrease successively in each analysis year.

Table 4.3-5

Reference Case Alternative CAFE Standards

2025	0	-38	-40	-48	-51	-52	-108
2035	0	-66	-68	-81	-86	-86	-159
Work-loss days							
2015	0	-2,006	-2,162	-3,377	-3,772	-4,619	-19,392
2020	0	-14,796	-15,383	-19,552	-21,126	-21,824	-58,309
2025	0	-32,732	-33,787	-41,024	-43,814	-44,325	-92,403
2035	0	-56,293	-57,939	-69,110	-73,443	-73,833	-135,560

a/ Negative changes indicate reductions; positive emissions changes are increases.
b/ Changes in health outcomes for the No Action Alternative are shown as zero because the No Action Alternative is the baseline to which the emissions for the other alternatives are compared.

The economic value of health impacts would vary proportionately with changes in health outcomes, under the methodology defined in Section 3.3.2.4.2. The economic impacts analyzed here are the result of changes in ambient particulate matter (PM) and ozone concentrations as caused by changes in precursor criteria pollutants NO_x, VOCs, SO_2 and $PM_{2.5}$. Alternative 1 (No Action) would result in no other change in health-related costs throughout the United States, compared to current trends.

Table 4.3-6 lists the nationwide changes in health costs from cumulative emissions from passenger cars and light trucks. Results for each analysis year are shown for the No Action Alternative in the left column, and for other alternatives from left to right in order of increasing fuel economy requirements. As with health outcomes, the economic impacts of each alternative decrease across successive alternatives and years compared to the health costs of emissions under the No Action Alternative.

Table 4.3-6

Reference Case Alternative CAFE Standards
Nationwide Changes in Health Costs from Criteria Air Pollutant Emissions from Passenger Cars and Light Trucks (U.S. million dollars/year)
Cumulative Effects with MY 2011-2015 Standards and Potential MY 2016-2020 Standards a/

2025	0	-414	-426	-515	-552	-622	-2,228
2035	0	-680	-694	-871	-933	-1,034	-3,703

a/ Negative changes indicate economic benefit; positive emissions changes are economic costs.
b/ Changes for the No Action Alternative are shown as zero because the No Action Alternative is the baseline to which the emissions for the other alternatives are compared.

4.3.3.3 Alternative 2: 25 Percent Below Optimized

4.3.3.3.1 Criteria Pollutants

CAFE standards under the 25 Percent Below Optimized Alternative (Alternative 2) would require increased fuel economy compared to the No Action Alternative (Alternative 1). Alternative 2 would increase fuel economy less than would Alternatives 3 through 7. Under Alternative 2, cumulative emissions are generally less than Alternative 1, but greater than all other alternatives. However, Alternative 2 would have greater cumulative emissions of CO than the No Action Alternative.

Emissions in individual nonattainment areas might follow different patterns than nationwide emissions. Emissions of criteria pollutants vary due to interrelations among upstream emissions, VMT increases, and diesel share of fuel. Compared to Alternative 1, cumulative emissions of NO_x, SO_x, and VOCs under Alternative 2 decrease in all nonattainment areas. In contrast, CO emissions increase in almost all nonattainment areas, while PM emissions vary. Tables in Appendix B-2 list the emissions reductions for each nonattainment area.

Cumulative fuel economy standards would lead to lower emissions of most pollutants compared to non-cumulative standards, due to the impact of more stringent standards in the cumulative case. In

Alternative 2, cumulative emissions of all pollutants are lower than non-cumulative emissions. However, emissions of CO are higher under the cumulative case than the non-cumulative case.

4.3.3.3.2 Air Toxics

Under Alternative 2, cumulative emissions would generally be less than non-cumulative emissions for the same combinations of pollutant and year.

There would be reductions in cumulative nationwide emissions of all toxic air pollutants (except acrolein and acetaldehyde in 2035) under Alternative 2 compared to the No Action Alternative. Compared to Alternative 3, Alternative 2 would have higher emissions of DPM and formaldehyde but lower emissions of benzene. Compared to Alternatives 4 through 7, Alternative 2 would generally have higher emissions of benzene, 1,3-butadiene, and DPM, but lower emissions of acrolein and formaldehyde, and mixed results for acetaldehyde depending on the year and alternative.

At the nationwide level, the reduction in upstream emissions of toxic air pollutants tends to offset the increase in VMT and emissions due to the rebound effect. However, as noted above, the reductions in upstream emissions are not uniformly distributed to individual nonattainment areas. Net emission reductions can occur if the reduction in upstream emissions in the nonattainment area more than offsets the increase within the area due to the rebound effect. Under Alternative 2, many nonattainment areas would experience net increases in emissions of one or more toxic air pollutants in at least one of the analysis years (*see* Appendix B-2). However, the emission increases would be quite small, as shown in Appendix B-2, and emissions increases would be distributed throughout each nonattainment area.

4.3.3.3.3 Health Outcomes and Costs

Compared to Alternative 1 (No Action), the cumulative impact of Alternative 2 would result in 316 fewer mortalities and 56,293 fewer work-loss days in 2035. Cumulative health benefits would exceed non-cumulative benefits, reducing mortalities by an additional 238 cases and lost-work days by an additional 42,415 cases in 2035. In that same year, Alternative 2 would reduce health costs by $680 million, an additional $507 million over non-cumulative benefits.

4.3.3.4 Alternative 3: Optimized

4.3.3.4.1 Criteria Pollutants

CAFE standards under the Optimized Alternative (Alternative 3) would require increased fuel economy compared to Alternatives 1 and 2, but less than Alternatives 4 through 7. Under Alternative 3, cumulative emissions are generally less than Alternative 1, but greater than all other alternatives. However, Alternative 3 would have greater cumulative emissions of CO than any other alternative. Alternative 3 would also have slightly greater cumulative emissions of NO_x and VOCs than Alternative 2.

Emissions in individual nonattainment areas could follow different patterns than nationwide emissions. Emissions of criteria pollutants vary due to interrelations among upstream emissions, VMT increases, and diesel share of fuel. Compared to Alternative 1, cumulative emissions of NO_x, SO_x, and VOCs under Alternative 3 decrease in almost all nonattainment areas. In contrast, CO emissions increase in almost all nonattainment areas, while PM emissions vary. Tables in Appendix B-2 list the emissions reductions for each nonattainment area.

As with previously discussed alternatives, cumulative fuel economy standards would lead to lower emissions of most pollutants compared to non-cumulative standards. In Alternative 3, cumulative emissions of all pollutants are lower than non-cumulative emissions.

4.3.3.4.2 Air Toxics

Under Alternative 3, cumulative emissions would generally be less than non-cumulative emissions for the same combinations of pollutant and year.

Alternative 3 would reduce air toxics emissions compared to the No Action Alternative for all air toxics (except acetaldehyde in 2035, and acrolein). Alternative 3 would have higher emissions of benzene, 1,3-butadiene (2015 and 2020), and DPM compared to Alternatives 4 through 7. Alternative 3 would have lower emissions of acrolein and formaldehyde compared to Alternatives 4 through 7, and mixed results for acetaldehyde depending on the year and alternative.

Nationwide, emissions of toxic air pollutants can decrease because the reduction in upstream emissions more than offsets the increase in VMT and emissions due to the rebound effect. However, the reductions in upstream emissions are not uniformly distributed to individual nonattainment areas. Under Alternative 3, many nonattainment areas would experience net increases in emissions of one or more toxic air pollutants in at least one of the analysis years (*see* Appendix B-2). However, the emission increases would be quite small, as shown in Appendix B-2, and emission increases would be distributed throughout each nonattainment area.

4.3.3.4.3 Health Outcomes and Costs

Compared to Alternative 1 (No Action), the cumulative impact of Alternative 3 would result in 325 fewer mortalities and 57,939 fewer work-loss days in 2035. Cumulative health benefits would exceed non-cumulative benefits, reducing mortalities by an additional 242 cases and lost-work days by an additional 43,150 cases in 2035. In that same year, Alternative 3 would reduce health costs by $694 million, an additional $515 million over non-cumulative benefits.

4.3.3.5 Alternative 4: 25 Percent Above Optimized

4.3.3.5.1 Criteria Pollutants

CAFE standards under the 25 Percent Above Optimized Alternative (Alternative 4) would require increased fuel economy compared to Alternatives 1 through 3, but less than Alternatives 5 through 7. Under Alternative 4, cumulative emissions would be less than under Alternatives 1, 2, and 3, but greater than all other alternatives.

Emissions in individual nonattainment areas could follow different patterns than nationwide emissions. Emissions of criteria pollutants vary due to interrelations among upstream emissions, VMT increases, and diesel share of fuel. Compared to Alternative 1, cumulative emissions of CO, NO_x, SO_x, VOCs, and PM under Alternative 4 decrease in almost all nonattainment areas. However, PM emissions could increase or decrease depending on nonattainment area. Tables in Appendix B-2 list the emissions reductions for each nonattainment area.

As with previously discussed alternatives, cumulative fuel economy standards would lead to lower emissions of most pollutants compared to non-cumulative standards. In Alternative 4, cumulative emissions of all pollutants are lower than non-cumulative emissions.

4.3.3.5.2 Air Toxics

Under Alternative 4, cumulative emissions would generally be less than non-cumulative emissions for the same combinations of pollutant and year.

Alternative 4 would reduce air toxics emissions compared to the No Action Alternative for all air toxics except acetaldehyde, acrolein, and formaldehyde in 2015. Compared to Alternatives 5 through 7, Alternative 4 would have higher emissions of benzene, 1,3-butadiene (except in 2015), and DPM. Alternative 4 would have lower emissions of acrolein and formaldehyde compared to Alternatives 5 through 7, and mixed results for acetaldehyde depending on the year and alternative.

At the nationwide level, emissions of toxic air pollutants can decrease because the reduction in upstream emissions more than offsets the increase in VMT and emissions due to the rebound effect. However, the reductions in upstream emissions are not uniformly distributed to individual nonattainment areas. Under Alternative 4, many nonattainment areas would experience net increases in emissions of one or more toxic air pollutants in at least one of the analysis years (*see* Appendix B-2). However, the emission increases would be quite small, as shown in Appendix B-2, and emission increases would be distributed throughout each nonattainment area.

4.3.3.5.3 Health Outcomes and Costs

Compared to Alternative 1 (No Action), the cumulative impact of Alternative 4 would result in 388 fewer mortalities and 69,110 fewer work-loss days in 2035. Cumulative health benefits would exceed non-cumulative benefits, reducing mortalities by an additional 262 cases and lost-work days by an additional 46,654 cases in 2035. In that same year, Alternative 4 would reduce health costs by $871 million, an additional $564 million over non-cumulative benefits.

4.3.3.6 Alternative 5: 50 Percent Above Optimized

4.3.3.6.1 Criteria Pollutants

CAFE standards under the 50 Percent Above Optimized Alternative (Alternative 5) would require increased fuel economy compared to Alternatives 1 through 4, but less than Alternatives 6 and 7. Under Alternative 5, cumulative emissions would be less than Alternatives 1 through 4, but greater than all other alternatives.

Emissions in individual nonattainment areas could follow different patterns than nationwide emissions. Emissions of criteria pollutants vary due to interrelations among upstream emissions, VMT increases, and diesel share of fuel. Compared to Alternative 1, cumulative emissions of CO, NO_x, SO_x, and VOCs under Alternative 5 decrease in all nonattainment areas. PM emissions increase or decrease depending on nonattainment area. Tables in Appendix B-2 list the emissions reductions for each nonattainment area.

As with previously discussed alternatives, cumulative fuel economy standards would lead to lower emissions of most pollutants compared to non-cumulative standards. In Alternative 5, cumulative emissions of all pollutants are lower than non-cumulative emissions.

4.3.3.6.2 Air Toxics

Under Alternative 5, cumulative emissions would generally be less than non-cumulative emissions for the same combinations of pollutant and year, with the exception of acrolein, butadiene, and acetaldehyde in 2035.

Alternative 5 would reduce air toxics emissions of benzene, 1,3-butadiene, formaldehyde (except in 2015), and DPM compared to the No Action Alternative, but would increase emissions of acetaldehyde and acrolein compared to the No Action Alternative. Alternative 5 would have higher emissions of benzene, 1,3-butadiene (except for Alternative 7 in 2015), and DPM compared to Alternatives 6 and 7. Alternative 5 would have lower emissions of acrolein and formaldehyde compared to Alternatives 6 and 7, and mixed results for acetaldehyde depending on year and alternative.

At the nationwide level, emissions of toxic air pollutants can decrease because the reduction in upstream emissions more than offsets the increase in VMT and emissions due to the rebound effect. However, the reductions in upstream emissions are not uniformly distributed to individual nonattainment areas. Under Alternative 5, many nonattainment areas would experience net increases in emissions of one or more toxic air pollutants in at least one of the analysis years (*see* Appendix B-2). However, the emission increases would be quite small, as shown in Appendix B-2, and emission increases would be distributed throughout each nonattainment area.

4.3.3.6.3 Health Outcomes and Costs

Compared to Alternative 1 (No Action), the cumulative impact of Alternative 5 would result in 412 fewer mortalities and 73,443 fewer work-loss days in 2035. Cumulative health benefits would exceed non-cumulative benefits, reducing mortalities by an additional 270 cases and lost-work days by an additional 48,104 cases in 2035. In that same year, Alternative 5 would reduce health costs by $993 million, an additional $584 million over non-cumulative benefits.

4.3.3.7 Alternative 6: Total Costs Equal Total Benefits

4.3.3.7.1 Criteria Pollutants

CAFE standards under the Total Costs Equal Total Benefits Alternative (Alternative 6) would require increased fuel economy compared to Alternatives 1 through 5, but less than Alternative 7. Under Alternative 6, cumulative emissions would be less than Alternatives 1 through 5, but greater than Alternative 7.

Emissions in individual nonattainment areas could follow different patterns than nationwide emissions. Emissions of criteria pollutants vary due to interrelations among upstream emissions, VMT increases, and diesel share of fuel. Compared to Alternative 1, cumulative emissions of CO, NO_x, SO_x, and VOCs under Alternative 6 decrease in all nonattainment areas. PM emissions increase or decrease depending on nonattainment area. Tables in Appendix B-2 list the emissions reductions for each nonattainment area.

As with previously discussed alternatives, cumulative fuel economy standards would lead to lower emissions of most pollutants compared to non-cumulative standards. In Alternative 6, cumulative emissions of all pollutants are lower than non-cumulative emissions.

4.3.3.7.2 Air Toxics

Under Alternative 6, cumulative emissions would generally be less than non-cumulative emissions for the same combinations of pollutant and year, with the exception of acrolein, 1,3-butadiene, and acetaldehyde in 2035.

Alternative 6 would reduce air toxics emissions of acetaldehyde (in 2025-2035), benzene, 1,3-butadiene, and DPM compared to the No Action Alternative, but would increase emissions of acetaldehyde (in 2015), acrolein, and formaldehyde compared to the No Action Alternative. Alternative 6 would have higher emissions of acetaldehyde (in 2035), benzene, 1,3-butadiene (except in 2015), and DPM compared to Alternative 7. Alternative 6 would have lower emissions of acetaldehyde (in 2015-2025), acrolein, 1,3-butadiene (in 2015), and formaldehyde compared to Alternative 7.

At the nationwide level, emissions of toxic air pollutants can decrease because the reduction in upstream emissions more than offsets the increase in VMT and emissions due to the rebound effect. However, the reductions in upstream emissions are not uniformly distributed to individual nonattainment areas. Under Alternative 6, many nonattainment areas would experience net increases in emissions of one or more toxic air pollutants in at least one of the analysis years (*see* Appendix B-2). However, the emission increases would be quite small, as shown in Appendix B-2, and emission increases would be distributed throughout each nonattainment area.

4.3.3.7.3 Health Outcomes and Costs

Compared to Alternative 1 (No Action), the cumulative impact of Alternative 6 would result in 414 fewer mortalities and 73,833 fewer work-loss days in 2035. Cumulative health benefits would exceed non-cumulative benefits, reducing mortalities by an additional 272 cases and lost-work days by an additional 48,600 cases in 2035. In that same year, Alternative 6 would reduce health costs by $1.034 billion, an additional $599 million over non-cumulative benefits.

4.3.3.8 Alternative 7: Technology Exhaustion

4.3.3.8.1 Criteria Pollutants

Of all the alternatives analyzed, the Technology Exhaustion Alternative (Alternative 7) would increase fuel economy the most. In this alternative, the cumulative fuel economy standard has more impact than in any other alternative. Cumulative standards would lead to greater reductions in emissions of all criteria pollutants. The greatest impact would be on SO_x emissions, which in 2035 would be reduced by an additional 12.4 percent to a 25.8 percent reduction in cumulative emissions below No Action Alternative levels, compared to a 13.4 percent reduction in non-cumulative emissions below No Action Alternative levels. Also in 2035, NO_x, PM, and VOC emissions would be reduced by an additional 4.9 percent, 4.3 percent, and 5.6 percent, respectively, in cumulative emissions compared to the non-cumulative emissions reductions. Alternative 7 is the only alternative in which CO emissions would decrease under cumulative standards, by an additional 3.7 percent.

Emissions in individual nonattainment areas might follow different patterns than nationwide emissions. Emissions of criteria pollutants vary due to interrelations among upstream emissions, VMT increases, and diesel share of fuel. Compared to Alternative 1, cumulative emissions of CO, NO_x, SO_x, and VOCs under Alternative 6 decrease in all nonattainment areas. PM emissions increase or decrease depending on nonattainment area. Tables in Appendix B-2 list the emissions reductions for each nonattainment area.

As with previously discussed alternatives, cumulative fuel economy standards would lead to lower emissions of most pollutants compared to non-cumulative standards. Unlike the prior alternatives, most (but not all) cumulative emissions in Alternative 7 are less than non-cumulative emissions. The exceptions are CO and VOCs, which are slightly higher for the cumulative standards in 2035.

4.3.3.8.2 Air Toxics

Under Alternative 7, cumulative emissions would generally be greater than non-cumulative emissions for the same combinations of pollutant and year, with the exception of benzene in 2020 and 2025 and DPM in all analysis years.

Alternative 7 would reduce air toxics emissions of acetaldehyde (in 2035 only), benzene, 1,3-butadiene (2020-2035), and DPM compared to the No Action Alternative, but would increase emissions of acetaldehyde (in 2015-2025), acrolein, and formaldehyde compared to the No Action Alternative.

At the nationwide level, emissions of toxic air pollutants can decrease because the reduction in upstream emissions more than offsets the increase in VMT and emissions due to the rebound effect. However, the reductions in upstream emissions are not uniformly distributed to individual nonattainment areas. Under Alternative 7, many nonattainment areas would experience net increases in emissions of one or more toxic air pollutants in at least one of the analysis years (see Appendix B-2). However, the emission increases would be quite small, as shown in Appendix B-2, and emission increases would be distributed throughout each nonattainment area.

4.3.3.8.3 Health Outcomes and Costs

Compared to Alternative 1 (No Action), the cumulative impact of Alternative 7 would result in 760 fewer mortalities and 135,560 fewer work-loss days in 2035. Cumulative health benefits would exceed non-cumulative benefits, reducing mortalities by an additional 100 cases and lost-work days by an additional 17,943 cases in 2035. In that same year, Alternative 7 would reduce health costs by $3.703 billion, an additional $374 million over non-cumulative benefits.

4.3.4 Input Scenarios

4.3.4.1 Results of the Emissions Analysis

The High Scenario analysis in this section shows that the alternatives would lead to further reductions in cumulative emissions from passenger cars and light trucks. The amount of the reductions would vary by alternative. The more restrictive High Scenario alternatives would result in greater cumulative emission reductions compared to the No Action Alternative.

4.3.4.2 Alternative 1: No Action

4.3.4.2.1 Criteria Pollutants

For the High Scenario analysis of the No Action Alternative, the CAFE standards would remain at the MY 2010 level in future years. Current trends in the levels of emissions from vehicles would continue, with emissions continuing to decline due to the EPA emission standards despite a growth in total VMT. Therefore, there would be no cumulative impacts due to future actions.

Table 4.3-7 summarizes the cumulative national criteria pollutant emissions from passenger cars and light trucks for the High Scenario No Action Alternative for each of the criteria pollutants and analysis years. The table presents the other High Scenario alternatives (Alternatives 2 through 7) left to right in order of increasing fuel economy requirements. The No Action Alternative has the highest cumulative emissions of all the High Scenario alternatives for all criteria pollutants. Also, the High Scenario cumulative emissions are lower than the Reference Case cumulative emissions for all criteria pollutants.

Table 4.3-7

Table 4.3-8 lists the net change in nationwide cumulative emissions from passenger cars and light trucks for each alternative and analysis year for the High Scenario. The table presents Alternatives 1 through 7 left to right in order of increasing fuel economy requirements. In Table 4.3-8, the nationwide cumulative emissions reductions tend to increase from left to right, reflecting the increasing fuel economy requirements that are assumed for the High Scenario.

a/ Negative emissions changes indicate reductions; positive emissions changes are increases.
b/ Emissions changes for the No Action Alternative are shown as zero because the No Action Alternative is the baseline to which the emissions for the other alternatives are compared.

4.3.4.2.2 Air Toxics

With the No Action Alternative, the CAFE standards would remain at the MY 2010 level in future years. As with the criteria pollutants, the High Scenario analysis indicates that current trends in the levels of air toxics emissions from vehicles would continue, with emissions continuing to decline due to the EPA emission standards despite a growth in total VMT. Exceptions to this trend are emissions of benzene and formaldehyde, which increase in 2035 over 2025 levels with the No Action Alternative. Further, with current trends, emissions of diesel particulate matter (DPM) increase in every analysis year with the No Action Alternative. The High Scenario analysis of Alternative 1 (No Action) would result in no other increase or decrease in cumulative toxic air pollutant emissions in nonattainment and maintenance areas throughout the United States.

Table 4.3-9 summarizes the High Scenario total national cumulative emissions of air toxics from passenger cars and light trucks with the No Action Alternative for each pollutant and analysis year.

Unlike with the criteria pollutants, the No Action Alternative does not have the highest cumulative emissions of all the alternatives for all toxic air pollutants. Table 4.3-9 shows increases for acrolein with Alternatives 2 through 7 because data on upstream emissions reductions were not available. The cumulative emissions for acrolein in Table 4.3-9 reflect only the increases due to the rebound effect and technology changes that manufacturers would introduce in response to CAFE standards. Because the upstream emissions reductions result from the decline in the amount of fuel processed, it is reasonable that upstream acrolein emissions should decrease as the upstream emissions for other pollutants do. Thus, the cumulative acrolein emissions given in Table 4.3.9 are an upper bound estimate.

Table 4.3-9

2035	107,203	87,624	85,380	85,166	83,729	83,295	84,904
Formaldehyde							
2015	16,197	16,228	16,236	16,264	16,282	16,345	16,789
2020	12,928	12,999	12,980	13,047	13,146	13,291	14,660
2025	11,716	11,792	11,753	11,866	12,031	12,252	14,332
2035	11,694	11,783	11,730	11,897	12,127	12,433	15,281

a/ Data on upstream emissions reductions were not available for acrolein. Thus, the emissions for acrolein reflect only the change in tailpipe emissions.

High Scenario cumulative emissions of formaldehyde are lowest under the No Action Alternative. In contrast, cumulative emissions of benzene, DPM, and 1,3-butadiene are highest in the No Action Alternative, and are generally higher for the less restrictive alternatives than the more restrictive alternatives. An exception is 1,3-butadiene in 2015 under Alternative 7. Cumulative emissions of acetaldehyde are highest for Alternative 7 except in 2035.

Table 4.3-10 lists the net change in High Scenario cumulative nationwide emissions from passenger cars and light trucks in relation to the No Action Alternative for each air toxic pollutant and analysis year. The High Scenario results for Alternatives 2 through 7 are presented from left to right in order of increasing fuel economy requirements. In Table 4.3-10, the nationwide emissions reductions or increases tend to become greater from left to right, reflecting the increasing fuel economy requirements that are assumed under successive alternatives, except for the cases noted above.

2035	0	89	36	203	433	739	3,587

a/ Negative emissions changes indicate reductions; positive emissions changes are increases.
b/ Emissions changes for the No Action Alternative are shown as zero because the No Action Alternative is the baseline to which the emissions for the other alternatives are compared.
c/ Data on upstream emissions reductions were not available for acrolein. Thus, the emissions for acrolein reflect only the change in tailpipe emissions.

4.3.4.2.3 Health Outcomes and Costs

With the No Action Alternative (Alternative 1), the CAFE standards would remain at the MY 2010 level in future years. Current trends in the levels of criteria pollutants and air toxics emissions from vehicles would continue, with emissions continuing to decline due to the EPA emission standards despite an increase in total VMT. The human health effects and health-related costs that occur under current trends would continue, and are expected to decline in the future as a result of declines in pollutant emissions. The No Action Alternative under the High Scenario would result in no other increase or decrease in human health effects and health-related costs.

Table 4.3-11 list the net changes in health outcomes due to High Scenario analysis of cumulative emissions in each analysis year. Alternatives 1 through 7 are presented from left to right in order of increasing fuel economy requirements. The health impacts of vehicle emissions decrease for nearly all alternatives compared to the No Action Alternative and decrease successively in each analysis year.

Table 4.3-11

High Scenario Alternative CAFE Standards
Nationwide Changes in Health Outcomes from Criteria Air Pollutant Emissions from Passenger Cars and Light Trucks (cases/year)
Cumulative Effects with MY 2011-2015 Standards and Potential MY 2016-2020 Standards a/

Health Outcome and Year	Alt. 1 No Action b/	Alt. 2 25% Below Optimized	Alt. 3 Optimized	Alt. 4 25% Above Optimized	Alt. 5 50% Above Optimized	Alt. 6 Total Costs Equal Total Benefits	Alt. 7 Technology Exhaustion

2020	0	-32	-37	-36	-42	-46	-63
2025	0	-63	-70	-69	-78	-84	-98
2035	0	-103	-112	-110	-125	-131	-142
Work-loss days							
2015	0	-5,582	-7,277	-7,686	-8,790	-11,191	-18,070
2020	0	-27,684	-31,458	-31,134	-35,698	-39,466	-53,440
2025	0	-54,173	-59,978	-58,915	-66,935	-71,529	-83,728
2035	0	-87,883	-96,001	-94,366	-106,665	-112,073	-121,611

a/ Negative changes indicate reductions; positive emissions changes are increases.
b/ Changes in health outcome for the No Action Alternative are shown as zero because the No Action Alternative is the baseline to which the emissions for the other alternatives are compared.

The economic value of health impacts would vary proportionately with changes in health outcomes under the methodology defined in Section 3.3.2.4.2. The economic impacts analyzed here are the result of changes in ambient particulate matter (PM) and ozone concentrations as caused by changes in precursor criteria pollutants NO_x, VOCs, SO_2, and $PM_{2.5}$. Alternative 1 (No Action) would result in no other change in health-related costs throughout the United States, as compared to current trends.

Table 4.3-12 lists the nationwide changes in health costs in the High Scenario analysis of cumulative emissions from passenger cars and light trucks. Results for each analysis year are shown for the No Action Alternative in the left column, and for other alternatives from left to right in order of increasing fuel economy requirements. As with health outcomes, the economic impacts of each alternative decrease across nearly all successive alternatives and all successive years, compared to the health costs of emissions with the No Action Alternative.

Table 4.3-12

High Scenario Alternative CAFE Standards
Nationwide Changes in Health Costs from Criteria Air Pollutant Emissions from Passenger Cars and Light Trucks (U.S. million dollars/year)
Cumulative Effects with MY 2011-2015 Standards and Potential MY 2016-2020 Standards a/

	Alt. 1	Alt. 2	Alt. 3	Alt. 4	Alt. 5	Alt. 6	Alt. 7
Year	No Action b/	25% Below Optimized	Optimized	25% Above Optimized	50% Above Optimized	Total Costs Equal Total Benefits	Technology Exhaustion
2015	0	-50	-64	-84	-96	-112	-223
2020	0	-374	-420	-505	-559	-621	-1,079
2025	0	-763	-829	-988	-1,097	-1,209	-2,019
2035	0	-1,273	-1,351	-1,610	-1,809	-2,010	-3,322

a/ Negative changes indicate economic benefit; positive emissions changes are economic costs.
b/ Changes for the No Action Alternative are shown as zero because the No Action Alternative is the baseline to which the emissions for the other alternatives are compared.

4.3.4.3 Alternative 2: 25 Percent Below Optimized

4.3.4.3.1 Criteria Pollutants

With the High Scenario analysis for the 25 Percent Below Optimized Alternative (Alternative 2), the CAFE standards would require increased fuel economy compared to the No Action Alternative. The 25 Percent Below Optimized Alternative would increase fuel economy less than would Alternatives 3 through 7. Cumulative nationwide emissions of all criteria pollutants would be reduced compared to the Reference Case; the magnitude of the reductions increase with analysis year. Reductions in cumulative emissions under Alternative 2 are less than reductions under successive alternatives, except for CO and $PM_{2.5}$ for which the reductions are slightly less for Alternative 3.

Cumulative emissions in individual nonattainment areas could follow different patterns than nationwide emissions. Emissions of criteria pollutants decrease in part because the reduction in upstream emissions, among other effects related to technology changes introduced by manufacturers in response to CAFE standards, more than offsets the increase in VMT and emissions due to the rebound effect in every nonattainment area. While cumulative emissions of CO, NO_x, SO_x, and VOCs decrease in each nonattainment area for all years, emissions of $PM_{2.5}$ are projected to increase in some nonattainment areas. Appendix B-2 contains tables that list the emission reductions for each nonattainment area.

In Alternative 2, the reduction in cumulative emissions under the High Scenario is greater than that under the Reference Case, for each criteria pollutant and year.

4.3.4.3.2 Air Toxics

With the High Scenario analysis of the 25 Percent Below Optimized Alternative (Alternative 2), cumulative nationwide air toxics emissions would increase for some pollutants and decrease for others, as compared to the No Action Alternative. Benzene, 1,3-butadiene, and DPM cumulative emissions would decline, with reductions increasing with analysis year. Compared to the No Action Alternative, cumulative emissions would increase for acetaldehyde (except in 2035), acrolein, and formaldehyde.

High Scenario Alternative 2 would have generally higher cumulative emissions of benzene, 1,3-butadiene, and DPM compared to Alternatives 3 through 7. High Scenario Alternative 2 would have generally lower cumulative emissions of acrolein and formaldehyde compared to Alternatives 3 through 7. Results for acetaldehyde would be mixed depending on alternative and year. Cumulative emissions with High Scenario Alternative 2 would be less than with Reference Case Alternative 2 except for acrolein in 2035 and 1,3-butadiene in 2015 and 2020.

Under High Scenario Alternative 2, many nonattainment areas would experience net increases, and some would experience net decreases, in cumulative emissions of one or more toxic air pollutants in at least one analysis year (Appendix B-2). The cumulative emission increases are quite small, as shown in Appendix B-2. Air quality impacts from these increases would not be notable because the VMT and emission increases would be distributed throughout each nonattainment area.

4.3.4.3.3 Health Outcomes and Costs

The High Scenario analysis shows a decrease in cumulative adverse health effects nationwide for the Alternative 2 compared to Alternative 1 (No Action). These reductions primarily reflect the projected $PM_{2.5}$ reductions, as $PM_{2.5}$ tends to be the largest contributor to adverse health effects. Compared to Alternative 1 (No Action), the cumulative impact of Alternative 2 would result in 493 fewer mortalities and 87,883 fewer work-loss days in 2035. Cumulative health benefits are greater under the High Scenario than under the Reference Case, reducing mortalities by an additional 177 cases and lost-work days by an additional 31,590 cases in 2035. In that same year, Alternative 2 would reduce health costs by $1.273 billion, an additional $593 million compared to Reference Case benefits.

4.3.4.4 Alternative 3: Optimized

4.3.4.4.1 Criteria Pollutants

With the High Scenario analysis of Optimized Alternative (Alternative 3), the CAFE standards would require increased fuel economy compared to Alternatives 1 and 2, but less than Alternative 4 through 7. Reductions in cumulative nationwide emissions are similar to reductions under Alternative 2. Cumulative emissions reductions of CO and $PM_{2.5}$ are slightly less than under Alternative 2. In other cases, the cumulative emissions reductions are greater than under Alternative 2.

Cumulative emissions in individual nonattainment areas could follow different patterns than nationwide emissions. Emissions of criteria pollutants decrease in part because the reduction in upstream emissions, among other effects related to technology changes introduced by manufacturers in response to CAFE standards, more than offsets the increase in VMT and emissions due to the rebound effect in every nonattainment area. While cumulative emissions of CO, NO_x, SO_x, and VOCs decrease in each nonattainment area for all years, emissions of $PM_{2.5}$ are projected to increase in some nonattainment areas. Appendix B-2 contains tables that list the emission reductions for each nonattainment area.

In Alternative 3, the reduction in cumulative emissions under the High Scenario is greater than that under the Reference Case, for each criteria pollutant and year.

4.3.4.4.2 Air Toxics

Under High Scenario Alternative 3, nationwide cumulative emissions of benzene, 1,3-butadiene, and DPM would be lower compared to the High Scenario No Action Alternative. Nationwide cumulative emissions would be higher for acetaldehyde, acrolein, and formaldehyde compared to the High Scenario No Action Alternative.

High Scenario Alternative 3 would have generally higher emissions than would High Scenario Alternatives 4 through 7 for benzene, butadiene, and DPM. High Scenario Alternative 3 would have generally lower emissions than would High Scenario Alternatives 4-7 for acrolein and formaldehyde, and mixed results for acetaldehyde depending on alternative and year. Cumulative emissions under the High Scenario are lower than those under the Reference Case for Alternative 3 (except for acrolein in 2035).

Under High Scenario Alternative 3, many nonattainment areas would experience net increases, and some would experience net decreases, in cumulative emissions of one or more toxic air pollutants in at least one analysis year (Appendix B-2). The cumulative emission increases are quite small, as shown in Appendix B-2. Air quality impacts from these increases would not be notable because the VMT and emission increases would be distributed throughout each nonattainment area.

4.3.4.4.3 Health Outcomes and Costs

The High Scenario analysis shows a decrease in cumulative adverse health effects nationwide for Alternative 3 compared to Alternative 1 (No Action). These reductions primarily reflect the projected $PM_{2.5}$ reductions, because $PM_{2.5}$ tends to be the largest contributor to adverse health effects. Compared to Alternative 1 (No Action), the cumulative impact of Alternative 3 would result in 539 fewer mortalities and 96,001 fewer work-loss days in 2035. Cumulative health benefits are greater under the High Scenario than under the Reference Case, reducing mortalities by an additional 214 cases and lost-work days by an additional 38,062 cases in 2035. In that same year, Alternative 3 would reduce health costs by $1.351 billion, an additional $657 million compared to Reference Case benefits.

4.3.4.5 Alternative 4: 25 Percent Above Optimized

4.3.4.5.1 Criteria Pollutants

For the High Scenario analysis of the 25 Percent Above Optimized Alternative (Alternative 4), the CAFE standards would require increased fuel economy compared to Alternatives 1 through 3, but less than Alternatives 5 through 7. Cumulative nationwide emissions of all criteria pollutants for Alternative 4 would be reduced compared to Alternative 3. Compared to the No Action Alternative, the reductions increase for all analysis years.

Cumulative emissions in individual nonattainment areas could follow different patterns than nationwide emissions. Emissions of criteria pollutants decrease in part because the reduction in upstream emissions, among other effects related to technology changes introduced by manufacturers in response to CAFE standards, more than offsets the increase in VMT and emissions due to the rebound effect in every nonattainment area. While cumulative emissions of CO, NO_x, SO_x, and VOCs decrease in each nonattainment area for all years, emissions of $PM_{2.5}$ are projected to increase in some nonattainment areas Appendix B-2 contains tables that list the emission reductions for each nonattainment area.

In Alternative 4, the reduction in cumulative emissions under the High Scenario is greater than that under the Reference Case, for each criteria pollutant and year.

4.3.4.5.2 Air Toxics

Under High Scenario Alternative 4, nationwide cumulative emissions of acetaldehyde (except in 2015), benzene, 1,3-butadiene, and DPM would be lower compared to the High Scenario No Action Alternative. Nationwide cumulative emissions would be higher for acetaldehyde (in 2015), acrolein, and formaldehyde compared to the High Scenario No Action Alternative.

High Scenario Alternative 4 would have generally higher emissions than would High Scenario Alternatives 5 through 7 for acetaldehyde (in 2035), benzene, 1,3-butadiene, and DPM. High Scenario Alternative 3 would have generally lower emissions than would High Scenario Alternatives 5 through 7 for acetaldehyde (except in 2035), acrolein, and formaldehyde. Cumulative emissions under the High Scenario are lower than those under the Reference Case for Alternative 4 (except for acrolein in 2025 and 2035 and 1,3-butadiene in 2015).

Under High Scenario Alternative 4, many nonattainment areas would experience net increases, and some would experience net decreases, in cumulative emissions of one or more toxic air pollutants in at least one analysis year (Appendix B-2). The cumulative emission increases are quite small, as shown in Appendix B-2. Air quality impacts from these increases would not be notable because the VMT and emission increases would be distributed throughout each nonattainment area.

4.3.4.5.3 Health Outcomes and Costs

The High Scenario analysis shows a decrease in cumulative adverse health effects nationwide for Alternative 4 compared to Alternative 1 (No Action). These reductions primarily reflect the projected $PM_{2.5}$ reductions, because $PM_{2.5}$ tends to be the largest contributor to adverse health effects. Compared to Alternative 1 (No Action), the cumulative impact of Alternative 4 would result in 529 fewer mortalities and 94,366 fewer work-loss days in 2035. Cumulative health benefits are greater under the High Scenario than under the Reference Case, reducing mortalities by an additional 141 cases and lost-work days by an additional 25,256 cases in 2035. In that same year, Alternative 4 would reduce health costs by $1.610 billion, an additional $739 million compared to Reference Case benefits.

4.3.4.6 Alternative 5: 50 Percent Above Optimized

4.3.4.6.1 Criteria Pollutants

For the High Scenario analysis of the 50 Percent Above Optimized Alternative (Alternative 5), the CAFE standards would require increased fuel economy compared to Alternatives 1 through 4, but less than Alternatives 6 and 7. Cumulative nationwide emissions of all criteria pollutants for Alternative 5 would be reduced compared to Alternative 4. Compared to the No Action Alternative, the percent reductions increase for all analysis years.

Cumulative emissions in individual nonattainment areas could follow different patterns than nationwide emissions. Emissions of criteria pollutants decrease in part because the reduction in upstream emissions, among other effects related to technology changes introduced by manufacturers in response to CAFE standards, more than offsets the increase in VMT and emissions due to the rebound effect in every nonattainment area. While cumulative emissions of CO, NO_x, SO_x, and VOCs decrease in each nonattainment area for all years, emissions of $PM_{2.5}$ are projected to increase in some nonattainment areas. Appendix B-2 contains tables that list the emission reductions for each nonattainment area.

In Alternative 5, the reduction in cumulative emissions under the High Scenario is greater than that under the Reference Case, for each criteria pollutant and year.

4.3.4.6.2 Air Toxics

Under High Scenario Alternative 5, nationwide cumulative emissions of acetaldehyde (in 2025 and 2035), benzene, 1,3-butadiene, and DPM would be lower compared to the High Scenario No Action Alternative. Nationwide cumulative emissions would be higher for acetaldehyde (in 2015 and 2020), acrolein, and formaldehyde compared to the High Scenario No Action Alternative.

High Scenario Alternative 5 would have higher emissions than would High Scenario Alternatives 6 and 7 for acetaldehyde (in 2035), benzene, 1,3-butadiene (except Alternative 7 in 2015), and DPM (except Alternative 7 in 2035). High Scenario Alternative 5 would have lower emissions than would High Scenario Alternatives 6 and 7 for acetaldehyde (except in 2035), acrolein, 1,3-butadiene (Alternative 7 in 2015 only), and DPM (Alternative 7 in 2035 only), and formaldehyde. Cumulative emissions under the High Scenario are lower than cumulative emissions under the Reference Case for Alternative 5 (except for acrolein in 2025 and 2035, and 1,3-butadiene in 2015).

Under High Scenario Alternative 5, many nonattainment areas would experience net increases, and some would experience net decreases, in cumulative emissions of one or more toxic air pollutants in at least one analysis year (Appendix B-2). The cumulative emission increases are quite small, as shown in Appendix B-2. Air quality impacts from these increases would not be notable because the VMT and emission increases would be distributed throughout each nonattainment area.

4.3.4.6.3 Health Outcomes and Costs

The High Scenario analysis shows a decrease in cumulative adverse health effects nationwide for the Alternative 5 compared to Alternative 1 (No Action). These reductions primarily reflect the projected $PM_{2.5}$ reductions, because $PM_{2.5}$ tends to be the largest contributor to adverse health effects. Compared to Alternative 1 (No Action), the cumulative impact of Alternative 5 would result in 598 fewer mortalities and 106,665 fewer work-loss days in 2035. Cumulative health benefits are greater under the High Scenario than under the Reference Case, reducing mortalities by an additional 315 cases and lost-work days by an additional 56,220 cases in 2035. In that same year, Alternative 5 would reduce health costs by $1.809 billion, an additional $782 million compared to Reference Case benefits.

4.3.4.7 Alternative 6: Total Costs Equal Total Benefits

4.3.4.7.1 Criteria Pollutants

For the High Scenario analysis of the Total Costs Equal Total Benefits Alternative (Alternative 6), the CAFE standards would require increased fuel economy compared to Alternatives 1 through 5, but less than Alternative 7. Cumulative nationwide emissions of all criteria pollutants for Alternative 6 would be reduced compared to Alternative 5. Compared to the No Action Alternative, the percent reductions increase for all analysis years.

Cumulative emissions in individual nonattainment areas might follow different patterns than nationwide emissions. Emissions of criteria pollutants decrease in part because the reduction in upstream emissions, among other effects related to technology changes introduced by manufacturers in response to CAFE standards, more than offsets the increase in VMT and emissions due to the rebound effect in every nonattainment area. While cumulative emissions of CO, NO_x, SO_x, and VOCs decrease in each nonattainment area for all years, emissions of $PM_{2.5}$ are projected to increase in some nonattainment areas. Appendix B-2 contains tables that list the emission reductions for each nonattainment area.

In Alternative 6, the reduction in cumulative emissions under the High Scenario is greater than that under the Reference Case, for each criteria pollutant and year.

4.3.4.7.2 Air Toxics

Under High Scenario Alternative 6, nationwide cumulative emissions of acetaldehyde (in 2025 and 2035), benzene, 1,3-butadiene, and DPM would be lower compared to the High Scenario No Action Alternative. Nationwide cumulative emissions with High Scenario Alternative 6 would be higher for acetaldehyde (in 2015 and 2020), acrolein, and formaldehyde compared to the High Scenario No Action Alternative.

High Scenario Alternative 6 would have higher emissions than would High Scenario Alternative 7 for acetaldehyde (in 2035), benzene, 1,3-butadiene (except in 2015), and DPM (except in 2025 and 2035). High Scenario Alternative 6 would have lower emissions than would High Scenario Alternative 7 for acetaldehyde (except in 2035), acrolein, 1,3-butadiene (in 2015 only), and DPM (in 2025 and 2035), and formaldehyde. Cumulative emissions under the High Scenario are lower than cumulative emissions under the Reference Case for Alternative 6 (except for acrolein in 2020-2035 and 1,3-butadiene in 2015).

Under High Scenario Alternative 6, many nonattainment areas would experience net increases, and some would experience net decreases, in cumulative emissions of one or more toxic air pollutants in at least one analysis year (Appendix B-2). The cumulative emission increases are quite small, as shown in Appendix B-2. Air quality impacts from these increases would not be notable because the VMT and emission increases would be distributed throughout each nonattainment area.

4.3.4.7.3 Health Outcomes and Costs

The High Scenario analysis shows a decrease in cumulative adverse health effects nationwide for Alternative 6 compared to Alternative 1 (No Action). These reductions primarily reflect the projected $PM_{2.5}$ reductions, because $PM_{2.5}$ tends to be the largest contributor to adverse health effects. Compared to Alternative 1 (No Action), the cumulative impact of Alternative 6 would result in 629 fewer mortalities and 112,073 fewer work-loss days in 2035. Cumulative health benefits are greater under the High Scenario than under the Reference Case, reducing mortalities by an additional 215 cases and lost-work days by an additional 38,340 cases in 2035. In that same year, Alternative 6 would reduce health costs by $2.010 billion, an additional $976 million compared to Reference Case benefits.

4.3.4.8 Alternative 7: Technology Exhaustion

4.3.4.8.1 Criteria Pollutants

For the High Scenario analysis of the Technology Exhaustion Alternative (Alternative 7), the CAFE standards would require higher fuel economy than for all other alternatives. Cumulative nationwide emissions of all criteria pollutants for Alternative 7 would be reduced compared to Alternative 6. Compared to the No Action Alternative, the percent reductions increase for all analysis years. Cumulative emissions reductions would be greater in Alternative 7 than in any other alternative.

Cumulative emissions in individual nonattainment areas could follow different patterns than nationwide emissions. Emissions of criteria pollutants decrease in part because the reduction in upstream emissions, among other effects related to technology changes introduced by manufacturers in response to CAFE standards, more than offsets the increase in VMT and emissions due to the rebound effect in every nonattainment area. While cumulative emissions of CO, NO_x, SO_x, and VOCs decrease in each nonattainment area for all years, emissions of $PM_{2.5}$ are projected to increase in some nonattainment areas. Appendix B-2 contains tables that list the emission reductions for each nonattainment area.

In Alternative 7, the reduction in cumulative emissions under the High Scenario is greater than or equal to that under the Reference Case, for each criteria pollutant and year.

4.3.4.8.2 Air Toxics

Under High Scenario Alternative 7, nationwide cumulative emissions of benzene, 1,3-butadiene (except in 2015), and DPM would be lower compared to the High Scenario No Action Alternative. Nationwide cumulative emissions with High Scenario Alternative 7 would be higher for acetaldehyde (except in 2035), acrolein, and formaldehyde compared to the High Scenario No Action Alternative.

All cumulative air toxics emissions under the High Scenario are lower than or equivalent to cumulative emissions under the Reference Case for Alternative 7.

Under High Scenario Alternative 7, some nonattainment areas would experience net increases, and some would experience net decreases, in emissions of one or more toxic air pollutants in at least one analysis year (Appendix B-2). The emission increases are quite small, as shown in Appendix B-2. Potential air quality impacts from these increases would not be notable because the VMT and emission increases would be distributed throughout each nonattainment area.

4.3.4.8.3 Health Outcomes and Costs

The High Scenario analysis shows a decrease in cumulative adverse health effects nationwide for Alternative 7 compared to Alternative 1 (No Action). These reductions primarily reflect the projected $PM_{2.5}$ reductions, because $PM_{2.5}$ tends to be the largest contributor to adverse health effects. Compared to Alternative 1 (No Action), the cumulative impact of Alternative 7 would result in 682 fewer mortalities and 121,611 fewer work-loss days in 2035. In that same year, Alternative 7 would reduce health costs by $3.320 billion.

Unlike other Alternatives, cumulative health benefits are less under the High Scenario than under the Reference Case, increasing mortalities by 78 cases and lost-work days by 13,949 cases in 2035. Similarly, health costs would be $381 million greater under the High Scenario than under the Reference Case.

4.3.4.9 Mid-1 and Mid-2 Scenarios

Compared to the Reference Case, total cumulative emissions of criteria pollutants under the Mid-1 Scenario were lower for all alternatives. For toxic air pollutants, compared to the Reference Case, total cumulative emissions under the Mid-1 Scenario were lower except for emissions of acrolein and 1,3-butadiene for some alternatives and years. The cumulative emissions differences between the Reference Case and the Mid-1 Scenario reflect the differences in the forecasted levels of fuel economy, VMT, and diesel vehicle share of the vehicle fleet.

Compared to the Reference Case, total cumulative emissions of criteria pollutants under the Mid-2 Scenario were lower for all alternatives. For toxic air pollutants, compared to the Reference Case, total cumulative emissions under the Mid-2 Scenario were lower except for emissions of acrolein with Alternative 6 in 2035. The cumulative emissions differences between the Reference Case and the Mid-2 Scenario reflect the differences in the forecasted levels of fuel economy, VMT, and diesel vehicle share of the vehicle fleet.

Cumulative emissions of criteria pollutants would be generally higher with the Mid-2 Scenario than with the Mid-1 Scenario for Alternatives 2 through 6, and equivalent for Alternative 7. Cumulative emissions of toxic air pollutants would be generally higher with the Mid-2 Scenario than with the Mid-1 Scenario for benzene, 1,3-butadiene, and DPM for Alternatives 2 through 6. Cumulative emissions of toxic air pollutants would be generally lower with the Mid-2 Scenario than with the Mid-1 Scenario for acetaldehyde, acrolein, and formaldehyde. Cumulative emissions of toxic air pollutants with the Mid-1 and Mid-2 Scenarios would be equivalent for Alternative 7.

Appendix B presents the full results from analysis of the Mid-1 and Mid-2 Scenarios.

4.4 CLIMATE

Although the proposed rule covers model years only up to 2015, the Energy Policy and Conservation Act (EPCA) has directed the Secretary, after consultation with the Secretary of the U.S. Department of Energy (DOE) and the Administrator of EPA, to establish separate average fuel economy standards for passenger cars and for light trucks manufactured in each model year beginning with model 2011 "to achieve a combined fuel economy average for model year 2020 of at least 35 mpg for the total fleet of passenger and non-passenger automobiles manufactured for sale in the United States for that model year" (49 United States Code [U.S.C.] § 32902(b)(2)(A)).

In April 2008, NHTSA issued a supplemental notice of public scoping providing additional guidance for participating in the scoping process and additional information about the standards and the alternatives NHTSA expected to consider in its NEPA analysis. In that notice, NHTSA stated that it would consider the cumulative impacts of the standards for MY 2011-2015 automobiles together with estimated impacts of NHTSA's historic implementation of the CAFE Program through MY 2010 and NHTSA's future CAFE rulemaking for MY 2016-2020, as prescribed by EPCA, as amended by EISA.

Again, a cumulative impact is defined as "the impact on the environment which results from the incremental impact of the action when added to other past, present, and reasonably foreseeable future actions regardless of what agency … or person undertakes such other actions. Cumulative impacts can result from individually minor but collectively significant actions taking place over a period of time" (40 CFR § 1508.70).

This section on the cumulative impacts of the CAFE alternatives on climate covers many of the same topics as Section 3.4. However, Chapter 4 is broader than Chapter 3 because it compares foreseeable effects of both the MY 2011-2015 and future MY 2016-2020 CAFE standards to the MY 2020 levels affecting all passenger cars and light trucks built from 2020 through 2100 (Chapter 3 covers only the effects of the MY 2011-2015 standards).[1] Chapter 4 also addresses the consequences of emissions and effects on the climate system (both Section 4.4 and Section 3.4 address these topics), and the impacts of climate change on key resources (*e.g.*, freshwater resources, terrestrial ecosystems, and coastal ecosystems).

Understanding that many users of EIS documents do not read through in linear fashion, but instead focus on the sections of most interest, this section repeats some of the information in Section 3.4 with only minor modifications reflecting the slightly different scope (cumulative impacts versus the direct and indirect effects of the alternatives).

[1] Because EISA directs NHTSA to increase CAFE standards to reach a combined fleet average CAFE level of at least 35 mpg by model year 2020, MY 2016-2020 CAFE standards are reasonably foreseeable and must be accounted for when analyzing the cumulative impacts of the MY 2011-2015 CAFE standards. For each alternative, NHTSA assumed that passenger-car and light-truck CAFE standards would continue to increase over MY 2016-2020 at their average annual rate of increase over MY 2011-2015. This assumption results in passenger-car and light-truck CAFE standards under each action alternative that meet or exceed the EISA requirement of a combined fleet average of at least 35 mpg by model year 2020. NHTSA assumed further that the fuel economy standards for model year 2020 would remain in effect through the end of the analysis period. Because the CAFE standards apply to new vehicles, this assumption results in emissions reductions and fuel savings that continue to grow as new vehicles meeting the CAFE standards for MY 2020 and beyond are added to the fleet in each subsequent year, reaching their maximum values when all passenger cars and light trucks in the U.S. fleet meet these standards.

4.4.1 Introduction – Greenhouse Gases and Climate Change

A series of intensive and extensive analyses has been conducted by the IPCC, the scientific body tasked by the United Nations to evaluate the risk of human-induced climate change), the United States Climate Change Science Program (USCCSP), and many other programs sponsored by government, non-governmental organizations (NGO), and industry. Our discussion relies heavily on the most recent, thoroughly peer-reviewed, and credible assessments of global and U.S. climate change: the IPCC Fourth Assessment Report (*Climate Change 2007*), and reports by the USCCSP that include the *Scientific Assessment of the Effects of Global Change on the United States* and Synthesis and Assessment Products (SAPs). These sources and the studies they review are frequently quoted throughout this FEIS. Because new evidence is continuously emerging on the subject of climate change impacts, the discussions on climate impacts in this FEIS also draw on more recent studies, where possible.

Global climate change refers to long-term fluctuations in global surface temperatures, precipitation, ice cover, sea levels, cloud cover, ocean temperatures and currents, and other climatic conditions. Scientific research has shown that, in the past century, Earth's surface temperature and sea levels have risen, and most scientists attribute this to GHGs released by human activities, primarily the combustion of fossil fuels. The IPCC recently asserted that, "Most of the observed increase in global average temperatures since the mid-20th century is *very likely* due to the observed increase in anthropogenic greenhouse gas concentrations" (IPCC 2007c).

The primary GHGs – CO_2, methane (CH_4), and nitrous oxide (N_2O) – are created by both natural and human activities. Human activities that emit GHGs to the atmosphere include the combustion of fossil fuels, industrial processes, solvent use, land use change and forestry, agricultural production, and waste management. These gases trap heat in Earth's atmosphere, changing the climate, which then impacts resources such as ecosystems, water resources, agriculture, forests, and human health. As the world population grows and developing countries industrialize, fossil fuel use and resulting GHG emissions and their concentrations in the atmosphere are expected to grow substantially over the next century. For a more in-depth discussion of the science of climate change, *see* Section 3.4.1.

4.4.2 Affected Environment

The affected environment can be characterized in terms of GHG emissions and climate. Section 3.4.2 provides a discussion of both topics, including a description of conditions in both the United States and the global environment. Because there is no distinction between the affected environment for purposes of the direct/indirect effects analysis and the cumulative impacts analysis, the reader is referred to Section 3.4.1.

4.4.3 Methodology

The methodology used to characterize the effects of the alternative CAFE standards on climate has two key elements:

1. Analyzing the effects of the alternatives on GHG emissions, and
2. Analyzing how the GHG emissions affect the climate system (climate effects).

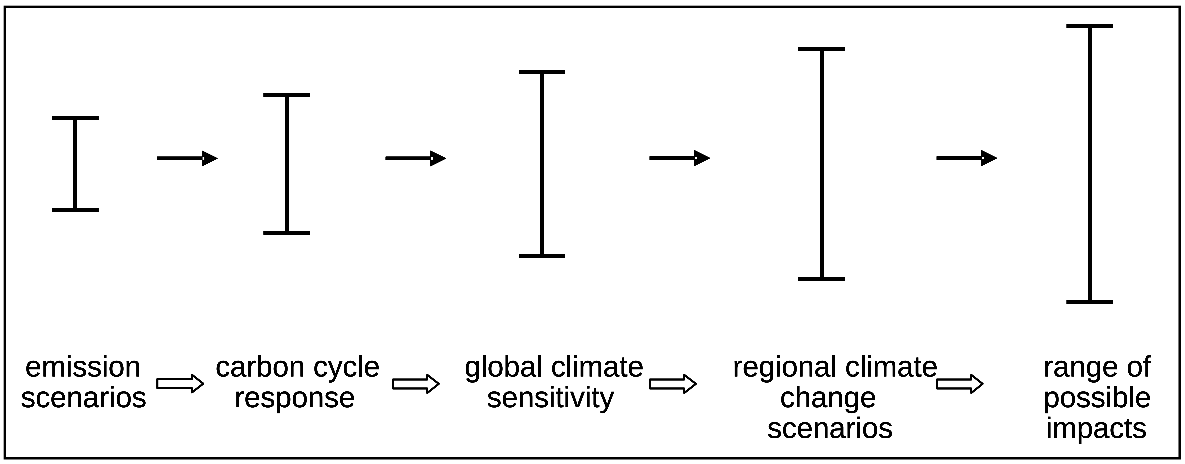
Each element is discussed below.

This FEIS expresses results for each alternative in terms of the environmental attribute being characterized (emissions, CO_2 concentrations, temperature, precipitation, sea level). It also presents the change between the No Action Alternative and each of the other six alternatives to illustrate the differences in environmental impacts across the CAFE alternatives.

The methods used to characterize emissions and climate change impacts involve considerable uncertainty. Sources of uncertainty include the pace and effects of technology change in both the transportation sector and other sectors that emit GHGs; changes in the future fuel supply that could affect emissions; the sensitivity of climate to increased GHG concentrations; the rate of change in the climate system in response to changing GHG concentrations; the potential existence of thresholds in the climate system (which could be difficult to predict and simulate); regional differences in the magnitude and rate of climate changes; and many other factors.

Moss and Schneider (2000) characterize the "cascade of uncertainty" in climate change simulations (Figure 4.4-1). As indicated in the figure, the emissions estimates used in this FEIS are less uncertain than the global climate effects (as illustrated by the heights of the bars), which in turn are less uncertain than the regional climate change effects. The effects on climate are in turn less uncertain than the impacts of climate changes on affected resources (terrestrial and coastal ecosystems, human health, and other resources discussed in Section 4.5).

Figure 4.4-1. Cascade of Uncertainty in Climate Change Simulations a/



a/ Source: Moss and Schneider (2000) – "Cascade of uncertainties typical in impact assessments showing the 'uncertainty explosion' as these ranges are multiplied to encompass a comprehensive range of future consequences, including physical, economic, social, and political impacts and policy responses."

Where information in the analysis included in this FEIS is incomplete or unavailable, NHTSA has relied on CEQ regulations regarding incomplete or unavailable information (40 CFR § 1502.22(b)). The understanding of the climate system is incomplete; like any analysis of complex, long-term changes to support decisionmaking, the analysis described below involves many assumptions and uncertainties in the course of evaluating reasonably foreseeable significant adverse impacts on the human environment. This FEIS uses methods and data that represent the best available information on this topic, and which have been subject to peer review and scrutiny. In fact, the information cited throughout this section that is extracted from the IPCC and USCCSP has endured a more thorough and systematic review process than information on virtually any other topic in environmental science and policy. The Model for Assessment of Greenhouse Gas-induced Climate Change (MAGICC) and the IPCC emissions scenarios described below are generally accepted in the scientific community.

NHTSA notes that the USCCSP recently released for comment a draft SAP 3.1 regarding the strengths and limitations of climate models (CCSP 2008a). The reader might find the discussions in this draft SAP useful in understanding the methodological limitations regarding modeling the environmental impacts of the proposed action and the range of alternatives on climate change.

4.4.3.1 Methodology for Greenhouse Gas Emissions Modeling

GHG emissions were estimated using the Volpe model, described in Section 3.1.4. These emissions estimates include CO_2, CH_4, and N_2O emissions from both direct fuel consumption and upstream sources. The following non-GHGs were also estimated by the Volpe model and taken into account in the climate modeling: SO_2, NO_x, CO, and VOCs.

The Volpe model assumes that major manufacturers will exhaust all available technology before paying noncompliance civil penalties. In the more stringent alternatives, the Volpe model predicts that increasing numbers of manufacturers will run out of technology to apply and, theoretically, resort to penalty payment. Setting standards this high might not be technologically feasible, nor might it serve the need of the Nation to conserve fuel and reduce emissions.

Fuel savings from stricter CAFE standards also result in lower emissions of CO_2, the main GHG emitted as a result of refining, distribution, and use of transportation fuels.[2] Lower fuel consumption reduces carbon dioxide emissions directly, because the primary source of transportation-related CO_2 emissions is fuel combustion in internal combustion engines. NHTSA estimates reductions in CO_2 emissions resulting from fuel savings by assuming that the entire carbon content of gasoline, diesel, and other fuels is converted to CO_2 during the combustion process (*See* 73 *FR* 24352, 24412-24413, May 2, 2008). Reduced fuel consumption also reduces CO_2 emissions that result from the use of carbon-based energy sources during fuel production and distribution. NHTSA currently estimates the reductions in CO_2 emissions during each phase of fuel production and distribution using CO_2 emissions rates obtained from the Greenhouse Gases Regulated Emissions and Energy Use in Transportation (GREET) model. The previous assumptions about how fuel savings are reflected in reductions in each phase. The total reduction in CO_2 emissions from the improvement in fuel economy under each alternative CAFE standard is the sum of the reductions in emissions from reduced fuel use and reductions in emissions from lower fuel production and distribution.

4.4.3.2 Methodology for Estimating Climate Effects

This FEIS estimates and reports on four direct and indirect effects of climate change, driven by alternative scenarios of GHG emissions, including:

- Changes in CO_2 concentrations,
- Changes in global temperature,
- Changes in regional temperature and precipitation, and
- Changes in sea level.

The change in CO_2 concentration is a direct effect of the changes in GHG emissions, and influences each of the other factors.

---

[2] For purposes of this rulemaking, NHTSA estimated emissions of vehicular CO_2, CH_4, and N_2O emissions, but did not estimate vehicular emissions of hydrofluorocarbons (HFCs). Methane and nitrous oxide account for less than 3 percent of the tailpipe GHG emissions from passenger cars and light trucks, and CO_2 emissions account for the remaining 97 percent. Of the total (including non-tailpipe) GHG emissions from passenger cars and light trucks, tailpipe CO_2 represents about 93.1 percent, tailpipe methane and nitrous oxide represent about 2.4 percent, and hydrofluorocarbons (from air conditioner leaks) represent about 4.5 percent. Calculated from *Inventory of U.S. Greenhouse Gas Emissions and Sinks 1990-2006* (EPA 2008a).

This FEIS uses a climate model to estimate the key direct and indirect effects of the alternative CAFE standards. NHTSA chose to employ MAGICC Version 5.3 (Wigley 2008) to estimate changes in key direct and indirect effects. The application of MAGICC Version 5.3 uses the emissions estimates for CO_2, CH_4, and N_2O from the Volpe model. Sensitivity analyses examined the relationship among various CAFE alternatives, climate sensitivities, and scenarios of global emissions paths and the associated direct and indirect effects for each combination. These relationships can be used to infer the effect of the emissions associated with the regulatory alternatives on direct and indirect climate effects.

MAGICC , the modeling runs and sensitivity analyses, and the emissions scenarios used in the analysis are described in the three sections below.

4.4.3.3 MAGICC Version 5.3

The selection of MAGICC for this analysis was driven by a number of factors:

- MAGICC has been used in the peer-reviewed literature to evaluate changes in global mean surface temperature and sea-level rise. In the IPCC Fourth Assessment Report for Working Group I (WGI) (IPCC 2007a), it was used to scale the results from the atmospheric-ocean general circulation models (AOGCMs)[3] to estimate the global mean surface temperature and the sea-level rise for global emissions scenarios that the AOGCMs did not run.
- MAGICC is publicly available and is already populated with the Special Report on Emission Scenarios (SRES). The SRES scenarios are long-term emissions scenarios representing different assumptions about key drivers of GHG emissions. They are described in more detail below.
- MAGICC was designed for the type of analysis performed in this FEIS.
- More complex AOGCMs are not designed for the type of sensitivity analysis performed here and are best used to provide results for groups of scenarios with much greater differences in emissions such as the B1 (low), A1B (medium), and A2 (high) scenarios.[4]
- MAGICC has been updated to version 5.3 to incorporate the science from the IPCC Fourth Assessment Report (Wigley 2008).

For the primary analysis using MAGICC, NHTSA assumed that global emissions consistent with the No Action Alternative would follow the trajectory provided by the SRES A1B (medium) scenario.

4.4.3.4 Modeling Runs and Input Scenarios

The modeling runs and input scenarios are designed to use information on the alternatives, climate sensitivities, and SRES emissions scenarios provided by the IPCC WGI (IPCC 2007a)[5] to model relative changes in atmospheric concentrations, global mean surface temperature, precipitation, and sea-level rise.

---

[3] For a discussion of AOGCMs, *see* Chapter 8 in IPCC (2007a).

[4] The IPCC SRES scenarios were developed in the late 1990s and published in 2000 (Nakicenovic et al. 2000). The SRES scenarios were developed around four storylines. The A1 storyline included a strong commitment to market-based solutions, high savings, high economic growth, and globalization. The A2 storyline differs from A1 with lower trade flows and slower rates of technological improvement. The B1 storyline includes a global integrated approach to sustainable development. The B2 storyline includes increased local awareness of environmental issues with strong efforts at the local level and less reliance on international institutions.

[5] The use of three emission scenarios provides insight into the impact of alternative global emission scenarios on the effect of the action alternatives.

The primary modeling runs are based on the results provided for the seven alternatives using the Reference Case Volpe model assumptions, a climate sensitivity of 3 °C for a doubling of CO_2 concentrations in the atmosphere, and the SRES A1B (medium) scenario. These are referred to as the Reference Case results below, in contrast with various sensitivity runs that test high and low values of the key parameters.

The approach uses the following steps to estimate these changes for the Reference Case and an analysis that examined the alternatives using the high-level Volpe assumptions (*e.g.*, higher fuel prices and a higher social cost of carbon) referred to as the "High Scenario":

1. NHTSA assumed that global emissions consistent with the No Action Alternative (Alternative 1) follow the trajectories provided by the SRES A1B (A1B) scenario, providing results illustrating the uncertainty due to factors influencing future global emissions of GHGs.

2. NHTSA assumed that global emissions for the action alternatives (Alternatives 2 through 7) are equal to the global emissions from the No Action Alternative minus the emissions reductions from the Volpe model for CO_2, CH_4, N_2O, SO_2, NO_x, CO, and VOCs. All SO_2 reductions were applied to Aerosol Region 1 of MAGICC, which includes North America.

3. MAGICC 5.3 was used to estimate the changes in CO_2 concentrations, global mean surface temperature, and sea-level rise through 2100 using the No Action Alternative and the action alternatives developed in steps 1 and 2 above.

4. For the Reference Case results, the increase in global mean surface temperature was used along with factors that relate increase in global average precipitation to this increase in global mean surface temperature to estimate the increase in global averaged precipitation for each alternative for the A1B (medium) scenario.

The approach uses the following steps to estimate the sensitivity of the results to the selection of the SRES global emissions scenario:

1. NHTSA assumed that global emissions consistent with the No Action Alternative (Alternative 1) follow four potential trajectories represented by the SRES A2, B1, B2, and A1FI scenarios. The results of these simulations illustrate the uncertainty due to factors influencing future global emissions of GHGs (factors other than the CAFE rulemaking).

2. For each SRES scenario from step 1, NHTSA assumed that global emissions for the action alternatives are equal to the global emissions from the No Action Alternative minus the emissions reductions from the Volpe model for CO_2, CH_4, N_2O, SO_2, NO_x, CO, and VOCs. All SO_2 reductions were applied to Aerosol Region 1 of MAGICC, which includes North America.

3. MAGICC 5.3 was used to estimate the changes in CO_2 concentrations, global mean surface temperature, and sea-level rise through 2100 using the No Action Alternative (Alternative 1) and action alternatives developed in steps 1 and 2 above.

Section 3.4.4 reports the results of the primary modeling runs. Section 3.4.5 reports the results from similar runs in which the alternatives use the high-level Volpe assumptions (*e.g.*, higher fuel prices and a higher social cost of carbon), in effect providing a "CAFE assumption sensitivity analysis."

4.4.3.5 Emissions Scenarios

As described above, MAGICC uses long-term emissions scenarios representing different assumptions about key drivers of GHG emissions. All scenarios used are based on the IPCC effort to develop a set of long-term (1990-2100) emissions scenarios to provide some standardization in climate change modeling. The most widely used scenarios are those from SRES (Nakicenovic *et al.* 2000).

Both the Reference Case and the Input Scenarios analyses rely primarily on the SRES scenario referred to as "A1B" to represent a baseline emissions scenario, that is, emissions for the No Action Alternative. NHTSA selected this scenario because it is regarded as a moderate emissions case and has been widely used in AOGCMs, including several AOGCM runs developed for the IPCC WGI Fourth Assessment Report (IPCC 2007a).

NHTSA's choice of the A1B scenario is based on the following factors:

- IPCC WGI evaluated the climate effects from A1B extensively in the Fourth Assessment Report (IPCC 2007a), which provides a basis for comparing the results from the analysis using MAGICC to the IPCC Fourth Assessment Report.

- The A1B and B2 scenarios are "middle-of-the road" scenarios and provide the best comparison (see below) to the EIA AEO 2008 and International Energy Outlook (IEO) 2008 forecast of liquid energy use. The AEO-2008/IEO-2008 provide the base assumptions for key parameters in the Volpe model scenarios.

The A1B (medium) scenario provides a global context for emissions of a full suite of GHGs and ozone precursors for the Reference Case. There are some inconsistencies between the overall assumptions used by IPCC in its SRES (Nakicenovic *et al.* 2000) to develop global emissions scenarios and the assumptions used in the Volpe model in terms of economic growth, energy prices, energy supply, and energy demand. However, these inconsistencies affect the characterization of each CAFE alternative in equal proportion, so the relative estimates provide a reasonable approximation of the differences in environmental impact among the alternatives. NHTSA used the A1B scenario as the primary scenario for evaluating climate effects, but used the A2, B1, B2, and the A1FI scenarios to evaluate the sensitivity of the results to alternative emissions scenarios.[6]

Separately, each of the other alternatives was simulated by calculating the difference in annual GHG emissions with respect to the No Action Alternative, and subtracting this change in the A1B (medium) scenario to generate modified global-scale emissions scenarios, which each show the effect of the various regulatory alternatives on the global emissions path. For example, the emissions from U.S. passenger cars and light trucks in 2020 for the No Action Alternative (Alternative 1) are 1,651 million metric tons of carbon dioxide ($MMTCO_2$); the emissions in 2020 for the Optimized Alternative (Alternative 3) are 1,581 $MMTCO_2$. The difference is 70 $MMTCO_2$. Global emissions for the A1B (medium) scenario in 2020 are 46,339 $MMTCO_2$, and represent the emissions under the No Action Alternative. Global emissions for the Optimized Alternative are 70 $MMTCO_2$ less, or 46,269 $MMTCO_2$.

NHTSA's assumptions in the Volpe model for growth in the number of vehicles and miles driven for cars and light trucks in the United States are based on the AEO assumptions for 2008 (EIA, 2008a). These alone cannot be compared to the SRES assumptions because the IPCC SRES results are reported

[6] From SRES, NHTSA used the A1B scenario to represent the A1B storyline, the A2-ASF scenario to represent the A2 storyline, the B1-IMAGE scenario to represent the B1 storyline, the B2-MESSAGE scenario to represent the B2 storyline, and the A1G-MINICAM scenario to represent the A1FI storyline.

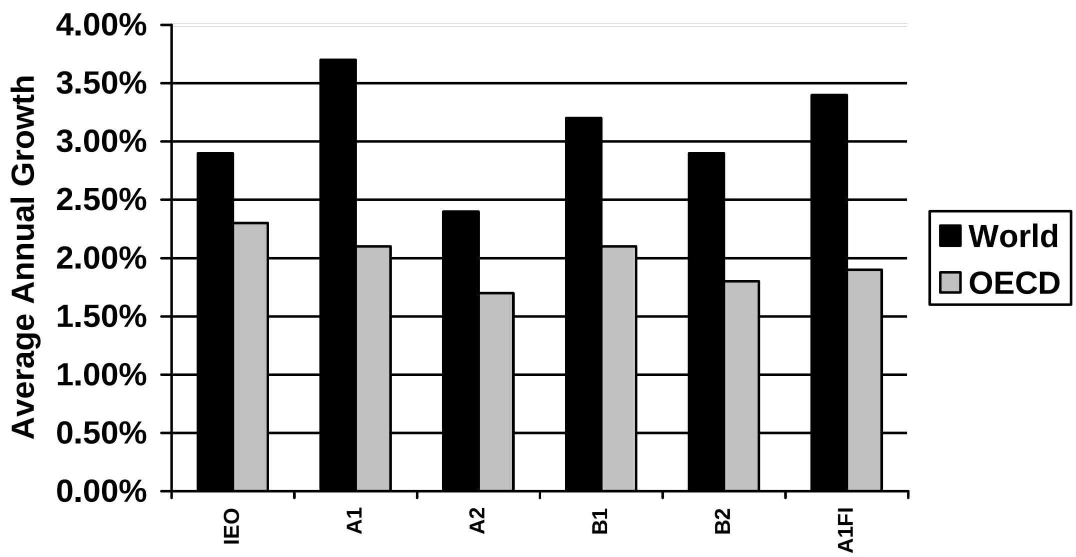
for four global regions including the Organization for Economic Cooperation and Development (OECD) and not for the United States separately. The EIA also published the IEO 2008 (EIA 2008c), which provides a global forecast of energy use and CO_2 from energy use through 2030 and which is consistent in assumptions to the IEO 2008.[7]

Figures 4.4-2 to 4.4-5 provide the forecast of gross domestic product (GDP), CO_2 emissions from energy use, primary energy use from the IEO-2008, and the five SRES scenarios for the World and the OECD 90 region.[8] The GDP growth assumptions for A1B for the OECD are close to those of the IEO-2008, but the A1B scenario has much higher GDP growth outside the OECD. This leads to higher global primary energy use by 2030, as shown in Figure 4.4-4, with much of the increase in natural gas use and higher emissions of CO_2, as shown in Figure 4.4-3. The global primary liquids energy use in A1B and the IEO-2008 compare well, considering that the IEO forecast for liquid fuels includes about 10 percent of the total in unconventional sources which are accounted for elsewhere in the SRES scenarios.

The forecast estimates for the OECD 90 region vary differently than the global numbers. The EIA shows a similar increase in primary energy use in the OECD 90 region but much greater increase in the use of primary liquid fuels even considering the reporting differences between the IEO and SRES.

Where information in the analysis included in this FEIS is incomplete or unavailable, NHTSA has relied on CEQ regulations regarding incomplete or unavailable information (40 CFR § 1502.22(b)). For this analysis, despite the inconsistencies between the IPCC assumptions on global trends across all GHG-emitting sectors (and the drivers that affect them) and the particularities of the Volpe model on the U.S. transportation sector, the approach used is valid; these inconsistencies affect all alternatives equally, and thus they do not hinder a comparison of the alternatives in terms of their relative effects on climate.

Figure 4.4-2. Average GDP Growth Rates (1990 to 2030)



---

[7] The IEO 2008 uses the energy supply and consumption from the AEO 2008 for the United States and uses the same forecast for world oil prices.
[8] The IEO nuclear primary energy forecast numbers were adjusted to account for differences in reporting primary energy use for nuclear energy and all IEO energy use estimates were converted to exajoules (EJ).

Figure 4.4-3. Global CO_2 Emissions from Fossil Fuel Use

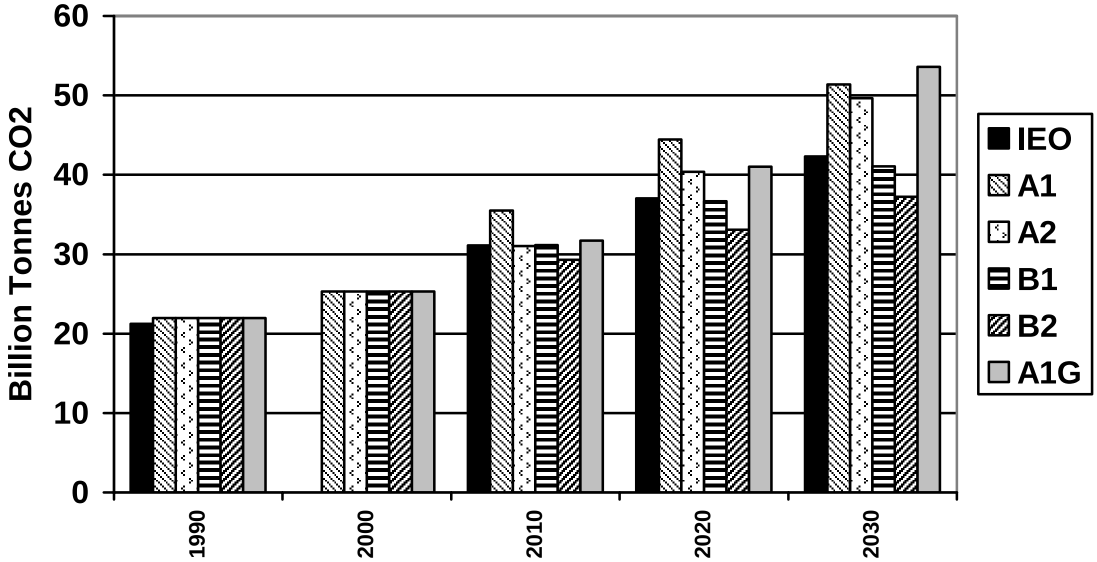


Figure 4.4-4. World Primary Energy Use Forecast

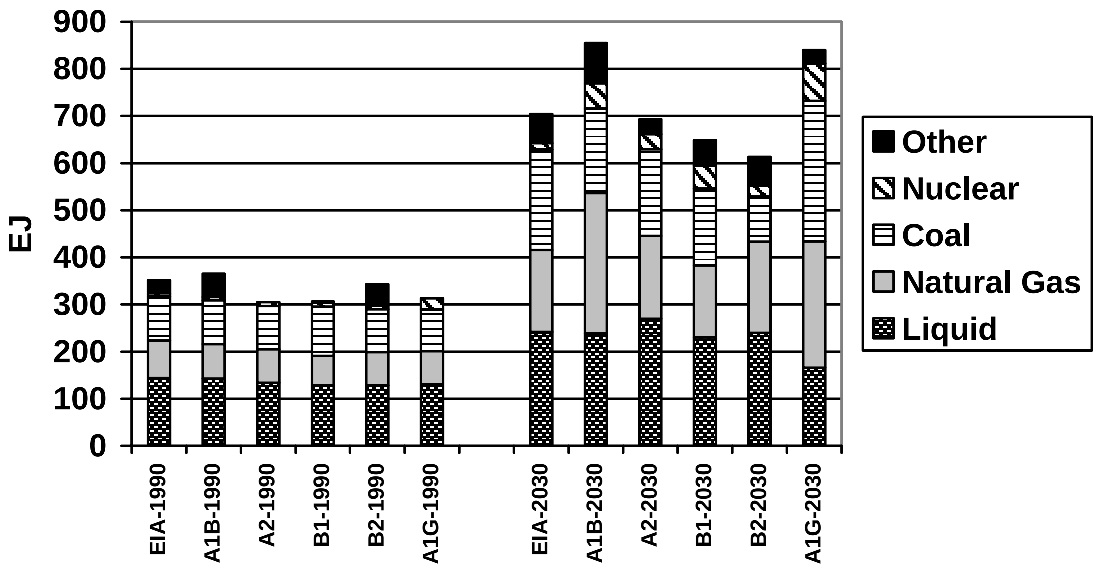

Figure 4.4-5. OECD 90 Primary Energy Use Forecast a/

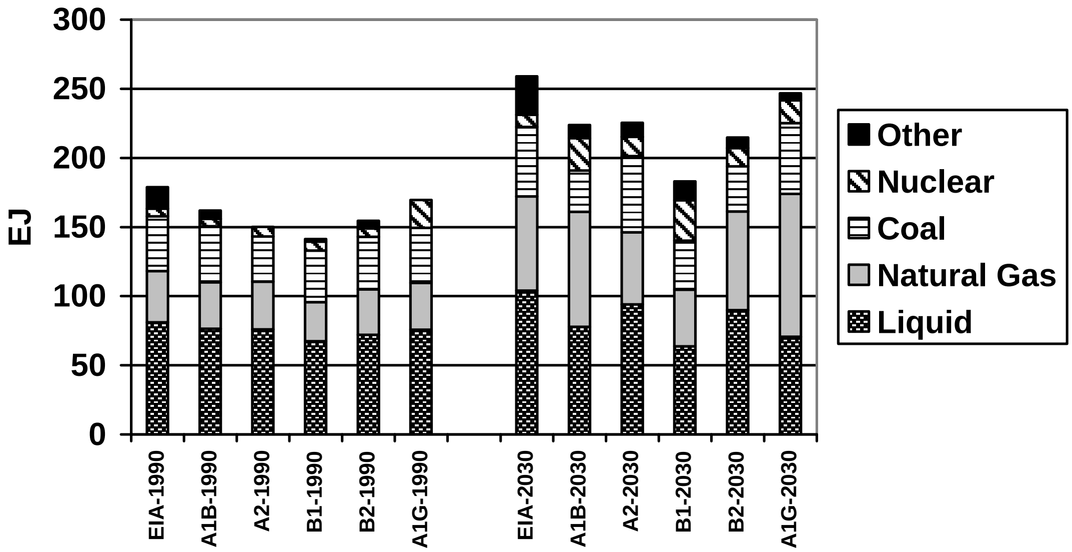


a/ The SRES results provide forecasts for countries that were members of the OECD in 1990 only and the IEO 1990 and 2030 estimates have been scaled to reflect only countries in the OECD in 1990.

The approaches focus on the marginal climate effects of marginal changes in emissions. Thus, they generate a reasonable characterization of climate changes for a given set of emissions reductions, regardless of the underlying details associated with those emissions reductions. The discussion that follows characterizes projected climate change under the No Action Alternative and the changes associated with each action alternative.

The SRES and climate sensitivity variants (*see* Section 4.4.4.2.5) analysis also uses the B1 (low), B2, A2 (high), and A1F1 emissions scenarios (Nakicenovic *et al.* 2000) as "reference" scenarios. This provides a basis for determining climate responses to varying levels of emissions and climate sensitivities for the Optimized Alternative (Alternative 3). Some responses of the climate system are believed to be non-linear; by using a range of emissions cases and climate sensitivities, it is possible to estimate the effects of the alternatives in relation to different reference cases.

4.4.3.5.1 Tipping Points and Abrupt Climate Change

The phrase "tipping point" is most typically used, in the context of climate change and its consequences, to describe situations in which the climate system (the atmosphere, oceans, land, cryosphere,[9] and biosphere) reaches a point at which there is a disproportionately large or singular response in a climate-affected system as a result of only a moderate additional change in the inputs to that system (such as an increase in the CO_2 concentration). Exceeding one or more tipping points, which "occur when the climate system is forced to cross some threshold, triggering a translation to a new state at a rate determined by the climate system itself and faster than the cause" (Committee on Abrupt Climate Change 2002), could result in abrupt changes in the climate or any part of the climate system. These changes would likely produce impacts at a rate and intensity far greater than the slower, steady changes currently being observed (and in some cases, planned for) in the climate system.

[9] The cryosphere describes the portion of Earth's surface that is frozen water, such as snow, permafrost, floating ice, and glaciers.

The phrase tipping point is also used outside the climate modeling community. In addition to climate scientists, many others – including biologists, marine chemists, engineers, and policymakers – are concerned about tipping points, because it is not just the climate that can change abruptly. The same type of non-linear responses exist in physical, environmental, and societal systems that climate affects. For example, ocean acidity resulting from an elevated atmospheric concentration of CO_2 might reach a point at which there would be a dramatic decline in coral ecosystems. Consideration of possible tipping points could therefore encompass sharp changes in climate-affected resources and not be restricted to climate change alone.

Using the broad definition of the term tipping point to include both climate change and its consequences, the scale of spatial responses can range from global (e.g., a "supergreenhouse" atmosphere with higher temperatures worldwide) to continental or subcontinental changes (such as dramatically altering the Asian monsoon), to regional (e.g., drying in the southwestern United States leading to increases in the frequency of fires, to local (such as loss of the Sierra Nevada snowpack). The definition of tipping point used by Lenton *et al.* (2008) (discussed below) specifically applies only to subcontinental or larger features, whereas public policy is concerned with a wider range of scales, as the IPCC analysis (discussed below) suggests.

The temporal scales considered are also important. On crossing a tipping point, the evolution of the climate-affected system is no longer controlled by the time scale of the climate forcing (such as the heat absorption by GHGs), but rather is determined by its internal dynamics, which can either be much faster than the forcing, or substantially slower. The much faster case – abrupt climate change – might be said to occur when the:

- Rate of change is sharply greater than (or a different sign than) what has been prevailing over previous decades;
- State of the system exceeds the range of variations experienced in the past; or
- Rate has accelerated to a pace that substantially exceeds the resources and ability of nations to respond to it.

Climate changes could occur in many ways as tipping points are reached. These mechanisms range from the appearance or unusual strengthening of positive feedbacks – self-reinforcing cycles – and reversible-phase transitions in climate-affected systems to irreversible-phase transitions – where a threshold has been crossed that could lead to either abrupt or unexpected changes in the rate or direction of change in climate-affected systems. Although climate models incorporate many positive (and negative, or dampening) feedback mechanisms, the magnitude of these effects and the threshold at which the feedback-related tipping points are reached are only roughly known, especially regarding global impacts. In addition, models of climate and climate-affected systems do not contain all feedback processes. Although substantial progress has been made in understanding the qualitative processes associated with tipping points, there are limits to the quantitative understanding of many of these systems.

In recent years, the concept of a tipping point – or a set of tipping points – in Earth's climate system has been attracting increased attention among climate scientists and policy makers. The following sections draw on perspectives from four key analyses of the issue and other relevant research: the IPCC, the USCCSP, paleoclimate[10] evidence, and Lenton *et al.* (2008). The section concludes with a brief comparative evaluation.

IPCC Perspectives on Tipping Points

In its Fourth Assessment Report, the IPCC addresses the issue of tipping points in the discussion of "major or abrupt climate changes" and highlights three large systems: the meridional overturning circulation (MOC) system that drives Atlantic Ocean circulation, the collapse of the West Antarctic ice sheet, and the loss of the Greenland ice sheet (Meehl *et al.* 2007). The IPCC states that there is uncertainty in the understanding of these systems but concludes that these systems are unlikely to reach their tipping points within the 21st Century (Meehl *et al.* 2007). The IPCC also mentions additional systems, as noted below, that might have tipping points, but does not include estimates for them.

The IPCC WGI report (Meehl *et al.* 2007) describes various climate and climate-affected systems that might undergo abrupt change, contribute to "climate surprises," or experience irreversible impacts. The systems that the IPCC described include:

- Atlantic MOC (AMOC) and other ocean circulation changes
- Arctic sea ice
- Glaciers and ice caps
- Greenland and West Antarctic ice sheets
- Vegetation cover
- Atmospheric and ocean-atmosphere regimes

The IPCC Working Group II (WGII) report provides insight on the uncertainties surrounding tipping points, their systemic and impact thresholds, and the value judgments required to select a critical level of warming (Carter *et al.* 2007). The presence of these thresholds can also present their own physical and ecological limits and informational and cognitive barriers to adaptation (Adger *et al.* 2007). In the case of this FEIS, uncertainty prevents NHTSA from being able to quantify the impacts of the alternatives under consideration on specific tipping-point thresholds.

In the IPCC WG II report, certain thresholds are assumed and then used with analyses of emissions scenarios and stabilization targets to assess how certain impacts might be avoided (Schneider *et al.* 2007). For example, several authors hypothesize that a large-scale climatic event or other impacts (for example, widespread coral-reef bleaching; deglaciation of West Antarctica) would be likely if atmospheric CO_2 concentrations stabilize at levels exceeding 450 ppm, although the location of the tipping points and thresholds is uncertain (O'Neill and Oppenheimer 2002, Lowe *et al.* 2006, and Corfee-Morlot and Höhne 2003, all as cited in Schneider *et al.* 2007).

USCCSP Perspectives on Tipping Points

The USCCSP reaches similar conclusions in its report *Scientific Assessment of the Effects of Global Change on the United States* (National Science and Technology Council 2008). The USCCSP report summarizes scientific studies that suggest that there are several "triggers" of abrupt climate change and that "anthropogenic forcing *could* increase the risk of abrupt climate change;" however, "future abrupt changes cannot be predicted with confidence" because of the insufficiencies of current climate

[10] Paleoclimatology is the study of climate change through the physical evidence left on earth of historical global climate change (prior to the widespread availability of records to temperature, precipitation, and other data). *See generally* http://www.giss.nasa.gov/research/paleo/.

models, which reflect the limits of current understanding.[11] However, the USCCSP report does reiterate the conclusion that if it occurs, an abrupt climate change event would likely transpire over the course of many hundreds of years and that it is *"very unlikely"* that any abrupt climate change will occur "during the 21st century."

The USCCSP analysis considers the susceptibility of the same three systems to abrupt change as IPCC highlighted: the AMOC system that drives Atlantic Ocean circulation, the collapse of the West Antarctic ice sheet, and the loss of the Greenland ice sheet (National Science and Technology Council 2008). The USCCSP analysis also suggests that there are thresholds in non-climate systems influenced by CO_2 emissions, such as ocean acidification, where there could be a threshold beyond which existing coral reef ecosystems cannot survive (CCSP 2008e). The USCCSP report concludes that these impacts, including climate-related thresholds, could occur in groups as thresholds are crossed, but, due to the uncertainty, more research is needed to quantify the impacts of crossing particular thresholds and to determine when these thresholds would be reached (CCSP 2008e). A forthcoming USCCSP report, Synthesis and Assessment Product 3.4, "Abrupt Climate Change," will provide additional information on this topic, focusing on glaciers and ice sheets, hydrological change, the MOC, and methane releases.

Paleoclimate Evidence on Tipping Points

The paleoclimate record cited by IPCC, USCCSP, and others gives an indication of sea-level rise from previous ice-sheet melt, and the corresponding temperature for these periods. For example, geological evidence showing the presence of elevated beaches suggests that global sea level was 4 to 6 meters higher during the most recent interglacial period about 125,000 years ago (Jansen *et al.* 2007). Paleoclimatic reconstructions suggest that global average temperature then was about 1 °C (1.8 °F) warmer than during the present interglacial period (Hansen *et al.* 2007b). Corings from the ice sheets to determine their ages, supplemented by simulations of ice-sheet extent, suggest that large-scale retreat of the southern half of the Greenland ice sheet and other Arctic ice fields likely contributed roughly 2 to 4 meters of sea-level rise during the last interglacial, with most of any remainder likely coming from the Antarctic ice sheet (Jansen *et al.* 2007).

Paleoclimatic reconstructions also indicate occurrences of abrupt changes in the terrestrial, ice, and oceanic climatic records. For example, ice-core records suggest that temperatures atop the Greenland ice sheet warmed by 8 to 16 °C (14 to 29 °F) within a few decades during Dansgaard-Oeschger events,[12] which were likely caused by the North Atlantic Ocean being covered by catastrophic outflows of glacial meltwater from the North American ice sheet that was present during glacial times (Jansen *et al.* 2007). A more recent study (Steffensen *et al.* 2008) provides more detail, indicating that a there was a sharp warming over 1 to 3 years (that is, "abrupt climate change happens in [a] few years"), followed by a more gradual warming over 50 years.

Based on the IPCC estimates of temperature increases of approximately 2 to 4 °C in the next 100 years, MacCracken (2008) notes that paleoclimatic research indicates that corresponding sea-level rise could be 10 to 20 meters or more from the melting of the West Antarctic and Greenland ice sheets. The time required to melt the ice sheets is uncertain, ranging from decades to centuries or longer. MacCracken (2008) suggests that "significant sea level rise [over 1 meter] could happen relatively

[11] *See* U.S. Climate Change Science Program, Synthesis and Assessment Product 3.1 (Climate Models: An Assessment of Strengths and Limitations), Final Report (July 2008), *available at* http://www.climatescience.gov/Library/default.htm#sap.

[12] Dansgaard-Oeschger events are very rapid climate changes—up to 7 °C in some 50 years—during the Quaternary geologic period, and especially during the most recent glacial cycle. (A Dictionary of Geography. Oxford University Press, 1992, 1997, 2004.)

quickly," meaning less than a century. For example, the average rate of rise from 20 kiloannum[13] (ka) to 8 ka was about 1 meter per century, so there have been periods with high rates of rise, although the melting North American ice sheet was an order of magnitude larger than Greenland is today (MacCracken, personal communication, 2008). For the future, Hansen *et al.* (2007b) asserts that positive feedback mechanisms in the climate system have the potential to cause large and rapid shifts in climate and in factors like glacial melt and sea-level rise that are closely dependent on the climate; Rahmstorf (2007) presents a projected sea-level rise in 2100 of 0.5 to 1.4 meters above the 1990 level.

In a study utilizing model runs and paleoclimatic data[14], Hansen *et al.* (2007b) conclude that "…a CO_2 level exceeding about 450 ppm is 'dangerous,'" where "dangerous" is defined by the authors to be global warming of more than 1 ºC (1.8 ºF) above the level in 2000, potentially leading to highly disruptive effects. Although this 450-ppm estimate has limitations and uncertainties, Hansen actually considers this estimate of dangerous CO_2 concentration to be an upper limit because it depends on several simplifying assumptions (Hansen 2008b). He warns that the limit might be lower and that a "safe" level of CO_2 could be 350 ppm – lower than the CO_2-equivalent concentration, including the offsetting effects of aerosols, is today (Hansen 2008b).

The range of views linking past and future sea-level rise is clearly broad, with uncertainty attributable to each view. Therefore, the forthcoming USCCSP report – Synthesis and Assessment Product 3.4, "Abrupt Climate Change" – should provide additional, more complete information on the issue.

Perspectives on Tipping Points from a Critical Review of the Literature and an Expert Elicitation as Presented by Lenton *et al.* (2008)

Building on the IPCC and USCCSP research, during a workshop titled "Tipping Points in the Earth System," experts identified several climate systems that have tipping points and conducted an expert elicitation involving 52 members of the international scientific community, many of whom participated in the IPCC. This study identified nine systems facing separate tipping points due to increased CO_2 and temperature levels that met four scientifically based criteria to be considered "policy-relevant potential future tipping elements in the climate system" (Lenton *et al.* 2008). Additional systems were identified but insufficient information precluded these systems from meeting the definition of policy relevant. The systems at risk that the researchers identified are:

- Arctic sea ice
- Greenland ice sheet
- West Antarctic ice sheet
- Atlantic thermohaline circulation (a component of the AMOC)
- El-Niño-Southern oscillation
- Indian summer monsoon
- Sahara/Sahel and West African monsoon
- Amazon rainforest
- Boreal forest

[13] Kiloannum means 1,000 years ago.
[14] The authors compare the corresponding GHG concentrations and associated temperature increases alongside paleoclimatology research to demonstrate that abrupt changes have occurred in Earth's past, resulting from a similar range in increased temperature as those being predicted, and to argue the existence of a CO_2 concentration equivalent level (in atmospheric GHG concentration) at which the probability of abrupt, irreversible changes in climate-affected systems might occur.

The discussion that follows is drawn primarily from the Lenton *et al.* (2008) study, including the citations therein.

Arctic sea ice. The surface of Arctic sea ice has a higher reflectivity (albedo) than the darker ocean surface. As sea ice melts from higher air and ocean temperatures, more of the ocean is exposed, which allows more radiation to be absorbed, amplifying the sea-ice melt. In summer, Arctic sea-ice loss could lead to the ice cap melting beyond a certain size/thickness, making it unstable and leading to an ice-free Arctic. Recent record ice losses and modeling studies have led some researchers to suggest that the summer Arctic will be ice free within a decade or less, that there is a critical threshold for summer Arctic sea-ice loss, and that this threshold has already been crossed (Borenstein and Joling 2008).

Greenland ice sheet. The Greenland ice sheet is also susceptible to positive feedbacks. Melting at the glacial margins lowers the edge of the ice sheet to elevations that are warmer and where more melting will occur. The IPCC estimated the Greenland ice sheet threshold for negative surface mass at 1.9 to 4.6 °C (3.4 to 8.3 °F) above pre-industrial temperature, well within the predicted temperature range for this century. Dynamic ice-melting processes, regional temperatures, warming surrounding oceans, and recent observations indicating that both Greenland and Antarctica are now losing mass have led researchers to conclude that the timescale for Greenland ice-shelf collapse is conceivably on a scale of hundreds rather than thousands of years.

West Antarctic ice sheet. The West Antarctic ice sheet is grounded below sea level and positive feedbacks could result from the loss of buttressing sea-ice shelves and the ingress of warmer ocean water. While centuries or millennia could to pass before a collapse, the thresholds for ocean and surface atmospheric warming temperature are likely to be crossed this century. A recent study of ice-core records suggests strong links between past West Antarctic climate, and potentially its ice sheet, to large-scale changes in global climate, particularly major El Niño events (Schneider and Steig 2008). It should be noted that ice-sheet loss, even over millennia, could cause the sea level to rise at a rate greater than 1 meter per century – more than five times the rate of rise during the 20th Century. The level reached would be higher than has been the case during at least the past few thousand years when coastal cities were established.

Atlantic thermohaline circulation. The term thermohaline circulation (THC) refers to the physical driving mechanism of ocean circulation, resulting from fluxes of heat and freshwater across the sea surface, subsequent interior mixing of heat and salt, and geothermal heat sources. The MOC, discussed in the IPCC and USCCSP reports, is the observed response in an ocean basin to this type of ocean circulation coupled with wind-driven currents. The Lenton *et al.* (2008) paper refers to risk to the Atlantic THC instead of the AMOC because they are discussing the influence of climate change on the underlying cooling or freshwater forcing of the Atlantic Ocean circulation, even though this in turn dramatically affects the AMOC.

If enough freshwater enters the North Atlantic (such as from melting sea ice or the Greenland ice sheet), the density-driven sinking of North Atlantic waters might be reduced or even stopped, as evidence indicated occurred happened during the last glacial cycle. This would likely reduce the northward flow of energy in the Gulf Stream and result in less heat transport to the North Atlantic. At the same time, reduced formation of very cold water would likely slow the global ocean THC, leading to impacts on global climate and ocean currents. The IPCC review of the results of model simulations suggests that an abrupt transition of the Atlantic Ocean's component of the global THC is *very unlikely* this century. However, more recent modeling that includes increased freshwater inputs suggests there could be initial changes this century, with larger and more intense reductions in the overturning circulation persisting for many centuries (Mikolajewicz *et al*. 2007).

El-Niño-Southern oscillation (ENSO). The changes that might lead to increasingly persistent (and frequent) El Niño (or La Niña) conditions are particularly uncertain. Increases in ocean heat content could have an effect on ENSO conditions, but predictive and paleoclimate modeling studies do not agree on the magnitude, frequency, and direction of these effects. However, ENSO has substantial and large-scale effects on the global climate system.

Indian summer monsoon. The Indian summer monsoon is the result of land-to-ocean pressure gradients and advection of moisture from ocean to land. By warming the land more than the ocean, climate change generally strengthens the monsoon. However, reductions in the amount of solar radiation that is absorbed by the land surface, such as land-use change, generally weaken it. An albedo greater than roughly 50 percent is necessary to simulate the collapse of the Indian summer monsoon in a simple model (Zickfield *et al.* 2005). IPCC projections do not project passing a threshold this century, although paleoclimatic reconstructions do indicate that the monsoon has changed substantially in the past.

West African monsoon. Sahara/Sahel rainfall depends on the West African monsoon circulation, which is affected by sea-surface temperature. By warming the land more than the ocean and therefore causing greater upward movement of the air, GHG forcing is expected to draw more moist oceanic air inland and thereby increase rainfall in the region, which has been shown by some models. Other models, however, project a less productive monsoon. The reasons for this inconsistency are not clear.

Amazon rainforest. The recycling of precipitation in the Amazon rainforest means that deforestation, reductions in precipitation, a longer dry season, and increased summer temperature could cause forest dieback. These conditions are thought to be linked to a more persistent El Niño and an increase of global average temperature by 3 to 4 °C (5.4 to 6.8 °F). Important additional stressors also present include forest fires and human activity (such as land clearing). A critical threshold might exist in canopy cover, which could be reached through changes in land use or regional precipitation, ENSO variability, and global forcing.

Boreal Forest. The dieback of boreal forest could result from a combination of increased heat stress and water stress, leading to decreased reproduction rates, increased disease vulnerability, and subsequent fire. Although highly uncertain, studies suggest a global warming of 3 °C (5.4 °F) could be the threshold for loss of the boreal forest.

Comparative Evaluation

The Lenton *et al.* (2008) group's list differs slightly from that of the IPCC because of differences in definition and criteria, an attempt to be more explicit than the IPCC, and the inclusion of more recent studies. The scientists defined these tipping points as "tipping elements" and attempted to estimate when the tipping element of the various systems might be reached, ranging from about 1 year (rapid) to more than 300 years (slow). As with the IPCC and USCCSP conclusions, this group also concluded that the loss of the Greenland ice sheet, the collapse of the West Antarctic ice sheet, and the disruption of the Atlantic THC systems are not expected to cross their estimated tipping elements in this century (though actions this century could create enough momentum in the climate system to cross the threshold in future centuries[15]). However, this group determined that several other systems could reach a tipping threshold within the century: loss of Arctic sea ice, Indian summer monsoon disruption, Sahara/Sahel and West African monsoon changes, drying of the Amazon rainforest, and warming of the boreal forest.

Another factor that might accelerate climate change at rates faster than those currently observed is the possible shift of soil and vegetation-carbon feedbacks, causing the soil and vegetation to become

[15] *See* Lenton *et al.* (2008), p. 1787.

carbon sources rather than carbon sinks. Currently, soil and vegetation act as sinks, absorbing carbon from the atmosphere as plant material and storing carbon in the soil when the plants die. However, by mid-century (about the time the IPCC predicts the global average temperature reaches 2 ºC (3.6 ºF) above pre-industrial levels), increasing temperatures and precipitation could cause increased rates of transpiration, resulting in soil and vegetation becoming a potential source of carbon emissions (Cox *et al.* 2000 as cited in Meehl *et al.* 2007). Warming could also thaw frozen Arctic soils (permafrost), causing the wet soils to emit more methane, a GHG. There is evidence that this process is already taking place (Walter *et al.* 2007). This additional research clarifies the concept of tipping points by further revealing that several climate systems might have tipping points that could occur within the century, and in some systems changes are currently being observed. However, uncertainties exist, especially for timing estimates, and the uncertainties are at least partly responsible for the broad spectrum of views regarding the tipping point. Exactly where these tipping points exist, and the levels at which they occur, are still a matter in need of further scientific investigation before precise quantitative conclusions can be made.

Where information in this FEIS analysis is incomplete or unavailable, as here due to current climate modeling limitations, NHTSA has relied on CEQ regulations regarding incomplete or unavailable information (40 CFR § 1502.22(b)). CEQ regulations state, in part, that when an agency is evaluating "reasonably foreseeable significant adverse impacts on the human environment and …information relevant to…[the] impacts cannot be obtained because the overall costs of obtaining it are exorbitant or the means to obtain it are not known, the agency shall include within the [EIS]:

1. a statement that such information is incomplete or unavailable;
2. a statement of the relevance of the incomplete or unavailable information to evaluating reasonably foreseeable significant adverse impacts on the human environment;
3. a summary of existing credible scientific evidence which is relevant to evaluating the reasonably foreseeable significant adverse impacts on the human environment; and
4. the agency's evaluation of such impacts based upon theoretical approaches or research methods generally accepted in the scientific community. For the purposes of this section, "reasonably foreseeable" includes impacts which have catastrophic consequences, even if their probability of occurrence is low, provided that the analysis of the impacts is supported by credible scientific evidence, is not based on pure conjecture, and is within the rule of reason." 40 CFR § 1502.22 (b).

This FEIS addresses the requirements of 40 CFR § 1502.22 appropriately. The above survey of the current state of climate science tipping points provides a "summary of existing credible scientific evidence which is relevant to evaluating the…adverse impacts of the CAFE standards." In *Colorado Environmental Coalition v. Dombeck,* the Tenth Circuit found that the ultimate goal of the agency is to ensure that the EIS's "form, content, and preparation foster both informed decision making and informed public participation" (185 F.3d 1162, 1172 [10th Cir. 1999] [quoting *Oregon Envtl. Council v. Kunzman*, 817 F.2d 484, 492 (9th Cir. 1987)]. The Tenth Circuit held that 40 CFR § 1502.22 could not be read as imposing a "data gathering requirement under circumstances where no such data exists." *Id.*

In this case, this FEIS acknowledges that information on tipping points or abrupt climate change is incomplete, and the state of the science does not allow for a characterization of how the CAFE alternatives influence these risks. This action alone, even as analyzed for the most stringent alternative, does not produce sufficient CO_2 emissions reductions to avert levels of abrupt and severe climate change. To the degree that the action in this rulemaking reduces the rate of CO_2 emissions, the rule contributes to the general reduction or delay of reaching these tipping-point thresholds. These conclusions are not meant to be read as expressing NHTSA's view that tipping points in climate-related systems are not areas of concern for policymakers. Under NEPA, the agency is obligated to discuss "the environmental impact[s] *of the proposed action*" (42 U.S.C. § 4332(2)(C)(i) [emphasis added]). The above discussion fulfills NHTSA's NEPA obligations regarding this issue.

4.4.4 Environmental Consequences

This section describes the consequences of the MY 2011-2015 CAFE standards in relation to GHG emissions and climate effects.

4.4.4.1 Greenhouse Gas Emissions

To estimate the emissions resulting from changes in passenger car and light truck CAFE standards, NHTSA uses the Volpe model (*see* Section 3.1.3 for a description of the model). The change in fuel use projected to result from each alternative CAFE standard determines the resulting impacts on total and petroleum energy use, which in turn affects the amount of CO_2 emissions. These CO_2 emissions estimates also include upstream emissions, which occur from the use of carbon-based energy during crude oil extraction, transportation, and refining, and in the transportation, storage, and distribution of refined fuel. Because CO_2 accounts for such a large fraction of total GHG emitted during fuel production and use – more than 95 percent, even after accounting for the higher global warming potentials (GWPs) of other GHGs – NHTSA's consideration of GHG impacts focuses on reductions in CO_2 emissions resulting from the savings in fuel use that accompany higher fuel economy.[16]

NHTSA considers three measures of the cumulative impact of alternative CAFE standards (for MY 2011-2015 *and* using the assumption of reaching 35 mpg by 2020 to estimate the foreseeable MY 2016-2020) on CO_2 emissions:

- CO_2 emissions from the vehicles they would affect, namely, MY 2011-2020 passenger cars and light trucks;
- CO_2 emissions by the entire U.S. passenger car and light truck fleets that would result during future years (2021-2100) from each alternative increase in CAFE standards; and
- Cumulative emissions reductions over the history of the CAFE Program, including those projected to result from each alternative increase in CAFE standards considered for NHTSA's proposed action. Emissions reductions represent the differences in total annual emissions by all cars or light trucks in use between their estimated future levels under the No Action Alternative (baseline), and with each alternative CAFE standard in effect.

Under NEPA, the assessment of cumulative impacts must include the impact on the environment resulting from "the incremental impact of the action when added to other past, present, and reasonably foreseeable future actions." 40 CFR § 1508.7. Because EISA directs NHTSA to increase CAFE standards to reach a combined fleet average CAFE level of at least 35 mpg by model year 2020, MY 2016-2020 CAFE standards are reasonably foreseeable and must be accounted for when analyzing the cumulative impacts of the MY 2011-2015 CAFE standards. For each alternative, NHTSA assumed that passenger-car and light-truck CAFE standards would continue to increase over MY 2016-2020 at their average annual rate of increase over MY 2011-2015. This assumption results in passenger-car and light-truck CAFE standards under each action alternative that meet or exceed the EISA requirement of a combined fleet average of at least 35 mpg by model year 2020. NHTSA assumed further that the fuel economy

[16] Although this section only includes a discussion of CO_2 emissions, the climate modeling discussion in Section 3.4.4.4 assesses the direct and indirect effects associated with emissions reductions of multiple gases, including CO_2, CH_4, N_2O, SO_2, CO, NO_x, and VOCs.

standards for model year 2020 would remain in effect through the end of the analysis period. Because the CAFE standards apply to new vehicles, this assumption results in emissions reductions and fuel savings that continue to grow as new vehicles meeting the CAFE standards for MY 2020 and beyond are added to the fleet in each subsequent year, reaching their maximum values when all passenger cars and light trucks in the U.S. fleet meet these standards. Thus, NHTSA evaluated the effect of CAFE standards to date, and potential CAFE standards for MY 2016-2020 because they are considered a reasonably foreseeable action.

NHTSA estimates that the cumulative CO_2 reductions from CAFE to date, from 1978-2007, have been 8,911 $MMTCO_2$, according to the Volpe model. Assuming no further increases in fuel economy standards – that is, the standards for MY 2010 vehicles remain in force through 2100 – NHTSA estimates that continuation of the MY 2010 standards would result in further emissions reductions of 135,535 $MMTCO_2$ as compared to the reference case of no CAFE standards.

Emissions reductions resulting from the CAFE standards for MY 2011-2015 and MY 2016-2020 cars and light trucks were estimated from 2010 to 2100. Reductions begin in the year 2010, the first year that MY 2011 vehicles are on the road. For each alternative, all vehicles after MY 2020 were assumed to meet the MY 2020 CAFE standards. Emissions were estimated for all alternatives through 2100, and these emissions were compared against the NPRM baseline (which assumes all vehicles post-MY 2010 meet the MY 2010 standards) to estimate emissions reductions. The Volpe model estimates emissions through the year 2060. Annual emissions reductions from 2061-2100 were held constant at 2060 levels.

Table 4.4-1 lists total emissions reductions from MY 2010-2100 new passenger cars and light trucks for each of the seven alternatives. Projections of emissions reductions over the 2010 to 2100 period due to the MY 2011-2015 CAFE standards and the potential standards for MY 2016-2020 ranged from 24,321 to 49,157 $MMTCO_2$. Compared to global emissions of 4,850,000 $MMTCO_2$ over this period (projected by the A1B-medium scenario), the incremental impact of this rulemaking is expected to reduce global CO_2 emissions by about 0.5 to 1.0 percent.

Table 4.4-1

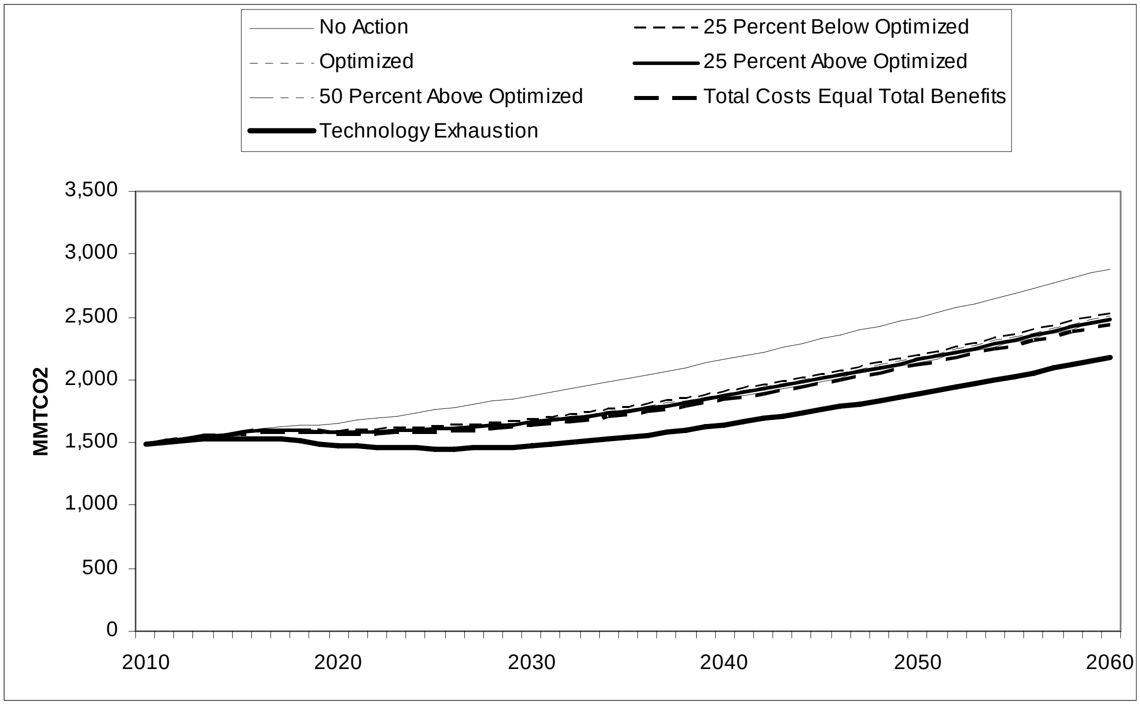
Reference Case Cumulative Emissions and Emissions Reductions Due to the MY 2011-2015 Standards and Potential MY 2016-2020 Standards Projected for 2010-2100 ($MMTCO_2$)

Alternative	Emissions	Emissions Reductions Compared to No Action Alternative
1 No Action	221,258	0
2 25 Percent Below Optimized	196,937	24,321
3 Optimized	195,816	25,442
4 25 Percent Above Optimized	194,057	27,201
5 50 Percent Above Optimized	192,478	28,780
6 Total Costs Equal Total Benefits	191,073	30,185
7 Technology Exhaustion	172,101	49,157

To gain a sense of the relative impact of these reductions, it can be helpful to compare them against emissions projections from the transportation sector, and expected or stated goals from existing programs designed to reduce CO_2 emissions. For ease of comparison, NHTSA focuses on the Optimized Alternative for this discussion.

As mentioned earlier, U.S. cars and light trucks account for 19.2 percent of CO_2 emissions in the United States. Thus, with the action alternatives reducing U.S. car and light truck CO_2 emissions by 11 to 22 percent, this would represent a reduction of 2.1 to 4.3 percent of total U.S. CO_2 emissions (assuming the relative contribution of cars and light trucks stays the same). Projected annual emissions from cars and light trucks under the MY 2011-2015 and MY 2016-2020 CAFE standards are shown in Figure 4.4-6.

Figure 4.4-6. Reference Case Cumulative Annual Emissions Under the MY 2011-2015 Standards and Potential MY 2016-2020 Standards (MMTCO$_2$)



Emissions of CO_2, the primary gas that drives climate effects, from the U.S. automobile and light truck fleet represented about 2.5 percent of total global emissions of CO_2 in 2000 (EPA 2008a, WRI 2008). Although substantial, this source is a still small percentage of global emissions. The relative contribution of CO_2 emissions from the U.S. light vehicle fleet is expected to decline in the future, due primarily to rapid growth of emissions from developing economies (which are due in part to growth in global transportation sector emissions). In the SRES A1B (medium) scenario (Nakicenovic *et al.* 2000), the share of liquid fuel use, mostly petroleum and biofuels, from OECD countries declines from 60 percent in 2000 to 17 percent in 2100.

In their *Annual Energy Outlook 2007*, the EIA projects U.S. transportation-derived CO_2 emissions will increase from 2,037 MMTCO$_2$ in 2010 to 2,682 MMTCO$_2$ in 2030, with cumulative emissions from transportation over this period reaching 49,287 MMTCO$_2$. Over this same period, the emissions reductions from this rulemaking are projected to be 1,582 to 3,870 MMTCO$_2$, which would yield a 3- to 8-percent reduction in emissions from the transportation sector. The emissions reductions as a result of increasing fuel economy standards would be expected to increase further as new vehicles enter the fleet and older vehicles are retired. For example, in 2030, projected emissions reductions would be 192 to 402 MMTCO$_2$, a 7- to 15-percent decrease from projected U.S. transportation emissions of 2,682 MMTCO$_2$ in 2030. It is important to note that the EIA did not account for the expected effects of this rulemaking in their forecast (EIA 2007), thus allowing a comparison of the impact of this rulemaking to U.S. transportation emissions under the No Action Alternative.

As another measure of the relative environmental impact of this rulemaking, these emissions reductions can be compared to existing programs designed to reduce GHG emissions in the United States. In 2007, Arizona, California, New Mexico, Oregon, and Washington formed the Western Climate

Initiative (WCI) to develop regional strategies to address climate change. WCI has a stated goal of reducing 350 $MMTCO_2$ equivalent over the period from 2009 to 2020 (WCI 2007a). Emissions levels in 2020 would represent a 33-percent reduction from the future baseline, and a 15-percent reduction from the beginning of the action (WCI 2007b). By comparison, this rulemaking is expected to reduce CO_2 emissions by 197 to 755 $MMTCO_2$ over the same time period, with emissions levels in 2020 representing a 4- to 11-percent reduction from the future baseline emissions for cars and light trucks. In the Northeast, nine Northeast and Mid-Atlantic states have formed the Regional Greenhouse Gas Initiative (RGGI) to reduce CO_2 emissions from power plants. Emissions reductions from 2006 to 2024 are estimated at 268 $MMTCO_2$ (RGGI 2006).[17] This represents a 23-percent reduction from the future baseline and a 10-percent reduction from the beginning of the action (RGGI 2006). By comparison, NHTSA forecasts that this rulemaking will reduce CO_2 emissions by 593 to 1,731 $MMTCO_2$ over this timeframe, with emissions levels in 2024 representing a 7- to 16-percent reduction from the future baseline emissions for cars and light trucks.

Two points are important to note. First, emissions from sources addressed in the WCI and RGGI both *decrease* compared to the beginning of the action, while emissions from cars and trucks continue to *increase* under this rulemaking – despite increased fuel efficiency – due to increases in VMT. Second, these projections are only estimates, and the scopes of these climate programs differ from this rulemaking in geography, sector, and purpose. Also, the approach, goals, and methods of reductions vary between NHTSA's action and these initiatives. However, the expected end result – reduction of tons of CO_2 – for all these initiatives is similar.

The Stabilization Wedge Theory described by Pacala and Socolow (2004) for climate change mitigation includes a graphical representation of the contributions of many GHG reduction initiatives and the ability for all of these "wedges," over time, to add up to a climate change solution. The reductions from this rulemaking could be viewed in this context as being one of many needed to reduce U.S. transportation emissions.

Where information in the analysis included in this FEIS is incomplete or unavailable, NHTSA has relied on CEQ regulations regarding incomplete or unavailable information (40 CFR § 1502.22(b)). In this case, the comparison of emissions reductions from the action alternatives to emissions reductions associated with other programs is intended to aid decisionmakers by providing relative benchmarks, rather than absolute metrics for selecting among alternatives. In summary, the alternatives analyzed here deliver GHG emissions reductions that are on the same scale as many of the most progressive and ambitious GHG emissions reduction programs underway in the United States.

4.4.4.2 Direct and Indirect Effects on Climate Change

The approach to estimating the cumulative effects of climate change from the MY 2011-2015 CAFE standards combined with the potential MY2016-2020 CAFE standards mirrors that used to estimate the direct and indirect effects of the MY 2011-2015 CAFE standards. Again, because EISA requires average fuel economy of the passenger cars and light trucks to reach a combined average of at least 35 mpg by 2020, the MY 2016-2020 CAFE standards are a reasonably foreseeable future action and, therefore, must be accounted for when analyzing the cumulative impacts of the MY 2011-2015 CAFE standards. For each alternative, NHTSA assumed that passenger-car and light-truck CAFE standards would continue to increase over MY 2016-2020 at their average annual rate of increase over MY 2011-2015. This assumption results in passenger-car and light-truck CAFE standards under each action alternative that meet or exceed the EISA requirement of a combined fleet average of at least 35 mpg by

[17] Emission reductions were estimated by determining the difference between the RGGI Cap and the Phase III RGGI Reference Case. These estimates do not include offsets.

model year 2020. NHTSA assumed further that the fuel economy standards for model year 2020 would remain in effect through the end of the analysis period. Because the CAFE standards apply to new vehicles, this assumption results in emissions reductions and fuel savings that continue to grow as new vehicles meeting the CAFE standards for MY 2020 and beyond are added to the fleet in each subsequent year, reaching their maximum values when all passenger cars and light trucks in the U.S. fleet meet these standards. Overall, the emissions reductions for the MY 2011-2015 CAFE standards have a small impact on climate change. The emissions reductions and resulting climate impacts for the MY 2011-2015 and MY 2016-2020 CAFE standards are larger, although they are still relatively small in absolute terms.

The direct and indirect effects of the alternatives on climate change are described in the following section in terms of (1) atmospheric CO_2 concentrations, (2) temperature, (3) precipitation, and (4) sea-level rise.

4.4.4.2.1 Atmospheric Carbon Dioxide Concentrations

MAGICC is a simple climate model that is well calibrated to the mean of the multi-model ensemble results for three of the most commonly used emissions scenarios – B1 (low), A1B (medium), and A2 (high) from the IPCC SRES series – as shown in Table 4.4-2.[18] As the table indicates, the model runs developed for this analysis achieve relatively good agreement with IPCC WGI estimates in terms of both CO_2 concentrations and surface temperature.

Table 4.4-2

Comparison of MAGICC Results and Reported IPCC Results (IPCC 2007a)

Scenario	CO_2 Concentration (ppm) IPCC WGI (2100)	CO_2 Concentration (ppm) MAGICC (2100)	Global Mean Increase in Surface Temperature (°C) IPCC WGI (2080-2099)	Global Mean Increase in Surface Temperature (°C) MAGICC (2090)	Sea-level Rise (cm) IPCC WGI (2090-2099) a/	Sea-level Rise (cm) MAGICC (2095)
B1	550	538.3	1.79	1.81	28	26
A1B	715	717.2	2.65	2.76	35	35
A2	836	866.8	3.13	3.31	37	38

a/ The IPCC values represent the average of the 5- to 95-percent range of the rise of sea level between 1980 to 1989 and 2090 to 2099.

A comparison of the sea-level rise from MAGICC 5.3 and the IPCC Fourth Assessment Report can be found in the release documentation for MAGICC 5.3 (Wigley 2008). In Table 3 of the documentation, Wigley (2008) presents the results for six SRES scenarios that show the comparable value for sea-level rise from MAGICC 5.3 (total sea-level rise minus estimates for contributions from non-melt sources such as warming of the permafrost) within 0.01 centimeter (cm) in 2095.

As discussed earlier in Section 3.4.2, the SRES A1B scenario was used to represent the No Action Alternative (Alternative 1) in the MAGICC runs for this FEIS. Table 4.4-3 and Figures 4.4-7 to 4.4-10 show the mid-range results of MAGICC model simulations for Alternative 1 and the six action alternatives for CO_2 concentrations and increase in global mean surface temperature in 2030, 2060, and 2100. As Figures 4.4-7 and 4.4-8 show, the impact on the growth in CO_2 concentrations and temperature is just a fraction of the total growth in CO_2 concentrations and global mean surface temperature. However, the relative impact of the CAFE alternatives is illustrated by the reduction in growth of both CO_2 concentrations and temperature in the Technology Exhaustion Alternative (Alternative 7).

[18] NHTSA used the default climate sensitivity in MAGICC of 3.0 °C.

Table 4.4-3

Reference Case MY 2011-2015 Standards and Potential MY 2016-2020 Standards Cumulative Impact on CO_2 Concentrations, Surface Temperature Increase, and Sea-level Rise Using MAGICC (A1B a/)

	CO_2 Concentration (ppm)			Surface Temperature Increase (°C)			Sea-level Rise (cm)

a/ The A1B scenario is the SRES marker scenario used by the IPCC WGI to represent the SRES A1B (medium) storyline.

As shown in Figures 4.4-9 and 4.4-10, the reduction in increase of CO_2 concentrations and the reduction in increase of temperature under the No Action Alternative is nearly twice that of the 25 Percent Below Optimized Alternative (Alternative 2).

As shown in the table and figures, there is a fairly narrow band of estimated CO_2 concentrations as of 2100, from 713 ppm for the Technology Exhaustion Alternative to 717 ppm for the No Action Alternative. For 2030 and 2060, the range is even smaller. Because CO_2 concentrations are the key driver of all other climate effects, this leads to small differences in these effects.

4.4.4.2.2 Temperature

The MAGICC simulations of mean global surface air temperature increases are shown above in Table 4.4-3. For all alternatives, the cumulative global mean surface temperature increase is about 0.87 °C as of 2030, 1.93 to 1.94 °C as of 2060, and 2.94 to 2.96 °C as of 2100 (Table 4.4-3). The differences among alternatives are small. For 2100, the reduction in temperature increase relative to the No Action Alternative ranges from 0.009 °C to 0.02 °C.

Table 4.4-4 summarizes the regional changes to warming and seasonal temperatures from the IPCC Fourth Assessment Report. Quantifying the changes to regional climate from the CAFE alternatives is not possible at this point, but it is expected that the alternatives would reduce the changes relative to the reduction in global mean surface temperature.

Table 4.4-4

Summary of Regional Changes to Warming and Seasonal Temperatures Extracted from the IPCC Fourth Assessment Report (Christensen *et al.* 2007)

Land Area	Sub-region	Mean Warming	Maximum Summer Temperatures
Africa	Mediterranean area and northern Sahara	*Likely* larger than global mean throughout continent and in all seasons	
	Southern Africa and western margins		
	East Africa		
Mediterranean and Europe	Northern Europe	*Likely* to increase more than the global mean with largest warming in winter	
	Southern and Central Europe		Maximum Summer Temperatures *likely* to increase more than average
	Mediterranean area		
Asia	Central Asia	*Likely* to be well above the global mean	
	Tibetan Plateau	*Likely* to be well above the global mean	
	Northern Asia	*Likely* to be well above the global mean	
	Eastern Asia	*Likely* to be above the global mean	*Very likely* that heat waves/hot spells in summer will be of longer duration, more intense and more frequent *Very likely* fewer very cold days
	South Asia	*Likely* to be above the global mean	*Very likely* fewer very cold days
	Southeast Asia	*Likely* to be similar to the global mean	
North America	Northern regions/Northern North America	*Likely* to exceed the global mean	Warming *likely* to be largest in winter Minimum winter temperatures *likely* to increase more than the average
	Southwest		Warming *likely* to be largest in summer Maximum summer temperatures *likely* to increase more than the average
	Northeast USA		
	Southern Canada		
	Canada		
	Northernmost part of Canada		

Table 4.4-4 (cont'd)

Summary of Regional Changes to Warming and Seasonal Temperatures Extracted from the IPCC Fourth Assessment Report (Christensen *et al.* 2007)

Land Area	Sub-region	Mean Warming	Maximum Summer Temperatures
Central and South America	Southern South America	*Likely* to be similar to the global mean	
	Central America	*Likely* to be larger than global mean	
	Southern Andes		
	Tierra del Fuego		
	Southeastern South America		
	Northern South America		
Australia and New Zealand	Southern Australia	*Likely* comparable to the global mean but less than in the rest of Australia	Increased frequency of extreme high daily temperatures and a decrease in the frequency of cold extremes *very likely*
	Southwestern Australia	*Likely* comparable to the global mean	
	Rest of Australia	*Likely* comparable to the global mean	
	New Zealand, South Island	*Likely* less than the global mean	
	Rest of New Zealand	*Likely* comparable to the global mean	
Polar Regions	Arctic	*Very likely* to warm during this century more than the global mean	Warming largest in winter and smallest in summer
	Antarctic	*Likely* to warm	
Small Islands		*Likely* to be smaller than the global annual mean	

MAGICC 5.3 estimates radiative forcing from black carbon, a primary aerosol emitted through the incomplete combustion of fossil fuel and biomass burning. However, emissions trends for black carbon are "hard-wired" in the model to follow emissions of SO_2, which means they cannot be specified separately in the model.[19] The radiative forcing of black carbon is difficult to quantify accurately as it is a function of microphysical properties, the geographic and vertical placement, and lifetime of the aerosol; however, black carbon clearly contributes substantially to global warming (Jacobson 2001). Total global black carbon emissions are estimated to be approximately 8 TgC/yr (Bond *et al.* 2004, as cited in Forster *et al.* 2007), with estimates of fossil fuel contributions ranging from 2.8 TgC/yr (Ito and Penner 2005, as cited in Forster *et al.* 2007) to 8.0 TgC/yr (Haywood and Boucher 2000, as cited in Forster *et al.* 2007). The United States is estimated to contribute 6.1 percent of the global soot emissions, with non-road vehicles, on road vehicles, stack emissions, and fugitive sources comprising major sources (Jacobson Testimony 2007). In summary, the climate modeling does take into account the effects of black carbon on climate variables.

[19] Accurately determining the magnitude of mobile source emissions of black carbon is difficult because the emissions vary with fuel properties and fluctuations in the combustion environment. MOBILE6.2 outputs particulate matter mass that is then incorporated in the Volpe model. This particulate matter is based on tailpipe emissions and thereby includes carbon emissions from the combustion process. Because the carbon emissions are lumped into the particulate matter and not treated independently, the Volpe model does not provide direct results of the impact of the carbon emissions.

4.4.4.2.3 Precipitation

According to the IPCC WGI (Meehl *et al.* 2007), global mean precipitation is expected to increase under all scenarios. Generally, precipitation increases would occur in the tropical regions and high latitudes, with decreases in the sub-tropics. The results from the AOGCMs suggest considerable uncertainty in future precipitation for the five SRES scenarios. Where information in the analysis included in this FEIS is incomplete or unavailable, the agency has relied on CEQ regulations regarding incomplete or unavailable information *(see* 40 CFR § 1502.22(b)). In this case, the IPCC (Meehl *et al.* 2007) summary of precipitation represents the most thoroughly reviewed, credible assessment of this highly uncertain factor. NHTSA expects that the CAFE alternatives would reduce the changes in precipitation in proportion to their effects on temperature.

The global mean change in precipitation provided by the IPCC for the A2 (high), A1B (medium), and B1 (low) scenarios (Meehl *et al.* 2007) is given as the scaled change in precipitation (as a percentage change from 1980-1999 averages) divided by the increase in global mean surface warming for the same period (per °C), as shown in Table 4.4-5 below. IPCC provided scaling factors in the year ranges 2011-2030, 2046-2065, 2080-2099, and 2180-2199. The scaling factors for the A1B (medium) scenario were used in this FEIS analysis because MAGICC does not directly estimate changes in global mean precipitation.

Table 4.4-5

Global Mean Precipitation Change (scaled, % per °C) (Meehl *et al.* 2007)

Scenario	2011-2030	2046-2065	2080-2099	2180-2199
A2	1.38	1.33	1.45	NA
A1B	1.45	1.51	1.63	1.68
B1	1.62	1.65	1.88	1.89

Applying these scaling factors to the reductions in global mean surface warming provides estimates of changes in global mean precipitation. Given that the action alternatives would reduce temperature increases slightly relative to the No Action Alternative, they also would reduce predicted increases in precipitation slightly, as shown in Table 4.4-6 (again, based on the A1B [medium] scenario).

In addition to changes in mean annual precipitation, climate change is anticipated to affect the intensity of precipitation as described below (Meehl *et al.* 2007):

> "Intensity of precipitation events is projected to increase, particularly in tropical and high latitude areas that experience increases in mean precipitation. Even in areas where mean precipitation decreases (most subtropical and mid-latitude regions), precipitation intensity is projected to increase but there would be longer periods between rainfall events. There is a tendency for drying of the mid-continental areas during summer, indicating a greater risk of droughts in those regions. Precipitation extremes increase more than does the mean in most tropical and mid- and high-latitude areas."

Regional variations and changes in the intensity of precipitation events cannot be quantified further. This inability is due primarily to the lack of availability of AOGCMS required to estimate these changes. AOGCMS are typically used to provide results among scenarios having very large changes in emissions such as the SRES B1 (low), A1B (medium), and A2 (high) scenarios; very small changes in emissions profiles produce results that would be difficult to resolve among scenarios having relatively small changes in emissions. Also, the multiple AOGCMs produce results that are regionally consistent in some cases but are inconsistent in others.

Table 4.4-6

Reference Case MY 2011-2015 Standards and Potential MY 2016-2020 Standards Cumulative Impact on Reductions in Global Mean Precipitation based on A1B a/ SRES Scenario (% change), Using Increases in Global Mean Surface Temperature Simulated by the MAGICC Model

Scenario	2020	2055	2090
Global Mean Precipitation Change (scaled, % K-1)

7. Technology Exhaustion	0.00%	0.01%	0.03%

a/ The A1B scenario is the SRES marker scenario used by the IPCC WGI to represent the SRES A1B (medium) storyline.

Table 4.4-7 summarizes the regional changes to precipitation from the IPCC Fourth Assessment Report. Quantifying the changes to regional climate from the action alternatives is not possible at this point, but the action alternatives would reduce the changes relative to the reduction in global mean surface temperature.[20]

Table 4.4-7

Summary of Regional Changes to Precipitation Extracted from the IPCC Fourth Assessment (Christensen *et al.* 2007)

Land Area	Sub-region	Precipitation	Snow Season and Snow Depth
Africa	Mediterranean area and northern Sahara	*Very likely* to decrease	
	Southern Africa and western margins	Winter rainfall *likely* to decrease in southern	
	East Africa	*Likely* to be an increase in annual mean precipitation	
Mediterranean and Europe	Northern Europe	*Very likely* to increase and extremes are *likely* to increase	*Likely* to decrease
	Southern and Central Europe		
	Mediterranean area	*Very likely* to decrease and precipitation days *very likely* to decrease	
Asia	Central Asia	Precipitation in summer *likely* to decrease	
	Tibetan Plateau	Precipitation in boreal winter *very likely* to increase	
	Northern Asia	Precipitation in boreal winter *very likely* to increase Precipitation in summer *likely* to increase	
	Eastern Asia	Precipitation in boreal winter *likely* to increase Precipitation in summer *likely* to increase *Very likely* to be an increase in the frequency of intense precipitation Extreme precipitation and winds associated with tropical cyclones *likely* to increase	

[20] *See* 42 U.S.C. § 4332 (requiring federal agencies to "identify and develop methods and procedures … which will insure that presently unquantified environmental amenities and values may be given appropriate consideration"); 40 CFR § 1502.23 (requiring an EIS to discuss the relationship between a cost-benefit analysis and any analyses of unquantified environmental impacts, values, and amenities); CEQ, *Considering Cumulative Effects Under the National Environmental Policy Act* (1984), *available at* http://ceq.hss.doe.gov/nepa/ccenepa/ccenepa.htm (last visited June 20, 2008) (recognizing that agencies are sometimes "limited to qualitative evaluations of effects because cause-and-effect relationships are poorly understood" or cannot be quantified).

Table 4.4-7 (cont'd)

Summary of Regional Changes to Precipitation Extracted from the IPCC Fourth Assessment (Christensen *et al*. 2007)

Land Area	Sub-region	Precipitation	Snow Season and Snow Depth
	South Asia	Precipitation in summer *likely* to increase *Very likely* to be an increase in the frequency of intense precipitation Extreme precipitation and winds associated with tropical cyclones *likely* to increase	
	Southeast Asia	Precipitation in boreal winter *likely* to increase in southern parts Precipitation in summer *likely* to increase in most parts of southeast Asia Extreme precipitation and winds associated with tropical cyclones *likely* to increase	
North America	Northern regions/Northern North America		Snow season length and snow depth *very likely* to decrease
	Southwest	Annual mean precipitation is *likely* to decrease	
	Northeast USA	Annual mean precipitation *very likely* to increase	
	Southern Canada		
	Canada	Annual mean precipitation *very likely* to increase	
	Northernmost part of Canada		Snow season length and snow depth *likely* to increase
Central and South America	Southern South America		
	Central America	Annual precipitation *likely* to decrease	
	Southern Andes	Annual precipitation *likely* to decrease	
	Tierra del Fuego	Winter precipitation *likely* to increase	
	Southeastern South America	Summer precipitation *likely* to increase	
	Northern South America	Uncertain how precipitation will change	
Australia and New Zealand	Southern Australia	Precipitation *likely* to decrease in winter and spring	
	Southwestern Australia	Precipitation *very likely* to decrease in winter	
	Rest of Australia		
	New Zealand, South Island	Precipitation *likely* to increase in the west	
	Rest of New Zealand		

Table 4.4-7 (cont'd)

Summary of Regional Changes to Precipitation Extracted from the IPCC Fourth Assessment (Christensen *et al*. 2007)

Land Area	Sub-region	Precipitation	Snow Season and Snow Depth
Polar Regions	Arctic	Annual precipitation *very likely* to increase; *Very likely* that the relative precipitation increase will be largest in winter and smallest in summer	
	Antarctic	Precipitation *likely* to increase	
Small Islands		Mixed, depending on the region	

4.4.4.2.4 Sea-level Rise

IPCC identifies four primary components to sea-level rise: thermal expansion of ocean water, melting of glaciers and ice caps, loss of land-based ice in Antarctica, and loss of land-based ice in Greenland (IPCC 2007c). Ice sheet discharge is an additional factor that could influence sea level over the long term. MAGICC calculates the oceanic thermal expansion component of global-mean sea-level rise, using a non-linear temperature- and pressure-dependent expansion coefficient (Wigley 2003 to 2008). The model also addresses the other three primary components using ice-melt models for small glaciers and the Greenland and Antarctic ice sheets, and excludes non-melt sources, which the IPCC Fourth Assessment Report also excluded. Neither MAGICC 5.3 nor the Fourth Assessment Report include the more recent information suggesting accelerated ice flow from Greenland and Antarctica, which the Fourth Assessment Report estimates to be between 9 and 17 centimeters by 2100 (Wigley 2008).

The state of the science reflected in the IPCC Fourth Assessment Report projects sea level to rise 18 to 59 centimeters by 2090-2099 (Parry *et al.* 2007, as cited in National Science and Technology Council 2008). This projection does not include all changes in ice sheet flow or the potential for rapid acceleration in ice loss (Alley *et al.* 2005, Gregory and Huybrechts 2006, Hansen 2005, all as cited in Pew 2007). Several recent studies have found that the IPCC projections of potential sea-level rise could underestimate ice loss from the Greenland and Antarctic ice sheets (Shepherd and Wingham 2007, Csatho *et al.* 2008) and ice loss from mountain glaciers (Meier *et al.* 2007). Further, IPCC might underestimate sea-level rise that would be gained through changes in global precipitation (Wentz *et al.* 2007, Zhang *et al.* 2007). Rahmstorf (2007) used a semi-empirical approach to project future sea-level rise. The approach yielded a proportionality coefficient of 3.4 millimeters (mm) per year per °C of warming, and a projected sea-level rise of 0.5 to 1.4 meter (m) above 1990 levels in 2100 when applying IPCC Third Assessment Report warming scenarios. Rahmstorf (2007) concludes that, "A rise over 1 m [meter] by 2100 for strong warming scenarios cannot be ruled out." Section 4.5.5 of this FEIS discusses sea-level rise in more detail.

The impact on sea-level rise from the scenarios is presented in Table 4.4-3, showing sea-level rise in 2100 ranging from 37.10 centimeters for the No Action Alternative to 36.92 centimeters for the Technology Exhaustion Alternative, for a maximum reduction of 0.18 centimeter by 2100 from the CAFE alternatives.

In summary, the impacts of the MY 2011-2015 and MY 2016-2020 standards on global mean surface temperature, sea-level rise, and precipitation are relatively small in the context of the expected changes associated with the emissions trajectories in the SRES scenarios. This is due primarily to the global and multi-sectoral nature of the climate problem.

4.4.4.2.5 SRES and Climate Sensitivity Variants

NHTSA examined the sensitivity of climate effects to key assumptions used in the analysis. This examination included reviewing the impact of the Optimized Alternative (Alternative 3) with various scenarios of global emissions and with various climate sensitivities. The results from the additional sensitivity runs for the action alternatives are presented with the Reference Case results (medium-level CAFE assumptions, 3.0 °C for a doubling of CO_2 climate sensitivity, SRES A1B emissions scenario).

The use of alternative global emissions scenarios can influence the results in several ways. Emissions reductions can lead to larger reductions in the CO_2 concentrations in later years because more of the anthropogenic emissions can be expected to stay in the atmosphere. The use of different climate sensitivities (the equilibrium warming that occurs at a doubling of CO_2 from pre-industrial levels) can affect not only warming but also indirectly affect sea-level rise and CO_2 concentration.

As shown in Table 4.4-8, the sensitivity of the simulated CO_2 emissions in 2030, 2060, and 2100 to assumptions of global emissions and climate sensitivity is low. The Optimized Alternative (Alternative 3) has the greatest impact in the SRES scenarios with the highest CO_2 emissions (A2 and A1FI) and the least impact in the scenarios with the lowest CO_2 emissions (B1). The total range of the impact of the Optimized Alternative on CO_2 concentrations in 2100 is from 2.1 to 2.6 ppm. The Reference Case using A1B and a 3.0 °C climate sensitivity has an impact of 2.4 ppm.

The sensitivity of the simulated global mean surface temperatures for 2030, 2060, and 2100 varies, as shown in Table 4.4-9. In 2030, the impact is low due primarily to the rate at which the global mean surface temperature increases in response to increases in radiative forcing. In 2100, the impact is large due not only to the climate sensitivity but also to the change in emissions. In 2030, the change from the 2.5 °C climate sensitivity to the 4.5 °C climate sensitivity is consistently 0.3 °C, as listed in Table 4.4-9. The impact on global mean surface temperature due to assumptions concerning global emissions of GHG is also important. The scenarios with the higher global emissions of GHGs such as A2 and A1FI have a lower reduction in global mean surface temperature and the scenarios with lower global emissions have a higher reduction. This is in large part due to the non-linear and near-logarithmic relationship between radiative forcing and CO_2 concentrations. At high emissions levels, CO_2 concentrations are high and, as a result, a fixed reduction in emissions yields a lower reduction in radiative forcing and global mean surface temperature.

The sensitivity of the simulated sea-level rise to change in climate sensitivity and global GHG emissions mirrors that of global temperature as shown in Table 4.4-10. Scenarios with lower climate sensitivities have lower increases in sea-level rise; the reduction in the increase in sea-level rise is lower with the Optimized Alternative. Conversely, scenarios with higher climate sensitivities have higher sea-level rise and the reduction in the increase of sea-level rise is less with the Optimized Alternative. Higher global GHG emissions have higher sea-level rise but the impact of the Optimized Alternative is less; conversely, lower global GHG emissions have lower sea-level rise and the reduction in sea-level rise is greater in the Optimized Alternative.

4.4.5 Input Scenarios

In response to public comments, and to test how different economic assumptions might affect estimates of emissions reductions and resulting climate effects, NHTSA modeled three additional scenarios – High, Mid-1, and Mid-2 – and compared the results to the Reference Scenario. Variables that were altered include fuel price, the social cost of carbon, oil import externalities, and the discount rate for other benefits.

For the High Scenario, NHTSA used the AEO 2008 high fuel prices, a social cost of carbon of $33/ton (2007 dollars), and a 3-percent discount rate for other benefits. Tables 4.4-11 and 4.4-12 show the emissions and emissions reductions due to the High Scenario.

Table 4.4-11

High Scenario MY 2011-2015 Standards and Potential MY 2016-2020 Standards Cumulative Emissions and Emissions Reductions for 2010 through 2100 (MMTCO$_2$)

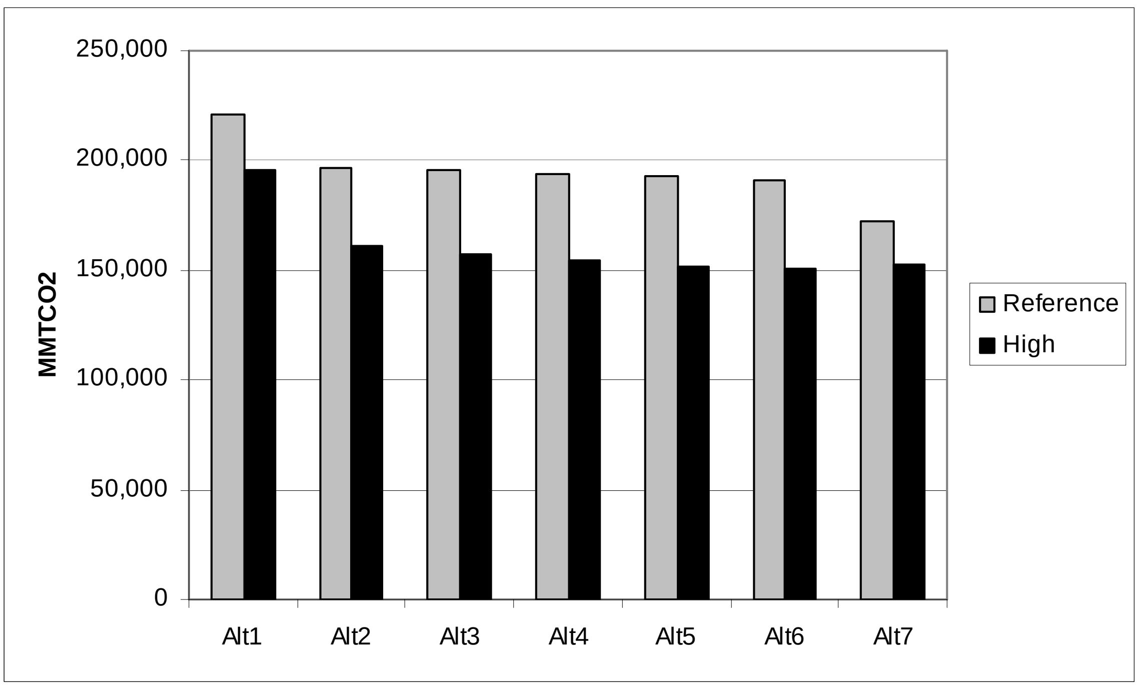
a/ The A1B scenario is the SRES marker scenario used by the IPCC WGI to represent the SRES A1B (medium) storyline.

Compared to the Reference Case, total emissions under the High Scenario were lower for all alternatives (*see* Figure 4.4-11). The primary reason for this difference is the lower VMT forecast under the High Scenario. Emissions reductions for Alternatives 2 through 7 compared to the No Action Alternative were all higher under the High Scenario than under the Reference Case, except for the Technology Exhaustion Alternative (*see* Figure 4.4-12). Emissions reductions were greater under the Technology Exhaustion Alternative for the Reference Case than for the High Scenario.

Table 4.4-12 lists the resulting effects on CO_2 concentration, global mean surface temperature, and sea-level rise. Under the High Scenario, the resulting CO_2 concentration, global mean surface temperature, and sea-level rise were lower than under the Reference Case for all action alternatives except the Technology Exhaustion Alternative. Thus, the differences for the action alternatives compared to the No Action Alternative are greater under the High Scenario than under the Reference Case, except for the Technology Exhaustion Alternative.[21]

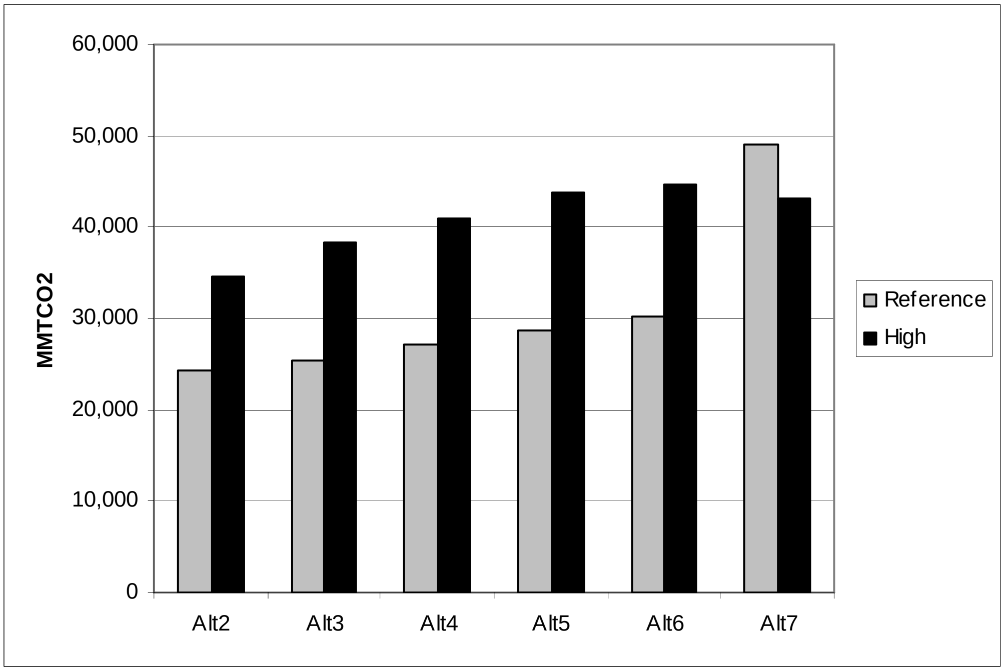
For the Mid-1 Scenario, NHTSA used the AEO 2008 high fuel prices, a social cost of carbon of $33/ton (2007 dollars), and a 7-percent discount rate for other benefits. Compared to the Reference Case, total emissions under the Mid-1 Scenario were lower for all alternatives. Emission reductions for all alternatives compared to the No Action Alternative were higher under the Mid-1 Scenario as compared to the Reference Case, except for the Technology Exhaustion Alternative. The primary reason for this

Figure 4.4-11. Comparison of Cumulative Emissions under the Reference Case and High Scenario Due to the MY 2011-2020 CAFE Standards from 2010-2100 (MMTCO$_2$)



[21] Note that in both the Reference Case and the High Scenario, the No Action Alternative is modeled to have the same emissions, *viz*. emissions set to the A1B scenario. This is the case even though, in absolute terms, U.S. passenger-care and light-truck emissions are lower in the High Scenario than in the Reference Case. In other words, the MAGICC model runs are intended to show relative differences in relation to a no action case; they are not intended to show absolute differences between Volpe model assumptions.

Figure 4.4-12. Comparison of Cumulative Emissions Reductions under the Reference Case and High Scenario Due to the MY 2011-2020 CAFE Standards from 2010-2100 ($MMTCO_2$)



difference is the lower VMT forecast under the Mid-1 Scenario. The resulting CO_2 concentration, global mean surface temperature, and sea-level rise were lower for all alternatives under the Mid-1 Scenario than under the Reference Case, except for the Technology Exhaustion Alternative. Thus, the differences between the action alternatives and the No Action Alternative are greater for the Mid-1 Scenario than for the Reference Case except for the Technology Exhaustion Alternative.

For the Mid-2 Scenario, NHTSA used the AEO 2008 high fuel prices, a social cost of carbon of $2/ton (2007 dollars), and a 7% discount rate for other benefits. Compared to the Reference Case, total emissions under the Mid-1 Scenario were lower for all alternatives. Emissions reductions compared to the No Action alternative were higher for all alternatives under the Mid-2 Scenario as compared to the Reference Case, except for the Technology Exhaustion Alternative. The primary reason for this difference is the lower VMT forecast under the Mid-2 Scenario. The resulting CO_2 concentration, global mean surface temperature, and sea-level rise were lower for all alternatives under the Mid-2 Scenario, except for the Technology Exhaustion Alternative. Thus, the differences between the action alternatives and to the No Action Alternative are greater under the Mid-2 Scenario than under the Reference Scenario, except for the Technology Exhaustion Alternative.

Appendix B presents the results from analysis of the Mid-1 and Mid-2 Scenarios.

4.5 RESOURCE IMPACTS OF CLIMATE CHANGE

4.5.1 Introduction

The effects of the alternative CAFE standards on climate as described in Section 4.4 – CO_2 concentrations, temperature, precipitation, and sea-level rise – can translate into impacts on key natural and human resources, including freshwater resources; terrestrial ecosystems; coastal systems and low-lying areas; managed ecosystems that produce food, fiber, and forest products; industry, settlements, society, and other aspects of the built environment; and human health. This section describes the impacts associated with climate change on each resource.

After a discussion of methodology, Section 4.5 is divided into six sections, one for each resource area. Each section discusses the affected environment, provides an overview of the resource globally and in the United States, and addresses the consequences of climate change on that resource. Observed changes are also reported. In each section, both positive and negative effects of climate change, as they are represented in the literature, are presented. The sections are:

- Freshwater resources
- Terrestrial ecosystems
- Coastal systems and low-lying areas
- Food, fiber, and forests
- Industry, settlements, and society
- Human health

The sections generally follow the organization of topic areas in the climate literature, notably by IPCC, which is a key source for much of the information presented in this section, and by USCCSP. These categories do not follow the classification of resources typically found in an EIS. *See* the chart in Section 4.1 to find where specific NEPA topics are covered.

As shown in Section 4.4, although the alternatives could substantially decrease GHG emissions, they do not prevent climate change from occurring; instead they would only result in small reductions in the anticipated increases in CO_2 concentrations, temperature, precipitation, and sea level. As discussed below, NHTSA's assumption is that these reductions in climate effects would be reflected in reduced impacts on affected resources. However, the magnitude of the changes in climate effects that the alternatives produce – a few ppm of CO_2, a hundredth of a °C difference in temperature, a small percentage change in the rate of precipitation increase, and 1 or 2 mm of sea-level rise – are too small to address quantitatively in terms of their impacts on resources. Given the enormous resource values at stake, these distinctions could be important – very small percentages of huge numbers can still yield substantial results – but they are too small for current quantitative techniques to resolve. Consequently, the discussion of resource impacts does not distinguish among the CAFE alternatives, but rather provides a qualitative review of the benefits of reducing GHG emissions and the magnitude of the risks involved in climate change.

4.5.2 Methodology

NHTSA reviewed various reports to assess the cumulative impacts of the proposed action. The key reports consulted for material include the IPCC Fourth Assessment Report by Working Group II (WGII) entitled *Climate Change 2007 – Impacts, Adaptation, and Vulnerability* (IPCC 2007b), and the

USCCSP SAP Reports. NHTSA reviewed the National Science and Technology Council's *Scientific Assessment of the Effects of Global Climate Change on the United States*, and SAP Reports, as follows:

- SAP 4.1, Coastal Elevations and Sensitivity to Sea Level Rise
- SAP 4.2, Thresholds of Change in Ecosystems
- SAP 4.3, The Effects of Climate Change on Agriculture, Land Resources, Water Resources, and Biodiversity
- SAP 4.4, Preliminary Review of Adaptation Options for Climate-Sensitive Ecosystems and Resources
- SAP 4.5, Effects of Climate Change on Energy Production and Use in the United States
- SAP 4.6, Analyses of the Effects of Global Change on Human Health and Welfare and Human Systems
- SAP 4.7, Impacts of Climate Variability and Change on Transportation Systems and Infrastructure — Gulf Coast Study

Not all of the SAP Reports are final; although publicly available and generally in later stages of review and revision, some were still in draft form at the time NHTSA prepared this FEIS. More information on the SAP Reports can be found at www.climatescience.gov/Library/sap. Researchers also referenced additional studies published since the release of the IPCC and SAP reports.

NHTSA compiled research was compiled on freshwater resources; ecosystems and biodiversity; coastal and low-lying areas; industry, settlement and society; food, fiber, and forest products; and human health. Each section provides an introduction and addresses the impacts and adaptations anticipated for both the United States and the global environment. To assess the impacts of climate change on the United States, NHTSA first consulted the SAP Reports and then examined more recent materials of relevance, such as the Natural Resources Defense Council (NRDC) *Cost of Climate Change* (NRDC 2008), the Union of Concerned Scientists (UCS) *Confronting Climate Change in the U.S. Northeast* (Frumhoff *et al.* 2007), and the University of Maryland's (UMD) *The US Economic Impacts of Climate Change and the Costs of Inaction* (CIER 2007). The global impacts sections focus on the IPCC Fourth Assessment Report because it is the most recent, comprehensive, and peer-reviewed material on this topic. Articles and studies cited within the IPCC Report also were consulted for additional information on various topics.

To accurately reflect the likelihood of climate change impacts for each sector, NHTSA referenced the IPCC uncertainty guidelines. This approach provided a consistent methodology to define confidence levels and percent probability of a predicted outcome or impact. More information on the uncertainty guidelines is provided in the *Treatment of Uncertainties in the IPCC's Working Group II Assessment* in Solomon *et al.* (2007).

4.5.2.1 Cumulative Climate Impacts of Alternative CAFE Standards

As described in Chapter 3, the alternative CAFE standards being considered result in different periods of CO_2 emissions associated with the operation of U.S. vehicles. These emissions, in combination with U.S. GHG emissions from other sources (such as power plants, natural gas use, and agricultural production) and with emissions of all GHGs globally, would alter atmospheric concentrations of GHGs. As the modeling results presented in Section 4.4 show, different atmospheric concentrations of GHGs will be associated with long-term changes in global climate variables, including global average temperature, precipitation, and rising sea level. In turn, these climate changes would result in changes to a range of natural and human resources and systems, including water supplies, human health, the built environment, and a host of others.

The most common approach to assessing the impacts of climate change is to construct future scenarios that represent combinations of changes in levels, and sometimes patterns or variability, of temperature, precipitation, sea-level rise, and other relevant climatic and related variables (IPCC 2007b). In some cases these scenarios will represent the results of specific climate modeling (the output of General Circulation Models [GCMs]), often downscaled to provide results at a finer level of geographic resolution. In other cases, scenarios might be designed to be representative of the *types* and *ranges* of effects that are expected to occur under climate change, and not the results of specific models (Parsons *et al.* 2007). Impacts associated with these scenarios are then estimated using a variety of techniques, including models of individual systems (specific ecosystems or geographic areas, such as a park) and examination of performance under similar historical conditions.

The impacts literature suggests that some regions and sectors will experience positive effects of future climate change, particularly at lower levels of temperature change (less than 1 to 3 °C above 1990 levels), while others will experience negative effects (IPCC 2007b). The IPCC WGII for the Fourth Assessment Report found that, at higher levels of temperature, on balance the net global effects are expected to be negative: "while developing countries are expected to experience larger percentage losses, global mean losses could be 1 to 5 percent gross domestic product (GDP) for 4 °C of warming" (IPCC 2007b). To put these numbers in context, the IPCC has projected longer term warming (associated with a doubling of CO_2 concentrations) in the range of 2 to 4.5 °C (IPCC 2007a). The modeling results presented in Section 4.4 suggest that, for the CAFE alternatives, the cumulative climate effects in terms of temperature rise under a moderate emissions scenario lie in the range of 2.7 to 2.8 °C as of 2100.

NHTSA's presumption, consistent with the general literature cited above and reviewed for Section 4.5, is that reducing emissions and concomitant climate effects will reduce the net negative long-term effects that have been projected for climate change. NHTSA has not, however, conducted a quantitative comparison of the climate impacts of the alternative CAFE standards, for several reasons.

First, as indicated above, analyses of impacts often focus on discrete climate scenarios, rather than a continuum of climate outcomes; the information to analyze small changes in climate variables is not, therefore, generally available in the literature. Moreover, as the global climate changes, so will regional and local climates. Changes in global climate variables will be reflected in regional and local changes in average climate variables, and in the variability and patterns of climate, such as seasonal and annual variations, the frequency and intensity of extreme events, and other physical changes, such as the timing and amount of snowmelt. Impacts assessments often rely on highly localized data for both climate and other conditions and circumstances (CCSP 2008f). Thus, changes in impacts due to changes in global average climate, as projected in this analysis, likely will not be adequately represented by a simple scaling of results. Where information in the analysis included in the FEIS is incomplete or unavailable, the agency has relied on CEQ regulations regarding incomplete or unavailable information (*see* 40 CFR § 1502.22(b)). Information on the effect of very small changes in temperature, precipitation, and sea-level rise (at the scale of the distinctions among the alternative CAFE standards) is not currently available. Nevertheless, NHTSA's qualitative characterization – that the greater the reductions in GHG emissions, the lower the environmental impact – is consistent with theoretical approaches and research methods generally accepted in the scientific community.

Second, there is considerable debate about the likely shape of a global climate impacts damage function; although many believe the function to be upwardly sloped (so that marginal net damages increase with increasing levels of climate change), fewer agree on its shape, that is, how *rapidly* net climate damages increase as temperature and other variables increase (IPCC 2007b). There is also the important question of whether thresholds exist, that is, stress points at which ecosystems collapse or the negative impacts rapidly accelerate – a topic important enough to warrant attention in an SAP Report on which the U.S. Geological Survey (USGS) is the lead agency. Finally, much of the work on impacts – both global and more localized – is, in and of itself, qualitative and so does not lend itself to further quantification.

NHTSA assumes that reductions in climate effects due to the alternative CAFE standards would be reflected in reduced impacts on affected resources. However, the magnitudes of the changes in these climate effects that the alternatives might produce – a few ppm of CO_2, a hundredth of a °C difference in temperature, a small percentage change in the rate of precipitation increase, and 1 or 2 mm of sea level – are too small to address quantitatively in terms of their impacts on resources. Consequently, the discussion of resource impacts does not distinguish among the alternative CAFE standards, but rather provides an overview of climate impacts and therefore a qualitative review of the benefits of reducing GHG emissions and the magnitude of the risks involved in climate change.

NHTSA assumes that reductions in emissions and, therefore, climate effects would be reflected in reduced impacts on affected resources. However, the magnitudes of the changes in the climate effects that the alternative CAFE standards might produce are too small to address quantitatively in terms of their impacts on resources. Consequently, as discussed further in Section 4.5.2, the discussion of resource impacts does not distinguish among the CAFE alternatives. Where information in the analysis included in this FEIS is incomplete or unavailable, the agency has relied on CEQ regulations related to incomplete or unavailable information (40 CFR § 1502.22(b)). Information on the effects of very small changes in temperature, precipitation, and sea-level rise (at the scale of the distinctions among the CAFE alternatives) is not currently available. Nevertheless, NHTSA's qualitative characterization - that the greater the reductions in GHG emissions, the lower the environmental impact - is consistent with theoretical approaches and research methods generally accepted in the scientific community.

4.5.2.2 Treatment of Uncertainties in the Working Group I Assessment

Uncertainties can be classified in several different ways. "Value uncertainties" and "structural uncertainties" are two primary types of uncertainties. When data are inaccurate or do not fully represent the phenomenon of interest, value uncertainties arise. These types of uncertainties are typically estimated with statistical techniques, and then expressed probabilistically. An incomplete understanding of the process that controls particular values or results generates structural uncertainties. These types of uncertainties are described by presenting the authors' collective judgment of their confidence in the correctness of a result. As stated in the WGI Assessment, a "careful distinction between levels of confidence in scientific understanding and the likelihoods of specific results" are drawn in the uncertainty guidance provided for the Fourth Assessment Report.

The standard terms used to define levels of confidence are:

Confidence Terminology	Degree of Confidence in Being Correct
Very high confidence	At least 9 out of 10 chance
High confidence	About 8 out of 10 chance
Medium confidence	About 5 out of 10 chance
Low confidence	About 2 out of 10 chance
Very low confidence	Less than 1 out of 10 chance

The standard terms used to define the likelihood of an outcome or result where the outcome or result can be estimated probabilistically are:

Likelihood Terminology	Likelihood of the Occurrence/Outcome
Virtually certain	Greater than 99% probability
Extremely likely	Greater than 95% probability
Very likely	Greater than 90% probability
Likely	Greater than 66% probability
More likely than not	Greater than 50% probability
About as likely as not	33 to 66% probability
Unlikely	Less than 33% probability
Very unlikely	Less than 10% probability
Extremely unlikely	Less than 5% probability
Exceptionally unlikely	Less than 1% probability

4.5.3 Freshwater Resources

This section addresses climate-related impacts on freshwater resources. Water is necessary to support life, societal welfare, and economic activity. "Given water's importance, plant, animal, and human communities are all sensitive to variations in the availability, storage, fluxes, and quality of surface and groundwater. These, in turn, are sensitive to climate change" (National Science and Technology Council 2008).

4.5.3.1 Affected Environment

This affected environment section for freshwater resources is based on information contained in *World Water Resources at the Beginning of the 21st Century* (Shiklomanov and Rodda 2003), the United Nations Educational, Scientific and Cultural Organization – World Water Assessment Program (UNESCO-WWAP) *World Water Development Report 2* (UNESCO and WWAP 2006), and *Pilot Analysis of Global Ecosystems: Freshwater Systems* (Revenga *et al.* 2000).

Water supports all life on Earth. About 70 percent of Earth's surface is covered by water, and most (97.5 percent) is contained in the oceans. Freshwater refers to the 2.5 percent of Earth's hydrosphere that is not saline. The freshwater resource is divided among glaciers (68.7 percent), groundwater (30.1 percent), permafrost (0.8 percent), and surface and atmospheric water (0.4 percent). The 0.4 percent occurs as freshwater lakes (67.4 percent) and wetlands (8.5 percent), rivers (1.6 percent), soil moisture (12.2 percent), water in the atmosphere (9.5 percent), and water in living organisms (0.8 percent) (Shiklomanov and Rodda 2003, as cited in UNESCO and WWAP 2006).

The largest volume of freshwater is frozen in glaciers and ice sheets, most of which occur in Antarctica (almost 90 percent), with the remainder found in Greenland (almost 10 percent) and in mountain glaciers. Permafrost extends over northeastern Europe and the northern and northeastern parts of Asia, including the Arctic islands, northern Canada, the fringes of Greenland and Antarctica, and the high-altitude areas of South America.

Groundwater is the second largest source of freshwater. Groundwater occurs in the pores of soils and fractures of rocks and is the largest source of unfrozen freshwater. Groundwater feeds springs, streams, and lakes; supports wetlands; and is a critical source of water for human consumption. Groundwater also includes aquifers, underground strata of water-bearing permeable rock or unconsolidated materials (sand, gravel, and some silts and clays) from which water can be extracted using well systems.

Lakes, which can be broadly defined as bodies of water collected in depressions in Earth's surface, are widespread and numerous (there are around 15 million) and store the largest volume of fresh surface waters. Reservoirs, which could be considered lakes, are enclosed areas constructed for the storage of water, and are typically created by damming a river channel in a valley.

Wetlands, such as marshes, swamps, bogs, and estuaries, are transitional zones between land and water environments where the soil is frequently or permanently waterlogged. Wetlands of various types exist all over the world. During the 20^{th} Century, half of them are estimated to have been lost as land was converted to agriculture and urban use or filled to combat disease.

Rivers are bodies of flowing water that drain surface runoff from land to the seas and oceans. They begin in higher elevations such as mountains and hills where rainwater and snowmelt collect, forming small tributary streams that flow into larger streams and rivers.

Soil moisture is water that drains into the soil, mainly the top 2 meters, and becomes part of the soil water store, where it is used by plants.

Water exists in the atmosphere in the form of water vapor, water drops, and ice crystals, and falls as precipitation, which occurs as rain, snow, sleet, hail, frost, or dew. Biological water is the water contained in living organisms such as plants and animals.

Much of the discussion that follows below is drawn from the following studies and their citations: the IPCC *Freshwater Resources and their Management* (Kundzewicz *et al.* 2007), the National Science and Technology Council *Scientific Assessment of the Effects of Global Change on the United States* (National Science and Technology Council 2008), *World Water Resources at the Beginning of the 21^{st} Century* (Shiklomanov and Rodda 2003), *Pilot Analysis of Global Ecosystems: Freshwater Systems* (Revenga *et al.* 2000), and *Threats to the World's Freshwater Resources* (Glick *et al.* 2001).

4.5.3.2 Non-climate Threats to Freshwater Resources

Pressure on global freshwater resources during recent decades is a result of non-climatic as well as climatic drivers. The non-climate threats include changes in population, economy, and technology. Population growth and economic development create increasing demands from the industrial, municipal, and agricultural sectors. For example, irrigated agriculture to support the demand for food accounts for nearly 70 percent of global freshwater withdrawals and for more than 90 percent of global consumptive use (Shiklomanov and Rodda 2003, as cited in Kundzewicz *et al.* 2007). The extent of irrigated areas, which is expected to expand in areas that are already water-stressed, will determine the effect that this use will have on global water use in the future.

The driving threats to the world's supply of freshwater resources are consistently reported in the literature: population growth and increased demand; infrastructure development (dams, dikes, levees, and river diversions); poor land use (urbanization, conversion to crop or grazing lands, wetland removal or reduction, deforestation); overexploitation (groundwater aquifer depletion and reduced water levels in lakes, rivers, and wetlands); water pollution from industrial, municipal, and agricultural sources (phosphorus and nitrogen from fertilizers, pesticides, pathogens and microbial contaminants, heavy metals, toxic organic compounds and micro-organic pollutants); silt and suspended particles (from soil erosion); acidification (from air pollution); and thermal pollution (from industrial discharges and slow flows caused by dams and reservoirs).

Shiklomanov and Rodda (2003) state that "Every year human influences grow and cause more and more changes to natural processes…These changes bring about alterations to the water balance and to water resources and their availability. The rapid growth of population, the development of industrial production and the rise of agriculture have resulted in the increased use of water…Human activities have also changed the character of groundwater…more often the water table has been lowered to provide water for drinking…The construction of reservoirs has led to the slowing down of the movement of river waters. Slowing the movement of water can influence its quality particularly by the accumulation of pollutants."

The freshwater resources in the United States are affected by the same non-climate threats discussed above. The National Science and Technology Council (2008) found that "most water quality changes observed so far across the continental United States are likely attributable to causes other than climate change." EPA cites siltation, nutrients, and metals (*e.g.*, mercury) as the main sources of pollution in U.S. waters, primarily as a result of nonpoint source pollution from urban and agricultural lands (EPA 2000b, EPA 2002b).

Ecosystem integrity, as defined by Glick *et al.* (2001), is the interaction between the biological processes and chemical processes that support the functioning of an ecosystem and the health of the species it supports. Water withdrawal and consumption by humans is directly connected to the integrity of freshwater ecosystems, because these uses compete with natural systems for water and lead to pollution, disrupting natural ecosystem processes. As a result, the health of habitats, and the species that live in them, is affected. Revenga *et al.* (2000) found that between 1900 and 1995, world water withdrawals increased six-fold, more than twice the rate of population growth. As water withdrawals increase, more stress will be put on freshwater ecosystems.

4.5.3.3 Environmental Consequences

Much of the discussion that follows is drawn from the following studies including the citations therein: the IPCC *Freshwater Resources and their Management* (Kundzewicz *et al.* 2007), *Scientific Assessment of the Effects of Global Change on the United States* (National Science and Technology Council 2008), and *The Effects of Climate Change on Agriculture, Land Resources, Water Resources, and Biodiversity in the United States* (Lettenmaier *et al.* 2008). Additional recent studies from peer-reviewed literature are also cited.

Non-climate-related impacts on freshwater resources have received more attention than climate-related impacts to date. However, "climate change is expected to result in increasing effects in the future" (National Science and Technology Council 2008). Climate change effects are especially relevant to freshwater resource management for the future. Freshwater resource infrastructure has been designed to accommodate the variability in water supply based on the historical record. This assumption – that, on average, the future will be the same as the past – is referred to as the "stationarity assumption" (Lettenmaier *et al.* 2008, as cited in National Science and Technology Council 2008). However, this assumption is now challenged by the demonstrated occurrence of climate change (Arnell 2002, Lettenmaier 2003, and Milly *et al.* 2008, all as cited in National Science and Technology Council 2008). As a result, "the global population is highly vulnerable to climate change impacts on freshwater resources" (National Science and Technology Council 2008).

Global warming resulting from the enhanced greenhouse effect causes changes in temperature, precipitation, ice melt, and other climate change effects. Evaporation, transpiration, and the water-holding capacity of the atmosphere all increase at higher temperatures. Increased atmospheric water content favors increased climate variability – more intense droughts and more intense precipitation (Trenberth *et al.* 2003, as cited in Kundzewicz *et al.* 2007).

"While temperatures are expected to increase everywhere over land and during all seasons of the year, although by different increments, precipitation is expected to increase globally and in many river basins, but to decrease in many others" (Kundzewicz *et al.* 2007). Precipitation might also increase in one season and decrease in another (Meehl *et al.* 2007, Section 10.3.2.3, as cited in Kundzewicz *et al.* 2007). Changes in temperature and precipitation are the main climatic drivers observed to affect freshwater availability, quality, and water use. A recent study by Allan and Soden (2008) using satellite observations and model simulations showed a link between rainfall extremes and temperature. The observed amplification of rainfall extremes was larger than other model predictions, leading the authors to infer that "projections of future changes in rainfall extremes due to anthropogenic global warming may be underestimated."

4.5.3.3.1 Globally Observed Climate Effects

General climate change impacts on hydrology and freshwater resources identified to date include the following (Arnell *et al.* 2001, as cited in Kundzewicz *et al.* 2007):

- Changes in streamflow volume – increases and decreases
- Variation in streamflow and groundwater recharge – largely following precipitation
- Shifts in peak streamflow timing – earlier snowmelt
- Lower streamflow in summer and autumn
- Glacier retreat and disappearance of small glaciers
- Water quality degradation – higher water temperatures
- Increases in flood magnitude and frequency

Climate-related trends have already been observed in various inputs, throughputs, and outputs to the freshwater system, including the following (Kundzewicz *et al.* 2007):

- Precipitation – increasing over northern (30°N) latitudes; decreasing over middle latitudes (10°S to 30°N); increasing in intensity

- Snow cover – decreasing in most regions

- Glaciers – decreasing almost everywhere

- Permafrost – thawing between 0.08 inch per year (Alaska) and 1.8 inches per year (Tibetan plateau)

- Streamflow – increasing in Eurasian Arctic, measurable increases or decreases in some river basins; earlier spring peak flows and increased winter-based flows in North America and Eurasia

- Evapotranspiration – increased actual evapotranspiration in some areas

- Lakes – warming, substantial increases and decreases in some lake levels, and reduction in ice cover

For other anticipated changes in the freshwater system, data are insufficient to observe a climate trend, especially when compared to the non-climatic pressures mentioned previously. The absence of an observed trend does not indicate that freshwater resources will not be sensitive to future climate trends. As described in the section on impacts below, changes are also anticipated for groundwater levels, floods, droughts, water quality, erosion and sediment transport, and irrigation water demand (Kundzewicz *et al.* 2007).

4.5.3.3.2 Observed and Projected Impacts of Climate Change on Freshwater Resources in the United States

Most of the freshwater resource analyses are keyed either to climate scenarios (what happens if temperature increases by 6 °F, and precipitation declines by 10 percent) or to global climate model outputs pegged to IPCC-reported emission scenarios. The projected impacts resulting from such analyses, current sensitivities, and potential vulnerabilities (including extreme events) are summarized in this section for the United States and in the next section for the globe.

The climate change impacts on freshwater resources in the United States are described by National Science and Technology Council (2008), Lettenmaier *et al.* (2008), and Field *et al.* (2007).

"In regards to the hydrologic observing systems on which these sections are based, Lettenmaier *et al.* (2008) found that the current hydrologic observing system was not designed specifically for the purpose of detecting the effects of climate change on water resources. In many cases, the resulting data are unable to meet the predictive challenges of a rapidly changing climate" (National Science and Technology Council 2008).

Several recent state and regional studies have examined specific climate change impacts on freshwater resources. For example, many impacts on freshwater resources described above have been predicted for New Mexico (D'Antonio 2006), New Jersey (EPA 1997b), and the West (Saunders *et al.* 2008).

"Projections for the western mountains of the United States suggest that warming, and changes in the form, timing, and amount of precipitation will *very likely* lead to earlier melting and significant reductions in snowpack by the middle of the 21st century" (*high confidence*). "In mountainous snowmelt-dominated watersheds, projections suggest advances in the timing of snowmelt runoff, increases in winter and early spring flows (raising flooding potential), and substantially decreased summer flows. Heavily utilized water systems of the western United States that rely on capturing snowmelt runoff, such as the Columbia River system, will be especially vulnerable" (Field *et al.* 2007, as cited in National Science and Technology Council 2008). Trends in declining snowpack are perhaps best illustrated from studies conducted for California. Reduced snowpack has been identified as a major concern for the State (California Energy Commission 2006, as cited in National Science and Technology Council 2008). Several authors anticipate a coming crisis in water supply for the western United States (Barnett *et al.* 2008), and have projected that Lake Mead (on the Colorado River system) might go dry (Barnett and Pierce 2008). While these studies focus on issues already identified in the literature, their findings suggest that freshwater resources might be more sensitive to climate change than previously projected. A recent article by Rauscher *et al.* (2008) used a high-resolution nested climate model to investigate future changes in snowmelt-driven runoff over the western United States; and modeled increases in seasonal temperature of approximately 3 to 5 °C by 2100, which could cause snowmelt-driven runoff to occur as much as two months earlier than present – twice as early as other predictions – affecting reservoir water storage and hydroelectric generation, and impacting land use, agriculture, and water management.

4.5.3.3.3 Precipitation

Precipitation is the primary driver of the land surface hydrological system. Precipitation variability, and subsequent surface water availability varies regionally across the United States depending on a catchment's (watershed) physical, hydrological, and geological characteristics (National Science and

Technology Council 2008). In general, conditions become increasingly dry from east to west. Upslope areas in the Cascade and coastal mountain ranges are more humid with relatively low precipitation variability. The Intermountain West and Southwest are driest, and the greatest precipitation variability is in the arid and semi-arid West (Lettenmaier *et al.* 2008, as cited in National Science and Technology Council 2008). Stream gauge data (Mauget 2003, as cited in Lettenmaier *et al.* 2008) showed increases in streamflow from 1939 through 1998 in the eastern United States and a more or less reverse pattern in the western United States (National Science and Technology Council 2008).

4.5.3.3.4 Surface Water

The observed impacts on surface water (Field *et al.* 2007, as cited in National Science and Technology Council 2008) include the following:

- Streamflow in the eastern United States has increased 25 percent in the past 60 years (Groisman *et al.* 2004), but over the past century has decreased by about 2 percent per decade in the central Rocky Mountain region (Rood *et al.* 2005).

- Since 1950, stream discharge in both the Colorado and Columbia River Basins has decreased, while over the same time period annual evapotranspiration from the conterminous United States increased by 2.2 inches (Walter *et al.* 2004).

- In regions with winter snow, warming has shifted the magnitude and timing of hydrologic events (Mote *et al.* 2005, Regonda *et al.* 2005, Stewart *et al.* 2005). From 1949 to 2004, the fraction of annual precipitation falling as rain (rather than snow) increased at 74 percent of the weather stations studied in the western mountains of the United States (Knowles *et al.* 2006).

- Spring and summer snow cover has decreased in the western United States (Groisman *et al.* 2004). April snow water equivalent has declined 15 to 30 percent since 1950 in the western mountains of North America, particularly at lower elevations and primarily due to warming rather than changes in precipitation (Mote *et al.* 2003, 2005, Lemke *et al.* 2007, as cited in National Science and Technology Council).

- Streamflow peaks in the snowmelt-dominated western mountains of the United States occurred 1 to 4 weeks earlier in 2002 than in 1948 (Stewart *et al.* 2005).

Lettenmaier *et al.* (2008) assessed the following potential impacts on surface water in the United States (National Science and Technology Council 2008):

- There is a trend toward reduced mountain snowpack and earlier spring snowmelt runoff peaks across much of the western United States. Evidence suggests this trend is *very likely* attributable, at least in part, to long-term warming, although decadal-scale variability, including a shift in Pacific decadal oscillation in the 1970s, might have played some part. Where shifts to earlier snowmelt peaks and reduced summer and fall low flows have already been detected, continuing shifts in this direction are expected and could have substantial impacts on the performance of reservoir systems.

- Recent climate model simulations reported in the IPCC Fourth Assessment Report project increased runoff over the eastern United States, gradually transitioning to little change in the Missouri and lower Mississippi, to substantial decreases in annual runoff in the interior of the West (Colorado and Great Basin). The projected drying in the interior of the West is quite consistent among models. These changes are, very roughly, consistent with observed trends in the second half of the 20th Century, which show increased streamflow over much of the United States, but sporadic decreases in the West.

- Snowpack in the mountainous headwater regions of the western United States generally declined over the second half of the 20th Century, especially at lower elevations and in locations where average winter temperatures are close to or above 0 °C. These trends toward reduced winter snow accumulation and earlier spring melt are also reflected in a tendency toward earlier runoff peaks in the spring, a shift that has not occurred in rainfall-dominated watersheds in the same region.

- Climate model projections of increased temperatures and slight precipitation increases indicate that modest streamflow increases are expected in the East, but that larger (in absolute value) declines are expected in the West, where the balance between precipitation and evaporative demand will shift toward increased evaporative demand. However, because of the uncertainty in climate model projections of precipitation change, future projections of streamflow are highly uncertain across most of the United States. One exception is watersheds that are dominated by spring and summer snowmelt, most of which are in the western United States. In these cases, where shifts to earlier snowmelt peaks and reduced summer and fall low flows have already begun to be detected, continuing shifts in this direction are generally expected and could have substantial impacts on the performance of reservoir systems.

4.5.3.3.5 Groundwater

The effects of climate on groundwater – especially groundwater recharge – is a topic that requires further research to determine effects resulting from climate change. The available literature (Vaccaro 1992, Loaiciga *et al.* 2000, Hanson and Dettinger 2005, Scibek and Allen 2006, Gurdak *et al.* 2007, all as cited in Lettenmaier *et al.* 2008) implies that groundwater systems generally respond more slowly to climate change than surface water systems do. Groundwater levels correlate most strongly with precipitation. Temperature is a more important factor for shallow aquifers during warm periods (National Science and Technology Council 2008).

Groundwater and surface water might also be affected by sea-level rise. Saltwater intrusion into aquifers might occur in coastal areas, and increased salinity of ground and estuary water might reduce freshwater availability.

4.5.3.3.6 Water Quality

Chemical and microbial inputs, biogeochemical processes, water temperature, and water levels control water quality. Water temperature and water quantity are sensitive to climate change. However, pollution from land use – especially agricultural runoff, urban runoff, and thermal pollution from energy production – have caused most of the observed changes in water quality (National Science and Technology Council 2008).

Rising water temperatures negatively affect aquatic biota, especially certain fish species such as salmon (Bartholow 2005, Crozier and Zabel 2006, both as cited in Lettenmaier *et al.* 2008). Rising temperatures also affect dissolved oxygen, oxidation/reduction potentials, lake stratification, and mixing rates. However, the direction of climate change effects associated with water quantity on water quality is not as evident. Increased streamflow can dilute pollutant concentrations or transport additional pollutants into surface water sources. Extreme events – floods and droughts – generally exacerbate water quality problems.

Region-specific studies conducted for the United States were reviewed by IPCC (Field *et al.* 2007, Kundzewicz *et al.* 2007). Projected impacts on water quality include the following (National Science and Technology Council 2008):

- Changes in precipitation could increase nitrogen loads from rivers in the Chesapeake and Delaware Bay regions by up to 50 percent by 2030 (Kundzewicz *et al.* 2007).

- Decreases in snow cover and increases in winter rain on bare soil will *likely* lengthen the erosion season and enhance erosion intensity. This will increase the potential for sediment-related water quality impacts in agricultural areas (Field *et al.* 2007).

- Increased precipitation amounts and intensities will lead to greater rates of erosion in the United States and in other regions unless protection measures are taken (Kundzewicz *et al.* 2007). Soil management practices (crop residue, no-till) in some regions (*e.g.*, the Corn Belt) might not provide sufficient erosion protection against future intense precipitation and associated runoff (Field *et al.* 2007).

- For the Midwest, in simulated low flows used to develop pollutant discharge limits (Total Maximum Daily Loads) flows decrease more than 60 percent with a 25-percent decrease in mean precipitation, declining by 100 percent with the incorporation of irrigation demands (Eheart *et al.* 1999).

- Restoration of beneficial uses (to address habitat loss, eutrophication, beach closures) under the Great Lakes Water Quality Agreement will *likely* be vulnerable to declines in water levels, warmer water temperatures, and more intense precipitation (Mortsch *et al.* 2003).

- Based on simulations, phosphorus remediation targets for the Bay of Quinte (Lake Ontario) and the surrounding watershed could be compromised as 5.4- to 7.2-°F warmer water temperatures contribute to 77 to 98 percent increases in summer phosphorus concentrations in the Bay (Nicholls 1999), and as changes in precipitation, streamflow, and erosion lead to increases in average phosphorus concentrations in streams of 25 to 35 percent (Walker 2001, as cited in Field *et al.* 2007).

Kundzewicz *et al.* (2007) also concluded (*high confidence*) that climate change is *likely* to make achieving existing water quality goals for North America more difficult (National Science and Technology Council 2008).

4.5.3.3.7 Extreme Events—Floods and Drought

Extreme events such as floods and drought affect freshwater resources. Climatic phenomena – intense/long-lasting precipitation, snowmelt, ice jams – and non-climatic phenomena – dam failure, landslides – can exacerbate floods and drought.

As previously mentioned, research to date has not provided clear evidence for a climate-related trend in floods during past decades. However, evidence suggests that the observed increase in precipitation intensity and other observed climate changes could have affected floods (National Science and Technology Council 2008).

Because the intensity and mean amount of precipitation will increase across the United States at middle and high latitudes, the risk of flash flooding and urban flooding will increase in these areas (Kundzewicz *et al.* 2007, as cited in National Science and Technology Council 2008). At the same time, greater temporal variability in precipitation increases the risk of drought (Christensen *et al.* 2007, as cited in National Science and Technology Council 2008).

There is some evidence of long-term drying and increase in drought severity and duration in the West and Southwest (National Science and Technology Council 2008) that is probably a result of decadal-scale climate variability and long-term change (Lettenmaier *et al.* 2008, as cited in National Science and Technology Council 2008).

Over-allocation and continuing competition for freshwater resources for agriculture, cities, and industry increases vulnerability to extended drought in North America (Field *et al.* 2007), despite the fact that per capita water consumption has declined over the past two decades in the United States (Lettenmaier *et al.* 2008). Reducing water consumption will mitigate the impacts of climate change on freshwater resources.

4.5.3.4 Projected Impacts of Climate Change on Global Fresh Water Resources

The IPCC report is the most recent, comprehensive, and peer-reviewed summary of impacts on global freshwater resources available. Kundzewicz *et al.* (2007) summarized the conclusions from the freshwater resources and management chapter as follows:

- The impacts of climate change on freshwater systems and their management are mainly due to the observed and projected increases in temperature, sea level, and precipitation variability (*very high confidence*).

- More than one-sixth of the world's population lives in glacier- or snowmelt-fed river basins and will be affected by the seasonal shift in streamflow, an increase in the ratio of winter to annual flows, and possibly the reduction in low flows caused by decreased glacier extent or snow water storage (*high confidence*).

- Sea-level rise will extend areas of salinization of groundwater and estuaries, resulting in a decrease in freshwater availability for humans and ecosystems in coastal areas (*very high confidence*).

- Increased precipitation intensity and variability is projected to increase the risks of flooding and drought in many areas (*high confidence*).

- Semi-arid and arid areas are particularly exposed to the impacts of climate change on freshwater (*high confidence*).

- Many of these areas (Mediterranean basin, western United States, southern Africa, and northeastern Brazil) will suffer a decrease in water resources due to climate change (*very high confidence*).

- Efforts to offset declining surface water availability due to increasing precipitation variability will be hampered by the fact that groundwater recharge will decrease considerably in some already water-stressed regions (*high confidence*), where vulnerability is often exacerbated by the rapid increase in population and water demand (*very high confidence*).

- Higher water temperatures, increased precipitation intensity, and longer periods of low flows exacerbate many forms of water pollution, with impacts on ecosystems, human health, water system reliability, and operating costs (*high confidence*).
- These pollutants include sediments, nutrients, dissolved organic carbon, pathogens, pesticides, salt, and thermal pollution.
- Climate change affects the function and operation of existing water infrastructure as well as water management practices (*very high confidence*).
- Adverse effects of climate on freshwater systems aggravate the impacts of other stresses, such as population growth, changing economic activity, land use change, and urbanization (*very high confidence*).
- Globally, water demand will grow in the coming decades, primarily due to population growth and increased affluence; regionally, large changes in irrigation water demand as a result of climate change are *likely* (*high confidence*).
- Current water management practices are very likely to be inadequate to reduce the negative impacts of climate change on water supply reliability, flood risk, health, energy, and aquatic ecosystems (*very high confidence*).
- Improved incorporation of current climate variability into water-related management would make adaptation to future climate change easier (*very high confidence*).
- Adaptation procedures and risk management practices for the water sector are being developed in some countries and regions (the Caribbean, Canada, Australia, Netherlands, United Kingdom, United States, and Germany) that have recognized projected hydrological changes with related uncertainties (*very high confidence*).
- Since the IPCC Third Assessment, uncertainties have been evaluated, their interpretation has improved, and new methods (*e.g.*, ensemble-based approaches) are being developed for their characterization (*very high confidence*).
- Nevertheless, quantitative projections of changes in precipitation, river flows, and water levels at the river-basin scale remain uncertain (*very high confidence*).
- The negative impacts of climate change on freshwater systems outweigh its benefits (*high confidence*).
- All IPCC regions (*see* Chapters 3 through16 of the IPCC report) show an overall net negative impact of climate change on water resources and freshwater ecosystems (*high confidence*).
- Areas in which runoff is projected to decline are *likely* to face a reduction in the value of the services provided by water resources (*very high confidence*).
- The beneficial impacts of increased annual runoff in other areas will be tempered by the negative effects of increased precipitation variability and seasonal runoff shifts on water supply, water quality, and flood risks (*high confidence*).

Observed global climate-related trends affecting freshwater resources were identified previously. The following discussion identifies key projected impacts on surface waters, groundwater, extreme events, and water quality.

4.5.3.4.1 Surface Water

Data from 24 climate model runs generated by 12 different general circulation models (Milly *et al.* 2005, as cited in Kundzewicz *et al.* 2007) generally agreed that by 2050:

- Annual average river runoff and water availability will increase by 10 to 40 percent at high latitudes (North America, Eurasia) and in some wet tropical areas.
- Annual average river runoff and water availability will decrease by 10 to 30 percent over some dry regions at mid-latitudes and in the dry tropics, some of which are presently water-stressed areas (Mediterranean, southern Africa, and western United States/northern Mexico).

Hydrological impact studies have shown that warming leads to changes in the seasonality of river flows where much winter precipitation currently falls as snow, including the European Alps, the Himalayas, western North America, central North America, eastern North America, the Russian territory, Scandinavia, and Baltic regions. Winter flows will increase, summer flows will decrease, and peak flow will occur at least one month earlier in many cases (Kundzewicz *et al.* 2007).

Higher temperatures increase glacier melt. Glacier melt sustains many rivers during the summer in the Hindu Kush Himalaya and the South American Andes (Singh and Kumar 1997, Mark and Seltzer 2003, Singh 2003, Barnett *et al.* 2005, all as cited in Kundzewicz *et al.* 2007). The mass of some northern hemisphere glaciers is projected to decrease up to 60 percent by 2050 (Schneeberger *et al.* 2003, as cited in Kundzewicz *et al.* 2007).

Predictions for rain-fed basins describe higher flows in peak-flow season with either lower flows in low-flow season or extended dry periods (Kundzewicz *et al.* 2007).

Lake levels are determined by river and rain water inputs and evaporation outputs. By the end of the 21st Century, water levels are predicted to change between −4.5 feet and +1.15 feet in the Great Lakes (Lofgren *et al.* 2002, Schwartz *et al.* 2004b, both as cited in Kundzewicz *et al.* 2007) and to drop about 29.5 feet in the Caspian Sea (Elguindi and Giorgi 2006, as cited in Kundzewicz *et al.* 2007).

From 2010 to 2015, the ice cover on Siberian rivers is expected to melt 15 to 27 days sooner than it did from 1950 to 1979. The maximum ice cover is also expected to be 20 to 40 percent thinner (Vuglinsky and Gronskaya 2005, as cited in Kundzewicz *et al.* 2007).

A combination of land-use changes and climate change could affect annual runoff. Land-use changes are predicted by model studies to have a small effect compared to climate change in the Rhine basin, southeastern Michigan, Pennsylvania, and central Ethiopia. In southeastern Australia and southern India, predictions are comparable, with climate change having the potential to exacerbate reductions in runoff caused by afforestation (Kundzewicz *et al.* 2007).

Evapotranspiration – water loss from plant leaves – responds to increases in carbon dioxide in two distinct ways. First, higher CO_2 concentrations cause leaf stomata to close, reducing evapotranspiration. Second, CO_2 fertilization encourages plant growth, increasing total leaf area and subsequent evapotranspiration. Considering these vegetation effects, global mean runoff has been predicted to increase by 5 percent for a doubling of CO_2 concentration (Betts *et al.* 2007, Leipprand and

Gerten 2006, both as cited in Kundzewicz *et al.* 2007) compared to a 5 to 17 percent increase under climate change alone (Kundzewicz *et al.* 2007).

4.5.3.4.2 Groundwater

Climate change will mainly affect groundwater recharge rates, although very little research has been done on the issue. Groundwater levels could change as a result of thawing permafrost, vegetation changes, changes in river level (where hydraulic connection is adequate), and changes in floods. Global hydrological models predict that globally averaged groundwater recharge will increase less (2 percent) than total runoff (9 percent) in the 2050s compared to recharge and runoff rates from 1961 to 1990. In northeastern Brazil, southwestern Africa, and the southern Mediterranean coast, groundwater recharge is predicted to decrease by more than 70 percent. In contrast, recharge is predicted to increase by more than 30 percent in the Sahel, Near East, northern China, Siberia, and the western United States (Döll and Flörke 2005, as cited in Kundzewicz *et al.* 2007). Projected impacts on individual aquifers return very site-specific results.

Any decrease in groundwater recharge will exacerbate the effect of saltwater intrusion. Saltwater intrusion has been projected for a sea-level rise of 0.33 feet on two coral islands off the Indian coast – the thickness of the freshwater lens decreasing from 82 feet to 32 feet and from 118 feet to 92 feet (Bobba *et al.* 2000, as cited in Kundzewicz *et al.* 2007). Saltwater intrusion from sea-level rise might also affect groundwater/aquifer water supplies on similar small islands.

4.5.3.4.3 Extreme Events—Floods and Droughts

As discussed earlier, increased climate variability increases the risks of both floods and droughts depending on climatic and non-climatic variables. Extreme floods and extreme droughts are predicted to become more frequent in the future under various climate models (Kundzewicz *et al.* 2007). However, climate change impacts on flood magnitude and frequency can be both positive and negative depending on the global climate model used, snowmelt contributions, catchment characteristics, and location (Reynard *et al.* 2004, as cited in Kundzewicz *et al.* 2007).

By the 2090s, the proportion of the total land surface in extreme drought is predicted to increase from the current rate of 1 to 3 percent to 30 percent; extreme drought events per 100 years are predicted to double; and mean drought duration is predicted to increase by a factor of six (Burke *et al.* 2006, as cited in Kundzewicz *et al.* 2007).

More floods are predicted for northern and northeastern Europe, while more drought is predicted for southern and southeastern Europe (Lehner *et al.* 2005, as cited in Kundzewicz *et al.* 2007).

The area flooded in Bangladesh is projected to increase by 23 to 29 percent for a global temperature rise of 3.6 °F (Mirza 2003, as cited in Kundzewicz *et al.* 2007). Up to 20 percent of the world’s population lives in river basins at risk from increased flooding (Kleinen and Petschel-Held 2007, as cited in Kundzewicz *et al.* 2007).

4.5.3.4.4 Water Quality

Higher water temperatures and runoff variations are *likely* to affect water quality negatively (Patz 2001, Lehman 2002, O’Reilly *et al.* 2003, Hurd *et al.* 2004, all as cited in Kundzewicz *et al.* 2007). Negative impacts on water quality from changes in water quantity include resuspension of bottom sediments, increased turbidity (suspended solids), pollutant introduction, and reduced dilution. Negative impacts from water temperature include algal blooms, increased microbial concentrations, and outgassing of volatile and semi-volatile compounds like ammonia, mercury, dioxins, and pesticides (Kundzewicz *et al.* 2007).

Acidic atmospheric deposition is projected to increase acidification in rivers and lakes (Ferrier and Edwards 2002, Gilvear *et al.* 2002, Soulsby *et al.* 2002, all as cited in Kundzewicz *et al.* 2007).

Salt concentration is expected to increase in estuaries and inland reaches under decreasing streamflows. For example, salinity is projected to increase in the tributary rivers above irrigation areas in Australia's Murray-Darling Basin by 13 to 19 percent by 2050 and by 21 to 72 percent by 2100 (Kundzewicz *et al.* 2007).

No quantitative studies projecting the impact of climate change on microbiological water quality for developing countries are cited by the IPCC. However, climate change will be an additional stressor affecting water quality and public health. Potential impacts include increased waterborne disease with increases in extreme rainfall, and great incidence of diarrheal and water-related diseases in regions with increased drought (Kundzewicz *et al.* 2007). A brief overview of the effects of climate change on the availability and quality of drinking water is provided by Anderson *et al.* (2005).

Developed countries are also experiencing water quality issues in their water and wastewater treatment plants. Increased filtration is required in drinking water plants to address micro-organism outbreaks following intense rain, thus increasing some operating costs by 20 to 30 percent (AWWA 2006, as cited in Kundzewicz *et al.* 2007). Other stressors on water quality include the following (Kundzewicz *et al.* 2007):

- More water impoundments for hydropower (Kennish 2002, Environment Canada 2004).
- Stormwater drainage operation and sewage disposal disturbances in coastal areas resulting from sea-level rise (Haines *et al.* 2000).
- Increasing water withdrawals from low-quality sources.
- Greater pollutant loads resulting from increased infiltration rates to aquifers or higher runoff to surface waters (resulting from high precipitation).
- Water infrastructure malfunctioning during floods (GEO-LAC 2003, DFID 2004).
- Overloading the capacity of water and wastewater treatment plants during extreme rainfall (Environment Canada 2001).
- Increased amounts of polluted storm water.

In many regions, there is no alternative supply even as water quality declines, and reusing wastewater (*e.g.*, to irrigate crops) can introduce other public health problems.

Global adaptation to freshwater resource stressors will require the availability of relevant information, more water resource options (*e.g.*, storage), and proactive responses in the face of climatic changes. These responses will include effluent disposal strategies accounting for reduced biodegradation; water and wastewater treatment plant design accounting for extreme climate conditions; and reducing, reusing, and recycling water (Luketina and Bender 2002, Environment Canada 2004, Patrinos and Bamzai 2005, all as cited in Kundzewicz *et al.* 2007).

4.5.4 Terrestrial Ecosystems

This section addresses climate-related impacts on terrestrial ecosystems. An ecosystem is defined as a complex of biological communities (plants, animals, and microorganisms) and their non-living environments, which act together as a unit (MA 2005e and Reid *et al.* 2005, as cited in Fischlin *et al.* 2007). By definition, relationships within an ecosystem are strong while relationships with components outside the ecosystem boundaries are weak (Reid *et al.* 2005, Part 2, as cited in Fischlin *et al.* 2007).

4.5.4.1 Affected Environment

Earth's biosphere is an interconnected network of individuals, populations, and interacting natural systems, referred to as ecosystems. Ecosystems are critical, in part, because they supply humans with services that sustain life and are beneficial to the functioning of society (Fischlin *et al.* 2007). Ecosystems include:

- Terrestrial communities, such as forests, grasslands, shrublands, savanna, and tundra
- Aquatic communities, such as rivers, coral reefs, lakes, and estuaries
- Wetlands, such as marshes, swamps, and bogs (Peterson *et al.* 2008)

The focus of this section is on terrestrial ecosystems.

4.5.4.1.1 Global Terrestrial Ecosystems

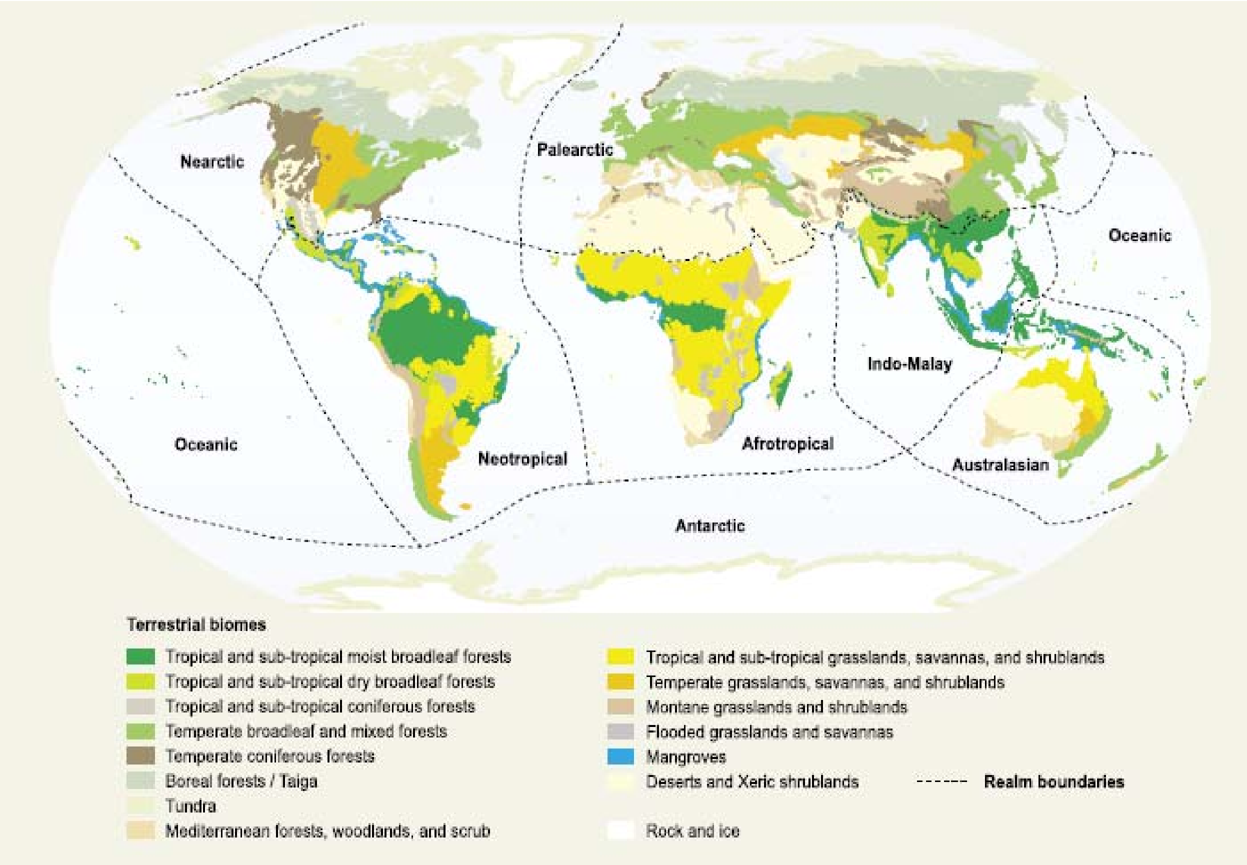
The World Wildlife Fund (WWF) has developed a widely accepted global ecosystem classification that consists of what are referred to as ecozones, biomes, and ecoregions. Similar to the classification of Miklos Udvary's (1975) biogeographical realm, the ecozone is the biogeographic division of Earth's surface at the largest scale. Terrestrial ecozones follow the floral and faunal boundaries that separate the world's major plant and animal communities. The WWF has identified eight ecozones, as indicated in Figure 4.5-1.

Biomes are climatically and geographically defined areas of ecologically similar communities of plants, animals, and microorganisms. These habitat types are defined by factors such as plant structures, leaf types, plant spacing, and climate. The land classification system developed by WWF identifies 14 major terrestrial habitat types, which can be further divided into 825 smaller, more distinct terrestrial ecoregions (WWF 2008a). The 14 primary terrestrial habitats recognized by WWF are as follows.

Tundra is a treeless polar desert found at high latitudes in the polar regions, primarily in Alaska, Canada, Russia, Greenland, Iceland, and Scandinavia, and sub-Antarctic islands. These regions are characterized by long, dry winters, months of total darkness, and extremely frigid temperatures. The vegetation is composed of dwarf shrubs, sedges and grasses, mosses, and lichens. A wide variety of animals thrive in the tundra, including herbivorous and carnivorous mammals and migratory birds.

Boreal Forests and Taiga are forests found at northerly latitudes in inland Alaska, Canada, Sweden, Finland, Norway, and Russia, and parts of the extreme northern continental United States, northern Kazakhstan, and Japan. Annual temperatures are low and precipitation ranges from 15 to 40 inches per year and can fall mainly as snow. Vegetation includes coniferous and deciduous trees, lichens, and mosses. Herbivorous mammals and small rodents are the predominant animal species; however, predatory birds and mammals also occupy this habitat type.

Figure 4.5-1. Ecozones and Biomes of the World a/



a/ Source: MA 2005f

Temperate coniferous forests are found predominantly in areas with warm summers and cool winters. Plant life varies greatly across temperate coniferous forests. In some forests, needleleaf trees dominate, while others consist of broadleaf evergreen trees or a mix of both tree types. Typically, there are two vegetation layers in a temperate coniferous forest: an understory dominated by grasses and shrubs and an overstory of large tree species.

Temperate broadleaf and mixed forests experience a wide range of variability in temperature and precipitation. In regions where rainfall is distributed throughout the year, deciduous trees are mixed with evergreens. Species such as oak, beech, birch, and maple typify the tree composition of this habitat type. Diversity is high for plants, invertebrates, and small vertebrates.

Mediterranean forests, woodlands, and shrub ecoregions are characterized by hot and dry summers, while winters tend to be cool and moist. Most precipitation arrives during winter. Only five regions in the world experience these conditions: the Mediterranean, south-central and southwestern Australia, the fynbos of southern Africa, the Chilean matorral, and the Mediterranean ecoregions of California. These regions support a tremendous diversity of habitats and species.

Tropical and subtropical coniferous forests are found predominantly in North and Central America and experience low levels of precipitation and moderate variability in temperature. These forests are characterized by diverse species of conifers, whose needles are adapted to deal with the variable climate conditions. These forests are wintering ground for a variety of migratory birds and butterflies.

Tropical and subtropical moist broadleaf forests are generally found in large, discontinuous patches centered on the equatorial belt and between the Tropics of Cancer and Capricorn. They are characterized by low variability in annual temperature and high levels of rainfall. Forest composition is dominated by semi-evergreen and evergreen deciduous tree species. These forests are home to more species than any other terrestrial ecosystem. A square kilometer can support more than 1,000 tree species. Invertebrate diversity is extremely high, and dominant vertebrates include primates, snakes, large cats, amphibians, and deer.

Tropical and subtropical dry broadleaf forests are found in southern Mexico, southeastern Africa, the Lesser Sundas, central India, Indochina, Madagascar, New Caledonia, eastern Bolivia, central Brazil, the Caribbean, valleys of the northern Andes, and along the coasts of Ecuador and Peru. Deciduous trees predominate in most of these forests and they are home to a wide variety of wildlife, including monkeys, large cats, parrots, various rodents, and ground-dwelling birds.

Temperate grasslands, savannas, and shrublands are known as prairies in North America, pampas in South America, veld in southern Africa, and steppe in Asia. They differ from tropical grasslands in species composition and the annual temperature regime under which they thrive. These regions are devoid of trees, except for riparian or gallery forests associated with streams and rivers. Biodiversity in these habitats includes a number of large grazing mammals and associated predators, burrowing mammals, numerous bird species, and a diversity of insects.

Tropical and subtropical grasslands, savannas, and shrublands are found in the large expanses of land in the tropics that do not receive enough rainfall to support extensive tree cover. However, there could be great variability in soil moisture throughout the year. Grasses dominate the species composition of these ecoregions, although scattered trees can be common. Large mammals that have evolved to take advantage of the ample forage typify the biodiversity associated with these habitats.

Montane grasslands and shrublands include high-elevation grasslands and shrublands, such as the puna and paramo in South America, subalpine heath in New Guinea and East Africa, steppes of the Tibetan plateaus, and other similar subalpine habitats around the world. Montane grasslands and shrublands are tropical, subtropical, and temperate. Mountain ecosystem services such as water purification and climate regulation extend beyond the geographical boundaries of the grasslands and shrublands and affect all continental mainlands (Woodwell 2004). Characteristic plants of these habitats display features such as rosette structures, waxy surfaces, and abundant pilosity (WWF 2008b).

Deserts and xeric shrublands across the world vary greatly with respect to precipitation and temperature. Generally, rainfall is less than 10 inches annually and evaporation exceeds precipitation. Temperature variability is also extremely diverse in these remarkable lands. Many deserts, such as the Sahara, are hot year-round, but others, such as Asia's Gobi, become quite cold in winter. Woody-stemmed shrubs and plants evolved to minimize water loss characterize vegetation in these regions. Animal species are equally well-adapted to the dry conditions, and species are quite diverse.

Mangroves occur in the waterlogged, salty soils of sheltered tropical and subtropical shores, where they stretch from the intertidal zone to the high tide mark. Associated with these tree species is a whole host of aquatic and salt-tolerant plants. Mangroves provide important nursery habitats for a vast array of aquatic animal species.

Flooded grasslands and savannas are common to four continents. These vast areas support numerous plants and animals adapted to the unique hydrologic regimes and soil conditions. Large congregations of migratory and resident water birds can be found in these regions. Ecosystem services include breeding habitat and the buffering of inland areas from the effects of wave action and storms (MA 2005e).

4.5.4.1.2 Terrestrial Ecosystems in the United States

Published in 1976, *Ecoregions of the United States* was one of the first attempts to divide the Nation into ecosystem regions systematically. Subsequently, Bailey (1980) provided, for each region, a brief description of the dominant physical and biological characteristics based on land-surface form, climate, vegetation, soils, and fauna. Bailey defined four major domains, 12 divisions, and 30 provinces. Since then, the ecoregions of North America have been further refined by the international working group of the Commission of Environmental Cooperation (CEC 1997). Their system divides the continent into 15 broad level I ecoregions, 52 level II ecoregions, and approximately 200 level III ecoregions. The level I ecoregions present in the United States include tundra, taiga, northern forests, northwestern forested mountains, marine west coast forests, eastern temperate forests, great plains, North American deserts, Mediterranean California, southern semi-arid highlands, temperate sierras, and tropical humid forests (*see* Figure 4.5-2).

Ecosystems are dynamic and can change naturally over time as a result of drivers such as climate change (natural or anthropogenic), geological processes (volcanic eruptions, earthquakes, landslides), fire, disease or pest outbreaks, and evolution. All organisms modify their environment to some extent; however, in the past century and especially in the past 50 years, human population growth and technological innovations have affected ecosystems drastically (Vitousek *et al.* 1997). In fact, the structure of the world's ecosystems have changed more rapidly in the second half of the 20th Century than in any time in recorded human history (MA 2005e). It is expected that during the course of this century, the resilience of many ecosystems is likely to be exceeded by anthropogenic pressures (Fischlin *et al.* 2007).

4.5.4.1.3 Non-climate Threats to Global Terrestrial Ecosystems

The Millennium Ecosystems Assessment (MA), a United Nations research project, focuses on identifying the current inventory and conditions of 10 categories of global ecosystems (including 5 categories of natural terrestrial ecosystems) and projecting changes and trends into the future.

In 2005, the MA released five technical volumes and six synthesis reports, providing a scientific appraisal of the condition and trends in the world's ecosystems and the services they provide. From 2001 to 2005, the MA involved the work of more than 1,360 experts worldwide. The MA included the following conclusions regarding the current state of global ecosystems (MA 2005e):

- Cultivated systems now cover one quarter of Earth's terrestrial surface. More than two thirds of the area of 2 of the world's 14 major terrestrial biomes and more than half of the area of 4 other biomes had been converted by 1990, primarily to agriculture.
- Across a range of taxonomic groups, for most species, either the population size or range or both is currently declining.
- The distribution of species on Earth is becoming more homogenous; in other words, the set of species in any one region of the world is becoming more similar to the set in other regions primarily as a result of introductions of species, both intentionally and inadvertently in association with increased travel and shipping.

Figure 4.5-2. Level I Ecoregions in the North America a/

a/ Source: CEC 1997

- The number of species on the planet is declining. Over the past few hundred years, humans have increased the species extinction rate by as much as 1,000 times over background rates typical over Earth's history. Some 10 to 30 percent of mammal, bird, and amphibian species are currently threatened with extinction.

- Only 4 of the 24 ecosystem services examined in this assessment have been enhanced, while 15 have been degraded (Hassan *et al.* 2005).

The MA concluded that biodiversity changes due to human activities were more rapid in the past 50 years than at any time in human history. Moreover, the forces causing biodiversity loss and leading to changes in ecosystem services are either steady, show no evidence of declining over time, or are increasing in intensity. The MA examined four plausible future scenarios and projected that the rates of biodiversity change will continue or accelerate (MA 2005e).

The changes in ecosystems identified in the MA can have impacts on ecological processes, species composition, and genetic diversity. Ecological processes, which include water, nitrogen, carbon, and phosphorous cycling, have all changed more rapidly in the second half of the 20th Century than at any time in recorded human history (MA 2005e). Human actions have not only changed the structure of ecosystems, but also the processes as functions of the ecosystems.

A change in ecosystem structure also affects the species within the system and vice versa. Historically, the natural processes of evolution and the combination of natural barriers to species migration and local adaptation resulted in substantial phenotypic differences in plant and animal species of different ecosystems. These regional differences are now becoming rare.

Some ecosystem changes have been the inadvertent result of activities unrelated to the use of ecosystem services, such as the construction of roads, ports, and cities and the discharge of pollutants. But most ecosystem changes were the direct or indirect result of changes made to meet growing demands for food, water, timber, fiber, and fuel (MA 2005e). Ecosystems change can be affected by a variety of human and natural drivers, including climate change, land use, land degradation, urbanization, pollution, natural climate change, geological processes, and invasive species. These drivers can act independently or in concert with each other (Lepers *et al.* 2004), and are summarized below.

Land Use Change

Land use change represents the anthropogenic replacement of one land use type by another, such as forest converted to cultivated land (or the reverse), and subtle changes of management practices within a given land use type, such as intensification of agricultural practices. Both forms of land use change are affecting 40 percent of the terrestrial surface (Foley *et al.* 2005). Land use change can lead to habitat loss and fragmentation and is an important driver in ecosystem change (Heywood and Watson 1995, Fahrig 2003). Overall, land transformation represents the primary driving force in the loss of biological diversity (Vitousek *et al.* 1997). In 9 of the 14 terrestrial biomes studied by the MA, over half the area has been transformed, largely by agricultural cultivation (Hassan *et al.* 2005). Only the biomes that are less suitable for agriculture, such as deserts, boreal forests, and tundra, have remained largely untransformed by human activity.

Virtually all of Earth's ecosystems have now been substantially transformed through human actions (MA 2005e). Roughly 70 percent of original temperate grasslands and forests and Mediterranean forests were lost by 1950, chiefly from conversion to agricultural lands. More land was converted to cropland in the 30 years after 1950 than in the 150 years between 1700 and 1850 (MA 2005a, Hassan *et al.* 2005).

Historically, terrestrial ecosystems that have been most substantially altered by human activity include temperate broadleaf forests, temperate grasslands, Mediterranean forests, and tropical dry forests (Hassan *et al.* 2005). Of these, more than two thirds of the temperate grasslands and Mediterranean forests, and more than half of tropical dry forests, temperate broadleaf forests, and tropical grasslands have been converted to agriculture (Hassan *et al.* 2005). Forest systems in general have been reduced by half over the past three centuries, and have effectively disappeared in 25 countries. Another 29 countries have lost 90 percent or more of their forest cover (Hassan *et al.* 2005).

Globally, the rate of ecosystem conversion has begun to decelerate, mainly because the rate of expansion of cultivated land has declined. Ecosystems are beginning to return to conditions and species compositions similar to their pre-conversion states. However, rates of ecosystem conversion remain high or are increasing for specific ecosystems and ecoregions (MA 2005f). Land use changes and land degradation are important drivers of ecosystem change globally and in the United States. For example, "between 1982 and 1997, 11 million acres of nonfederal grasslands and shrublands were converted to other uses" (The H. John Heinz III Center for Science 2002).

The increase in cultivated land, especially for the purpose of grazing, has led to an increase in desertification. Desertification involves the expansion of deserts into semi-arid and subhumid regions, and the loss of productivity in arid zones. Desertification is characterized by loss of groundcover and soils, replacement of palatable, mesophytic grasses by unpalatable xerophytic shrubs, or both (Ryan *et al.* 2008). Desertification affects the livelihoods of millions of people, including a large portion of the poor residents of drylands (Hassan *et al.* 2005). While desertification can certainly be exacerbated by changes in climate, there has been long-standing controversy over the relative contributions of climatic and anthropogenic factors as drivers of desertification (National Science and Technology Council 2008).

Fire

Fire influences ecosystem structure by promoting species that tolerate fire or even enhance fire spread, resulting in a relationship between the relative flammability of a species and its relative abundance in a particular community (Bond and Keeley 2005). Intensified and increasing wildfire occurrences appear to be changing vegetation structure and composition in some ecoregions. In the forest-tundra transition in eastern Canada, this transition is observed in a shift from *Picea*- to *Pinus*-dominated communities and 75 to 95 percent reductions in tree densities (Lavoie and Sirois 1998). Across the boreal forests of North America, total burned areas increased by a factor of 2.5 between the 1960s and the 1990s (Kasischke and Turetsky 2006).

Insect Outbreaks

Invasive alien species represent a major threat to endemic or native biodiversity in terrestrial and aquatic systems. Alien species invasions also interact with other drivers, sometimes resulting in unexpected outcomes. The impact of insect damage is substantial and can exceed the impacts of fire in some ecosystems, but especially in boreal forests (Logan *et al.* 2003). For example, spruce budworm defoliated more than 20 times the area burned in eastern Ontario between 1941 and 1996 (Fleming *et al.* 2002). Fires tended to occur 3 to 9 years after a spruce budworm outbreak (Fleming *et al.* 2002), suggesting that insect outbreaks can be a driver of increased fire events. Forest impacts by the forest tent caterpillar have also increased in western Canada over the past 25 years (Timoney 2003).

Species Decline and Extinction

Although extinction is a natural part of Earth's history, observed modern rates of extinction are not part of natural cycles. Over the past few hundred years, humans have increased the extinction rate by as much as 1,000 times over the rate expected based on natural history (Hassan *et al.* 2005). A decrease in global genetic diversity is linked to extinction. The loss of unique populations has resulted in the loss of genetic diversity. The loss of genetic diversity has also declined among cultivated species as farmers have shifted from locally adapted crop populations to more widely adapted varieties produced through formal breeding practices. Currently, for most species across a wide range of taxonomic groups, either the population size, population range, or both is in decline (MA 2005e).

Pollution

Pollution is another substantial threat to terrestrial ecosystems. Over the past four decades, excessive nutrient loading has emerged as one of the most important direct drivers of ecosystem change in terrestrial, freshwater, and marine systems. A known cause is the use of increasing amounts of synthetic nitrogen and phosphorous fertilizers, which can be lost to the environment after application. Consumption of nitrogen fertilizer grew nearly 800 percent between 1960 and 2003 (MA 2005f). In terrestrial ecosystems, excessive nitrogen flows contribute to acidification. Nitrogen also plays a role in ground-level ozone, which can lead to a loss of forest productivity (MA 2005f).

4.5.4.2 Environmental Consequences

This section discusses current climate change impacts that have already been observed and projected impacts (including the potential for adaptation to climate changes). Climate change impacts are discussed generally, and with specific attention to impacts in the United States. The IPCC WGI Fourth Assessment Report (Fischlin *et al.* 2007) was released in 2007, and in 2008 the USCCSP report on climate sensitive ecosystems was released (CCSP 2008a). The 2007 IPCC report is the most comprehensive, recent summary of projected impacts of global climate change. Many of the impacts discussed in this section were gathered from the 2007 IPCC report, which provides an analysis and discussion on a global scale. Information about impacts specific to ecosystems in the United States was obtained primarily from the 2008 USCCSP report. The projected impacts reported below were forecast with varying degrees of certainty. The level of certainty, as defined by IPCC, is noted in this report where relevant.

4.5.4.2.1 Observed Climate Change Impacts

Because terrestrial ecosystems are defined by the interactions of biotic factors (plants, animals, and microorganisms) and abiotic factors (geology, hydrology, weather), climate is a key factor in determining the different characteristics and distributions of natural systems.

<u>Observed Impacts on Terrestrial Ecosystems Globally</u>

Studies have noted the response of biological and chemical characteristics of ecosystems to climate conditions, especially temperature change. Substantial research has examined the effects of climate change on vegetation and wildlife, leading to the conclusion that the changing climate is already having a real and demonstrable effect on a variety of ecosystem types (CCSP 2008b). As noted in the IPCC report, plants and animals can reproduce, grow, and survive only within specific ranges of climate and environmental conditions (Fischlin *et al.* 2008). Changes in climate can affect terrestrial ecosystems in any of the following ways (Rosenzweig *et al.* 2007):

- Shifting the timing of life cycle events such as blooming or migration
- Shifting range boundaries or densities of individuals within their ranges
- Changing species morphology (body size, egg size), reproduction, or genetics
- Causing extirpation or extinction.

These changes are a result of many factors. Phenology – the timing of seasonal activities of animals and plants – is perhaps the simplest process by which to track changes in the ecology of species in response to climate change (Rosenzweig *et al.* 2007). Observed phenological events include leaf unfolding, flowering, fruit ripening, leaf coloring, leaf fall of plants, bird migration, chorusing of amphibians, and appearance or emergence of butterflies. Global daily satellite data, available since 1981, indicate an earlier onset of spring by 10 to 14 days over 19 years, particularly across temperate latitudes of the northern hemisphere (Zhou *et al.* 2001, Lucht *et al.* 2002). Leaf unfolding and flowering in spring and summer have, on average, advanced by 1 to 3 days per decade in Europe, North America, and Japan over the last 30 to 50 years (Fischlin *et al.* 2007). The seasonal timing of bird migration and egg laying has also changed, associated with the increase of temperature in breeding grounds and migration routes. According to IPCC (Rosenzweig *et al.* 2007), "Many small mammals have been observed to come out of hibernation and to breed earlier in the spring than they did a decade ago (Inouye *et al.* 2000, Franken and Hik 2004) and even larger mammals such as reindeer are showing phenological changes (Post and Forchhammer 2002), as are butterflies, crickets, aphids, and hoverflies (Forister and Shapiro 2003, Stefanescu *et al.* 2003, Hickling *et al.* 2005, and Newman 2005). Increasing regional temperatures are also associated with earlier calling and mating and shorter time to maturity of amphibians (Gibbs and Breisch 2001, Reading 2003, and Tryjanowski *et al.* 2003)."

Rapid global warming can directly affect the size of a species' range, the density of individuals within the range, and the abundance of preferred habitat within the range. Climate changes have affected the location of suitable habitat for several species of plants and animals. Changes in the distribution of species have occurred across a wide range of taxonomic groups and geographical locations (Rosenzweig *et al.* 2007). Several different bird species no longer migrate out of Europe in the winter as the temperature continues to warm (Rosenzweig *et al.* 2007). Over the past decades, a poleward extension of various species has been observed, which is probably attributable to increases in temperature (Parmesan and Yohe 2003, as cited in Rosensweig *et al.* 2007). Many Arctic and tundra communities are affected and have been replaced by trees and dwarf shrubs (Kullman 2002 and ACIA 2005, both as cited in Rosensweig *et al.* 2007). In some mountainous areas of the northern hemisphere, including in Alaska, tree lines have shifted to higher altitudes over the past century (Sturm *et al.* 2001, as cited in Rosensweig *et al.* 2007).

Decreases in the size of a species' range, the density of individuals within the range, and the abundance of its preferred habitat factors can lower species population size (Wilson *et al.* 2004, as cited in Rosensweig *et al.* 2007) and can increase the risk of extinction. Examples of declines in populations and subsequent extinction or extirpation are found in amphibians around the world (Alexander and Eischeid 2001, Middleton *et al.* 2001, Ron *et al.* 2003, and Burrowes *et al.* 2004, all as cited in Rosensweig *et al.* 2007).

Changes in morphology and reproduction rates have been attributed to climate change. For example, the egg sizes of many bird species are changing with increasing regional temperatures (Jarvinen 1996 and Tryjanowski *et al.* 2004). Several studies conducted in Asia and Europe found that some birds and mammals are experiencing increases in body size as temperatures increase, on a regional scale, most likely due to the increasing availability of food (Nowakowski 2002, Yom-Tov 2003, Kanuscak *et al.* 2004, and Yom-Tov and Yom-Tov 2004, as cited in Rosenzweig *et al.* 2007). Many northern insects have a 2-year life cycle, and warmer winter temperatures allow a larger fraction of overwintering larvae to survive. The mountain pine beetle has expanded its range in British Columbia into areas previously considered too cold (Carroll *et al.* 2003).

Observed Changes on Terrestrial Ecosystems in the United States

Changes and impacts on ecosystems in the United States are similar to those occurring globally. During the 20th Century, the United States already had begun to experience the effects of climate change. Precipitation over the contiguous United States increased 6.1 percent over long-term averages (CCSP 2008a), while a sea-level rise of 0.06 to 0.12 inch per year has occurred at most of the country's coastlines; the Gulf coast has experienced an even greater rise in sea level at a rate of 0.2 to 0.4 inch per year (CCSP 2008a).

Examples of observed changes to terrestrial ecosystems in the United States attributable to anthropogenic climate change include the following:

- Many plant species are expanding leaves or flowering earlier, for example: earlier flowering in lilac,1.8 days per decade (Schwartz and Reiter 2000) and honeysuckle, 3.8 days per decade (Cayan *et al.* 2001); earlier leaf expansion in apple and grape, 2 days per decade (Wolfe *et al.* 2005) and trembling aspen, 2.6 days per decade (Wolfe *et al.* 2005).

- Warmer springs have led to earlier nesting for 28 migrating bird species on the east coast of the United States (Butler 2003) and to earlier egg laying for Mexican jays (Brown *et al.* 1999) and tree swallows (Dunn and Winkler 1999).

- Several frog species now initiate breeding calls 10 to 13 days earlier than a century ago (Gibbs and Breisch 2001).

- In lowland California, 70 percent of 23 butterfly species advanced the date of first spring flights by an average of 24 days over 31 years (Forister and Shapiro 2003).

- Many North American plant and animal species have shifted their ranges, typically to the north or to higher elevations (Parmesan and Yohe 2003).

- Edith's checkerspot butterfly has become locally extinct in the southern, low-elevation portion of its western North American range but has extended its range 56 miles north and 394 feet higher in elevation (Parmesan 1996, Crozier 2003, and Parmesan and Galbraith 2004). Edith's checkerspot butterfly is important to the survival of its grassland and rocky outcrop habitat, and also provides essential ecosystem services because the adult butterflies pollinate various flowers (Scott 1986, as cited in Kayanickupuram 2002).

- The frequency of large forest fires and the length of the fire season in the western United States have increased substantially since 1985. These phenomena are related to the advances in the timing of spring snowmelt and increases in spring and summer air temperatures (Westerling *et al.* 2006).

- In the Great Basin region, the onset of snow runoff is currently 10 to 15 days earlier than it was 50 years ago (Cayan *et al.* 2001).

- The vegetation growing season has increased on average by about 2 days per decade since 1948, with the largest increase happening in the West (Easterling 2002; Feng and Hu 2004).

- Recently, spruce budworm in Alaska has completed its lifecycle in 1 year, rather than the 2 years previously (Volney and Fleming 2000). This allows many more individuals to survive the overwintering period with impacts on the boreal forests of North America.

- Over the past 3 to 5 decades, all the major continental mountain chains exhibited upward shifts in the height of the freezing level (Diaz *et al.* 2003).

- Populations of the American pika, a mountain-dwelling relative of the rabbit, are in decline (Beever *et al.* 2003). The pika might be the first North American mammal to become extinct as a result of anthropogenic climate change.

- Reproductive success in polar bears has declined as a result of melting Arctic Sea ice. Without ice, polar bears cannot hunt seals, their preferred prey (Derocher *et al.* 2004). On May 15, 2008, the U.S. Fish and Wildlife Service listed the polar bear as a threatened species, reflecting the loss of sea ice habitat that once encompassed more than 90 percent of the polar bear's habitat range (*FR* 73, 28212-28303, May 15, 2008).

4.5.4.2.2 Projected Impacts of Climate Change in the United States

The United States is projected to experience changes in average temperature and precipitation over the 21st Century of an even greater magnitude than those experienced in the 20th Century. Although the entire country is projected to experience some degree of change, particular regions of the United States could experience changes of a greater-than-average magnitude. For example, the greatest changes in temperature are projected for Alaska and the western continental United States (CCSP 2008a). In northern Alaska, the average temperatures are projected to increase 5 °C by the end of the 21st Century. Areas near coasts are projected to witness an increase of approximately 2 °C over the same period; summer temperatures nationwide could increase 3 to 5 °C; and winter temperatures are projected to increase 7 to 10 °C (CCSP 2008a).

Additional expected changes in United States climate include:

- More frequent hot days and hot nights (CCSP 2008a)
- Heavier precipitation events, primarily in the form of rain rather than snow (CCSP 2008a). Annual precipitation in the northeastern United States is projected to increase while precipitation in the Southwest is expected to decrease (Christensen *et al.* 2007)
- A decline in spring snow cover, leading to decreased availability of water in reservoirs (CCSP 2008a)

Ecosystems across the United States are projected to experience both positive and negative impacts from climate change over the next century. The degree of impacts will vary by region. Wildlife species have already responded to climate change and its effects on migration patterns, reproduction, and geographic ranges (Field *et al.* 2007, as cited in National Science and Technology Council 2008). Future, more substantial changes in climate are projected to affect many ecosystem services negatively (CCSP 2008a). The IPCC WGII has projected, with a high level of confidence, "that recent regional changes in temperature have had discernible impacts on many physical and biological systems" (National Science and Technology Council 2008).

The IPCC has determined that areas of the United States that experience temperature increases of 1.5 to 2.5 °C are at highest risk for modifications to ecosystem structure and composition (IPCC 2007b, as cited in CCSP 2008a). Over the next century, it is projected that species could move northward and to higher elevations (Field *et al.* 2007, as cited in National Science and Technology Council, 2008). In one example of possible future threats to ecosystem vegetation, the upward move in elevation of species as the snow and tree line advances suggests that alpine ecosystems could be endangered by the introduction of invasive species (National Science and Technology Council 2008).

Rather than experiencing impacts of climate change directly, most animals could experience the effects of climate change indirectly through changes to their habitat, food sources, and predators (Schneider and Root 1996, as cited in National Science and Technology Council 2008). A changing climate facilitates migration of certain species into non-native habitats, potentially affecting current goods and services (CCSP 2008a).

Animals in ecosystems in the United States are projected to experience a variety of climate change impacts. For example:

- Changes in hydrology as a result of changes in precipitation patterns could interrupt the breeding cycles of amphibians, which depend on the ability to migrate to breeding ponds.

The production of their eggs is also highly dependent on temperature and moisture availability (Fischlin *et al.* 2007, as cited in National Science and Technology Council 2008).

- Changes in climate that occur over at least several years are likely to affect the reproductive success of migratory birds and their ability to survive. A mismatch in timing between the migration and reproduction periods and peak food availability is the potential pathway for such impacts (Stenseth and Mysterud 2002, Visser *et al.* 2004, 2006, Visser and Both 2005, all as cited in National Science and Technology Council, 2008).

- The migration of butterflies is highly dependent on spring temperatures, and anthropogenic climate change is likely to lead to earlier spring arrivals. As with migratory birds, an earlier butterfly migration could result in a mismatch with food supply, thus threatening reproduction and survival (Forister and Shapiro 2003, as cited in National Science and Technology Council, 2008).

- Shifts in migration ranges could result in disease entering new areas, for example, avian malaria in Hawaii could move upslope as climate changes (CCSP 2008a).

In one prominent example of mammals experiencing the effects of a warming climate, the polar bear is specifically adapted to conditions in a narrow ecological slot (an environment with cold temperatures and access to snow, ice, and open water) and spends much of its time on the frozen sea (Gunderson 2007). As the climate warms and sea ice melts, the polar bear loses much of its natural habitat. If current trends in sea ice loss continue, the polar bear could become extirpated from most of their range within 100 years (IUCN 2008). Polar bears were listed as threatened under the Endangered Species Act on May 15, 2008 due to the ongoing and projected loss of their sea-ice habitat from global warming (*FR* 73, p 28212-28303, May 15, 2008).

The vegetation of terrestrial ecosystems in the United States is projected to experience a variety of direct impacts from climate change. For example, national forests, which harbor much of the Nation's biodiversity, and national grasslands are expected to experience an exacerbation of pre-existing stressors, such as wildfires, invasive species, extreme weather events, and air pollution (CCSP 2008a).

Warmer, drier climates weaken resistance of trees to insect infestation, as they are more likely to be wilted and weakened under those conditions. In a healthy state, trees can typically fight off beetle infestation by drowning them with resin as they bore through the bark. Drought reduces the flow of resin and beetles that are able to penetrate the bark introduce decay-causing fungus. This problem has already been documented. Since 1994, winter mortality of beetle larvae in Wyoming has been cut due to mild winters (from 80 percent to less than 10 percent mortality). As a result, the beetles have been able to strip 4 million acres of forests (Egan 2002, as cited in Center for Health & the Global Environment 2005). In the southwestern United States, high temperatures, drought, and the piñon ips bark beetle have had the cumulative effect of causing a mass die-back of piñon trees. From 2002 to 2003 alone, piñon mortality in Mesa Verde National Park in Colorado and Bandelier National Monument in New Mexico exceeded 90 percent. Researchers determined that climate factors drove the die-off (Saunders *et al.* 2008). The United States Forest Service indicates that, by 2012, almost all of the mature lodgepole trees in northern Colorado and southern Wyoming will have been killed by bark beetles. This will affect watersheds, timber production, and wildlife habitats, along with other human activities (USFS 2008).

Additional impacts on vegetation in ecosystems in the United States could include the following:

- Water management in the West would be complicated by increases in temperatures and changes in precipitation patterns, which lead to reduced snow pack, earlier snowmelt, and modified hydrology (CCSP 2008a).
- High latitudes would experience increased vegetation productivity. Regions in the mid-latitudes would experience either increased or decreased productivity, depending on whether the primary impact is more precipitation or higher temperatures (increasing evaporation and dryness) (Bachelet *et al.* 2001, Berthelot *et al.* 2002, Gerber *et al.* 2004, Woodward and Lomas 2004, all as cited in National Science and Technology Council 2008).
- Ecosystems in the East would be statistically "likely to become carbon sources, while those in the west would be likely to remain carbon sinks" (Bachelet *et al.* 2004, as cited in National Science and Technology Council 2008).
- The jet stream would move northward with increasing atmospheric temperatures. The consequence of this shift is a drying of the Southeast. Closed-canopy forest ecosystems could be converted to savanna ecosystems, woodlands, or grasslands, measurably increasing the threat of fire occurrence (CCSP 2008a).
- Growing seasons would lengthen, according to several predictive models; this would beneficially act to sustain carbon sinks (Cox *et al.* 2000, Berthelot *et al.* 2002, Fung *et al.* 2005, all as cited in National Science and Technology Council 2008).
- In the Olympic Range, a temperature increase of 2 °C would move tree species upwards 0.20 to 0.38 miles. Temperate species would replace subalpine species over 300 to 500 years (Zolbrod and Peterson 1999).

Adaptation to Climate Change by Terrestrial Ecosystems

The ability or inability of ecosystems to adapt to change is referred to as adaptive capacity. There could be notable regional differences in the adaptive capacity of ecosystems, and adaptive capacity is moderated by anthropogenic influences and capabilities. The ultimate impact of climate change on ecosystems depends on the speed and extent to which these systems can adapt to a changing climate. Adaptation occurs naturally in a biological system to varying degrees, but it can also be a planned human response to anticipated challenges (CCSP 2008a). Ecosystem managers could "proactively alter the context in which ecosystems develop… they can improve the resilience, *i.e.*, the coping capacity, of ecosystems. Such ecosystem management involves anticipatory adaptation options" (Fischlin *et al.* 2007). A strategy proposed for mitigating some of the loss of ecosystem biodiversity calls for moving species out of their native ranges into less threatened zones. Although this strategy could be viewed with suspicion due to the problems posed by some invasive species, the "assisted colonization" would likely be proposed only in situations and for species that are deemed low risk (Hoegh-Guldberg *et al.* 2007).

Because the effectiveness of specific adaptation strategies is uncertain, a "no regrets" path, consisting of practical adaptation options that account for current, known stressors along with the more uncertain future stressors (CCSP 2008a), is typically sought by ecosystem managers. For example, invasive species pose a known threat to many ecosystems. Future climate change is likely to exacerbate this stressor, so an adaptation strategy to tackle current invasive species problems could also address projected impacts of more serious, future invasive species challenges (CCSP 2008a). Another example of dual-purpose adaptation strategies lies with the construction of riparian buffer strips. These not only reduce agricultural runoff into freshwater systems, but also establish protective barriers against potential increases in both pollution and sediment loadings due to climate change in the future (CCSP 2008a).

4.5.4.2.3 Projected Impacts of Climate Change on Global Terrestrial Ecosystems

The IPCC concludes (*very high confidence*) that anthropogenic temperature rises have visibly altered ecosystems (Parry *et al.* 2007). The exact impacts of climate changes are difficult to discern, however, as they are mediated by other stressors and the capabilities of natural systems to adapt to changing climates to some degree (Parry *et al.* 2007).

Some regions of the world are more vulnerable to changes in climate than others. Regions of snow, ice, and tundra have been visibly altered by changes in global temperature. Observations of frozen regions already show larger glacial lakes and the destabilization of glacial debris that dam these lakes; changes in ecosystems at both poles; and increased melting of ice sheets, glaciers, and ice caps (Parry *et al.* 2007).

Ecosystems in all regions of the world are expected to respond to climate-change impacts with poleward and upward shifts of plants and animals; earlier onset of migration of terrestrial species such as birds and butterflies; and localized disappearance of particular species (Parry *et al.* 2007).

Additional factors, such as projected growth in human populations, are expected to exacerbate the effects of climate change. For example, river basin ecosystems that are already experiencing high levels of stress are projected, with *medium confidence*, to witness growth in human populations from approximately 1.4 to 1.6 billion in 1995 to roughly 4.3 to 6.9 billion by 2050 (Parry *et al.* 2007). River basins experience the stress of increasing human populations as manifested in increasing demands for water (CCSP 2008b) and more inputs of pollutants. A warmer, drier climate could increase these stressors and reduce access to other water sources (CCSP 2008b).

Other projected global impacts of climate change include the following:

- The hardiness of the world's ecosystems is expected (*high confidence*) to be challenged over the 21st Century with "an unprecedented combination of climate change, associated disturbances (*e.g.*, flooding, drought, wildfire, insects, and ocean acidification), and other global change drivers (especially land use, pollution, and over-exploitation of resources) (Fischlin *et al.* 2007).

- CO_2 levels are projected to be much higher than any in the past 650,000 years, and temperatures are projected to be as high as any in the past 740,000 years. Both increases are very likely to impact ecosystems (*very likely*) (Fischlin *et al.* 2007).

- Global average temperature increases in excess of 1.5 to 2.5 °C are statistically likely to threaten 20 to 30 percent of plant and animal species with extinction (Fischlin *et al.* 2007, as cited in National Science and Technology Council 2008).

- Carbon uptake by ecosystems such as forests and grasslands is statistically likely to peak during the 21st Century and might ultimately even reverse (forests and grasslands would emit carbon, rather than taking it in), which would amplify climate change due to increased atmospheric CO_2 (Fischlin *et al.* 2007, as cited in National Science and Technology Council 2008).

In addition to other anthropogenic stressors, "such as extractive use of goods, and increasing fragmentation and degradation of natural habitats" (Bush *et al.* 2004, as cited in Fischlin *et al.* 2007), climate change poses a threat to the wellbeing of ecosystems. Although many ecosystems have been resilient to historical changes in climate, it is not clear whether their resilience is enough to withstand the more rapid and profound changes that are projected given the buildup of GHGs in the atmosphere (Chapin *et al.* 2004, Jump and Peñuelas 2005, as cited in Fischlin *et al.* 2007). Predicted climate change and other anthropogenic stressors are "virtually certain to be unprecedented" (Forster *et al.* 2007, as cited in Fischlin *et al.* 2007). While some of the impacts expected with climate change serve to exacerbate existing stressors on ecosystems, other expected impacts could be altogether new. For example, increasing temperatures could cause some current sinks for GHGs, such as forest vegetation, to actually become sources for these gases (including CO_2 and methane) (Fischlin *et al.* 2007).

Effects of anthropogenic climate change on ecosystems are anticipated at different levels of severity and over varying time scales (decades to centuries) (Lischke *et al.* 2002, as cited in Fischlin *et al.* 2007). Some of the broad impacts on ecosystems associated with climate change are expected to include species extinctions, loss of habitat due to more severe tropical storms (Wiley and Wunderle 1994, as cited in Fischlin *et al.* 2007), changes in the types and abundance of vegetation present in an ecosystem (Schröter *et al.* 2005, Metzger *et al.* 2006, both as cited in Fischlin *et al.* 2007), and increased susceptibility of land to desertification (Burke *et al.* 2006, as cited in Fischlin *et al.* 2007).

Foreseeable pathways of climate change-induced impacts on ecosystems include the following:

- CO_2 fertilization effects on vegetation (Baker *et al.* 2004, Lewis *et al.* 2004, Malhi and Phillips 2004, all as cited in Fischlin *et al.* 2007).

- Higher atmospheric temperatures that could lead to more frequent insect and disease outbreaks (National Science and Technology Council 2008).

- Increased radiation due to a projected decrease in tropical cloud cover (Nemani *et al.* 2003, as cited in Fischlin *et al.* 2007). This is linked to warming, which can directly affect ecosystems and increase the frequency and severity of storms originating in the tropics.

4.5.5 Coastal Systems and Low-lying Areas

This section addresses climate-related impacts on coastal ecosystems. Coastal zones are unique environments where land and water meet. There is no single definition for coastal zones, but what is certain is that all coastal zones include an area of land and an area that is covered by saltwater. Burke *et al.* (2001) defines coastal zones as the "intertidal and subtidal areas on and above the continental shelf (to a depth of about 650 feet) – areas routinely inundated by saltwater – and immediately adjacent lands."

4.5.5.1 Affected Environment

Important ecosystems found in coastal zones can include estuaries, coral reefs, coastal lagoons, mangroves, seagrass meadows, upwelling areas, salt marshes, beaches, bays, deltas, kelp forests, and barrier islands. A variety of terminology exists for describing coastal zone ecosystems. Table 4.5-1 lists some of the more commonly described ecosystems found in coastal zones.

Table 4.5-1

Common Coastal Ecosystem

Coastal Ecosystem	Description
Coastal Wetlands	The broadest definition of wetlands occurring along coastal zones. They include a number of natural communities that share the unique combination of aquatic, semi-aquatic, and terrestrial habitats that results from periodic flooding by tidal waters, rainfall, or runoff. a/
Sandy Shorelines	Sandy areas along coastlines where high-energy wave actions deposit and move around sand and sediment.
Barrier Islands	Long narrow islands running parallel to the mainland that provide protection to the coast.
Tidal Wetlands	A type of coastal wetland that is affected by both tides and freshwater runoff.
Estuaries	Bodies of water and their surrounding coastal habitats typically found where rivers meet the ocean.
Mangroves	Coastal wetlands found in tropical and subtropical regions typically characterized by shrubs and trees with an affinity to saline tidal waters.
Tidal Salt Marshes	A type of coastal wetland frequently or continually inundated with water, characterized by soft-stemmed vegetation adapted to saturated soil conditions. b/
Coral Reefs	A large underwater calcium carbonate formation that includes a diverse collection of biological communities.
Coastal Deltas	Typically a triangular deposit of silt and sand deposited at the mouth of a river along a coast.

a/ California Environmental Resources Evaluation Systems (2000)
b/ EPA (2006b)

The world's coastal length is estimated to be 1,015,756 miles, with North America having the longest coastal length of all continents (Pruett and Cimino 2000, as cited in Burke *et al.* 2001). Canada has the longest coastal length of any country in the world and the United States has the second longest, at 164,988 miles and 82,836 miles, respectively (Pruett and Cimino 2000, as cited in Burke *et al.* 2001).

Coastal zones are areas of substantial biological productivity that provide food, shelter, spawning grounds, and nurseries for fish, shellfish, birds, and other wildlife. The interaction between aquatic and terrestrial components of coastal ecosystems creates a unique environment that is critical to the life cycles of many plant and animal species. In the United States, 85 percent of commercially harvested fish depend on estuaries and coastal waters at some stage in their life cycle (Summers *et al.* 2004), while as much as 95 percent of the world's marine fish harvest is caught or reared in coastal waters (Sherman 1993, as cited in Burke *et al.* 2001). Most historical information available on coastal ecosystems focuses on data related to fisheries. As more research is conducted on other increasingly important coastal ecosystems, new data and information are becoming available. For example, coral reefs alone, while representing only 0.2 percent of the total area of oceans, harbor more than 25 percent of all known marine fish (Bryant *et al.* 1998). In addition, the species in some coral reefs can reach densities of 1,000 per square meter (Tibbets 2004). In the United States, 85 percent of the country's essential nesting, feeding, and breeding habitat for waterfowl and migratory birds is found in coastal ecosystems (Summers *et al.* 2004). Coastal zones have also been found to support a much higher percentage of the world's threatened and endangered species.

Because a disproportionate percentage of the world's population lives in coastal zones, the activities of humans have created environmental pressures that threaten the very resources that make the coastal zones desirable (Summers *et al.* 2004). The impact of these activities varies from place to place and depends on the types and sensitivity of coastal ecosystems involved. A wide range of pressures has been identified as causing adverse changes in coastal ecosystems, but the leading causes of coastal ecosystem degradation include physical alteration, habitat degradation and destruction, water withdrawal, overexploitation, pollution, and the introduction of non-native species (UNESCO and WWAP 2006). In addition, climate change might compound these pressures through the effects of higher sea levels, warmer seawater, altered ocean circulation patterns, increased and extreme storm events, and increased carbon dioxide concentrations (UNESCO and WWAP 2006, Burke *et al.* 2001).

4.5.5.1.1 Coastal Conditions Globally and in the United States

The conditions of coastal ecosystems vary from place to place and depend on many factors. Attempts have been made to assess the global extent and distribution of aquatic habitats, but estimates vary considerably depending on the type and source of data (UNESCO and WWAP 2006). While inventories of coastal zones exist, no high-quality data sets or indicators are available at the global level that track changes in condition over time (UNESCO and WWAP 2006). Despite the lack of high-quality data, it is safe to assume that coastal zones with substantial human populations are vulnerable to a range of human activities that can increase pressure and cause adverse changes to coastal ecosystems. As mentioned above, typical coastal ecosystem degradation would include physical alteration, habitat degradation and destruction, water withdrawal, overexploitation, pollution, and the introduction of non-native species. The effects of sea-level rise from climate change could compound these potential impacts.

EPA considers the current overall coastal condition of the United States to be fair (Summers *et al.* 2004). Six geographic coastal regions (Great Lakes Coastal Area, Northeast Coastal Area, Southeast Coastal Area, Gulf Coast Coastal Area, West Coastal Area and Alaska, Hawaii, and Island Territories) were evaluated by EPA using five ecological health indicators to assess estuarine coastal conditions as good, fair, or poor. The five indicators are water quality, sediment quality, benthic, coastal habitat, and fish tissue contaminants. Of the five indicators, only the coastal habitat index received an overall poor rating. The benthic and sediment quality indices rated fair to poor, while the water quality and fish tissue contaminants indices received fair ratings. Of the six coastal regions, the Southeast Coastal Area ranked highest with all indicators rating fair to good. The region with the worst coastal condition was the Northeast Coastal Area, with four of the five indicators rating poor or fair to poor. In terms of human and aquatic life use, 21 percent of the assessed coastal resources of the country are considered unimpaired (good condition), whereas 35 percent are impaired (poor condition) and 44 percent threatened (fair condition).

4.5.5.1.2 Observed Trends in Coastal Zones Conditions

Impacts to coastal ecosystems are expected to continue as coastal populations increase and demand more coastal space and resources. Many coastal ecosystems around the globe have been substantially degraded, and many have been lost altogether. Quantifying the changes in coastal ecosystems is difficult because historical data describing the previous extent of coastal ecosystems are very limited. More and higher-quality data characterizing the world's coastal zones are needed. Burke *et al.* (2001) found the following trends in the conditions of coastal ecosystems:

- Many coastal habitats are disappearing at a fast pace, with extensive losses occurring in the past 50 years.
- Although some industrial countries have improved coastal water quality, chemical pollutant discharges are increasing overall as agriculture intensifies and new synthetic compounds are developed.
- Pollution filtering capacities are lost as coastal ecosystems are lost.

- Nutrient inputs to coastal waters appear to be increasing because of population increase and agricultural intensification.
- The frequency of harmful algal blooms resulting in mass mortality of marine organisms has increased substantially over the past few decades.
- Increased occurrences of hypoxia (shortage of oxygen in water) have been reported.
- More than 25 different coral reef diseases have been recorded since 1970, and reports of coral bleaching have increased measurably in recent years.
- Many commercial fish species and other marine wildlife have become threatened.
- Large-scale marine oil spills have been declining, but oil discharges from land-based sources are believed to be increasing.
- An increased number of invasive species is being reported throughout the world coastal ecosystems.
- The number of protected marine and coastal areas has increased, indicating greater awareness of the need to protect these environments.
- Global marine fish production has increased six-fold since 1950.
- The capacity of coastal ecosystems to produce fish for human harvest has been highly degraded by overfishing, destructive trawling techniques, and loss of coastal nursery areas.
- Notable ecosystem changes have occurred over the last half-century in some fishery areas, such as the North Atlantic and Northeast Pacific.

A number of marine wildlife species have been or could be adversely affected by environmental changes in temperature, availability of water and nutrients, runoff from land, wind patterns, and storminess that are associated with climate change (Kennedy *et al.* 2002). Marshes and mangroves are particularly susceptible to sea-level rise affecting the feeding or nesting grounds of black rail, clapper rail, some terns, and plovers (Kennedy *et al.* 2002). Over the short term, however, shrimp, menhaden, dabbling ducks, and some shorebirds would benefit from the release of nutrients from the breakup of marshes (Kennedy *et al.* 2002). The southern sea otter, a keystone species, is listed as threatened by the Endangered Species Act where the population has declined as a result of the increased contaminants associated with high runoff produced by El Niño Southern Oscillation-induced Pacific Ocean storms (Environmental and Energy Study Institute 2001). Marine turtles are affected by unusual changes in high/low temperatures, pollutants, infectious agents, and marine biotoxins, and have become threatened by an epidemic of fibropapillomatosis linked to polluted coastal areas, agricultural runoff, and biotoxins from algae (Environmental and Energy Study Institute 2001). The full effect of marine birds and species inhaling or ingesting biotoxins produced by algal blooms is of concern and not fully understood (Environmental and Energy Study Institute 2001).

There is strong evidence that temperature increases caused a rise in the global sea level during the 20th Century (Parry *et al.* 2007). Because each coastal area has its own unique geographic and environmental characteristics, consequences from adaptations to climate change are expected to differ for each community. Areas of critical sensitivity on the global scale include Tokyo, Shanghai, and London, and Thailand, India, and Vietnam (Nicholls *et al.* 2007, as cited in National Science and Technology

Council 2008). These areas share the characteristics of coastal location, low elevation, large population, and currently stressed resources. Because of their proximity to the water's edge and the high level of infrastructure typical of many coastal communities, these urban centers are sensitive to changes in sea-level rise (National Science and Technology Council 2008).

Recent data suggest that the rise in global sea level has had an effect on some coastal zones of the United States. Sea level data have shown a rise of 0.8 to 1.2 inches per decade since the beginning of the 20th Century along most of the Atlantic and Gulf Coasts in the United States (National Science and Technology Council 2008). Most of the Atlantic Ocean demonstrated a sea-level rise over the past decade at a rate greater than 0.1 inch per year in an east-northeast band from the United States east coast (National Science and Technology 2008). Coastal wetland loss is occurring where these ecosystems are squeezed between natural and artificial landward boundaries and rising sea levels (Field *et al.* 2007, as cited in National Science and Technology 2008). Rise in sea level could be contributing to coastal erosion across the eastern United States (Zhang *et al.* 2004, as cited in Rosenzweig *et al.* 2007). Sea-level rise in the Chesapeake Bay has accelerated erosion rates resulting in wetland destruction (National Science and Technology Council 2008). In Mississippi and Texas, more than half of the shorelines have eroded at average rates of 8.5 to 10.2 feet per year since the 1970s, while 90 percent of the Louisiana shoreline has eroded at a rate of 39.4 feet per year (Nicholls *et al.* 2007, as cited in National Science and Technology Council 2008). Areas in Louisiana are experiencing barrier island erosion resulting in an increased height of waves (Nicholls *et al.* 2007, as cited in National Science and Technology Council 2008). Furthermore, regional sea-level rise has contributed to increased storm surge impacts along the North American eastern coast (National Science and Technology Council 2008). Particularly becuase subsidence is occurring in parts of this area, areas such as the Louisiana and Gulf coasts are considered at high risk from erosion and storm surges, and any area along the coast with low elevation, large populations, and currently stressed resources could be expected to be at risk from any future sea-level rise.

4.5.5.2 Environmental Consequences

This section describes the potential cumulative effects of climate change on coastal zones, both in the United States and globally.

4.5.5.2.1 Projected Impacts of Climate Change for the United States

According to the National Science and Technology Council's Scientific Assessment, 50 percent of Americans live in coastal communities (National Science and Technology Council 2008). Coastal urban centers are expected to experience a surge in population growth of an additional 25 million people over the next 25 years. This change in population is expected to compound the anticipated adverse effects of climate change on coastal communities, placing heavier demand on already stressed resources (National Science and Technology Council 2008). Data have confirmed an average rise in sea level of 0.8 to 1.2 inches per decade since the beginning of the 20th Century along most coasts in the United States, with the Gulf Coast experiencing a rise of a few inches per decade (primarily due to land subsidence) and Alaskan coasts experiencing *decreases* in sea level of a few inches per decade (National Science and Technology Council 2008). In one example, the Union of Concerned Scientists' report (Frumhoff *et al.* 2007) discusses the impacts of surging waters during a coastal storm in December 1992, when strong winds and rising water levels disrupted the New York City public transit system and required the evacuation of communities in New Jersey and Long Island. Sea-level rise in the Chesapeake Bay has accelerated erosion rates, resulting in wetland destruction (National Science and Technology Council 2008). Sea-level rise in the 21st Century is expected to exceed that of past years, causing great alarm for coastal communities and the infrastructures they support.

Although a range of adverse effects from climate change is expected in the United States, one of the most damaging is expected to be that of sea-level rise. The IPCC predicts a sea-level rise of 7 to 23 inches by 2090-2099 (Parry 2007, as cited in National Science and Technology Council 2008). These figures do not include the anticipated sea-level rise from melting ice sheets and glaciers in Greenland and Antarctica where scientists have already noted a decrease in the thickness and depth of sea ice (National Science and Technology Council 2008) or the potential for rapid acceleration in ice loss (Alley *et al.* 2005, Gregory and Huybrechts 2006, Hansen 2005, all as cited in Pew Center on Climate Change 2007). Recent studies have found the IPCC's estimates of ice loss from the Greenland and Antarctic ice sheets and from mountain glaciers might be underestimated (Shepherd and Wingham 2007, Csatho *et al.* 2008, Meier *et al.* 2007). Further, IPCC might underestimate sea-level rise that would be gained through changes in global precipitation (Wentz *et al.* 2007, Zhang *et al.* 2007). Rahmstorf (2007) used a semi-empirical approach to project future sea-level rise. The approach yielded a proportionality coefficient of 3.4 mm per year per °C of warming, and a projected sea-level rise of 0.5 to 1.4 meters above 1990 levels in 2100 when applying IPCC Third Assessment Report warming scenarios. Rahmstorf (2007) concludes that "[a] rise over 1 meter by 2100 for strong warming scenarios cannot be ruled out."

Some general effects associated with rising sea levels include:

- Loss of land area due to submergence and erosion of lands in the coastal zone
- Changes to coastal environments
- More flooding due to storm surges
- Salinization of estuaries and groundwater (National Science and Technology Council 2008)

For islands such as those located in Hawaii and other U.S. territories in the Pacific, outcomes could include a reduction in island size and the abandonment of inundated areas (National Science and Technology Council 2008). Approximately one-sixth of U.S. land that is close to sea level is located in the mid-Atlantic region and, consequently, much of the reporting on effects focuses on this region (National Science and Technology Council 2008).

Over the past century, the highest rate of sea-level rise has been observed in the mid-Atlantic region, in part resulting from subsidence of the land surface (Gutierrez *et al.* 2007). For example, Virginia has observed sea-level rise at 4.4 mm per year compared to 1.8 mm per year in Maine (Zervas 2001, as cited in Gutierrez *et al.* 2007). New Jersey, with 60 percent of its population living along the 127 miles of coastline, has experienced coastline subsidence and beach erosion threatening communities and coastal wetlands (Union of Concerned Scientists 2007, Aucott and Caldarelli 2006, Metro East Coast Regional Assessment 2000).

The effects of sea-level rise on some coastal communities could be devastating with increased erosion and flooding. Extensive erosion has already been documented across the East Coast, as have notable decreases in the coastal wetlands of Louisiana, the mid-Atlantic region, New England, and New York (Rosenzweig *et al.* 2007, as cited in National Science and Technology Council 2008). Erosion is expected to be worse in sandy environments along the mid-Atlantic coast, Mississippi, and Texas (National Science and Technology Council 2008; Nicholls *et al.* 2007, as cited in National Science and Technology Council 2008). The IPCC notes that sandy shorelines are already retreating. Furthermore, areas in Louisiana are experiencing barrier island erosion, resulting in increases in the height of waves that make it to shore (Nicholls *et al.* 2007, as cited in National Science and Technology Council 2008). A large storm can affect the shoreline position for weeks to a decade or longer (Morton 1994, Zhang *et al.* 2004, List *et al.* 2006, Riggs and Ames 2003, all as cited in Gutierrez *et al.* 2007). Tidal wetlands, estuarine beaches, marshes, and deltas are expected to be inundated with water in areas such as the Mississippi River, Louisiana Delta, and the Blackwater River marshes in Maryland (Titus *et al.* 2008, as cited in National Science and Technology Council 2008). The "coastal squeeze" phenomenon, where wetlands are trapped between natural and human-made land boundaries, is causing wetland loss and habitat destruction (Field *et al.* 2007, as cited in National Science and Technology Council 2008). Freshwater resources are also at risk given the *likely* intrusion of saltwater into groundwater supplies, adversely affecting water quality and salinization rates (Kundzewicz *et al.* 2007, as cited in National Science and Technology Council 2008).

The height of storm surges will increase if sea level rises, regardless of storm frequency and intensity increases; thus, a storm of similar behavior will cause greater damage with rising sea level (Fisher *et al.* 2000). One study suggests the 100-year flood might actually occur every 25 to 30 years (Najjar *et al.* 1999, as cited in Fisher *et al.* 2000). By mid-century, Boston and Atlantic City could experience a 100-year flood event every 2 to 4 years and annually by the end of the century (Frumhoff *et al.* 2007).

Cayan *et al.* (2006) projected future sea-level rise and its implications for California. The study projected sea-level rise, relative to 2000, to range from 11 to 54 centimeters (4.3 to 21 inches); 14 to 61 centimeters (5.5 to 24 inches); and 17 to 72 centimeters (6.7 to 28 inches) by 2070 to 2099 for B1, A2, and A1 GHG modeling scenarios, respectively. The mean sea-level rise from a survey of several climate models was also determined to range from approximately 10 to 80 centimeters (3.9 to 3.15 inches) between 2000 and 2100. The historic rate of sea-level rise observed at San Francisco and San Diego during the past 100 years was 15 to 20 centimeters (5.9 to 7.9 inches). Parts of the California coast are at risk for flood damage, which could further jeopardize levees in the City of Santa Cruz (California Environmental Protection Agency 2006). Santa Cruz is 20 feet above sea level with levees built to contain the 100-year flood. If sea levels were to increase above 12 inches as predicted for the medium warming range of temperatures, a flood associated with a storm surge event at the 100-year level might happen once every 10 years (California Energy Commission 2006). The ENSO events of 1982-1983 and 1997-1998 corresponded to high sea level episodes (Flick 1998, as cited in Cayan *et al.* 2006). These high-sea-level episodes could intensify in future ENSO events if sea-level rise increases.

The frequency and intensity of storms are expected to become more prevalent at the same time as sea levels rise and sea surface temperatures increase. Some societal effects include the following:

- Infrastructure such as bulkheads, dams, and levees could be damaged by flooding and strong storms (Nicholls *et al.* 2007, as cited in National Science and Technology Council 2008).
- Coastal ports, roads, railways, and airports are at risk of disruption due to power outages, flooded routes, and poor travel conditions (Nicholls *et al.* 2007, as cited in National Science and Technology Council 2008).
- Industries reliant on coastal stability, such as travel and recreation, fishing and hunting, and trade, are expected to become increasingly sensitive to these temperature and precipitation changes in the coming decades (Nicholls *et al.* 2007, as cited in National Science and Technology Council 2008).
- The most at-risk state in the United States is expected to be Alaska because the indigenous communities depend on wildlife for hunting and fishing practices, reside within floodplains, and currently face water shortages (Field *et al.* 2007, as cited in National Science and Technology Council 2008).

Loss of coastal wetlands due to intense storms has been documented on many occasions. A prominent recent example is the loss of coastal lands as a result of Hurricane Katrina in 2005. In Louisiana alone, the loss of land during Hurricane Katrina was approximately 217 square miles. The

Chandeleur Islands, which New Orleans relied on as a tropical storm buffer, lost 85 percent of their surface area (CCSP 2008b).

Increases in storm frequency and severity, and sea-level rise itself, have detrimental effects on coastal areas with sandy beaches. Many species rely on the wellbeing of, and accessibility to, beaches. Examples include the following:

- Diamondback terrapins and horseshoe crabs rely on beach sands to bury their eggs. The eggs not only act to propagate the species, but some shorebirds, such as the piping plover, rely on these eggs as a food source (USFWS 1988, as cited in Titus *et al.* 2008).

- Horseshoe crabs rarely spawn unless sand is deep enough to nearly cover their bodies, about 10 centimeters (4 inches) (Weber 2001). Shoreline protection structures designed to slow beach loss can also block horseshoe crab access to beaches and can trap or strand spawning crabs when wave energy is high (Doctor and Wazniak 2005). So, in this case, the loss of beach, as well as the adaptation strategy selected by the community, can result in harm to local species.

- A rare firefly, *Photuris bethaniensis*, is found only in areas between dunes on Delaware's barrier beaches. Its habitat is at risk due to beach stabilization and hardening of shorelines; this limits migration of dunes and the formation of the swales between dunes where the firefly is found (Titus *et al.* 2008).

4.5.5.2.2 Adaptation to Climate Change

There are uncertainties regarding which effects of climate change could affect individual coastal and low-lying areas. However, because these areas are particularly sensitive to climate and hazardous weather events, adaptation to projected climate change remains a potentially attractive option. Adaptations can be preventative, taken before the arrival of an anticipated impact, or reactive, taken in response to the actual changes. Many of the adaptations for coastal and low-lying areas can overlap between these two categories and might differ only by the timing in which they are implemented. The CCSP (2008a, as cited in National Science and Technology Council 2008) outlines seven approaches to adaptation:

- Protecting key ecosystem features
- Reducing anthropogenic stresses
- Representation (maintaining species diversity)
- Replication of ecosystems to maintain species diversity and habitable lands
- Restoration of disturbed ecosystems
- Refugia (using less affected areas to "seed" new areas)
- Relocation

Some examples of possible adaptation strategies in the United States include shifting populations and infrastructure from coastal communities along the East and Gulf Coasts and mid-Atlantic region further inland (Nicholls *et al.* 2007, as cited in National Science and Technology Council 2008). Other possible strategies include elevating infrastructure, introducing barriers such as levees and dams to hold off storm surges; reducing fertilizer and pesticide use in nearshore coastal communities (Epstein *et al.* 2006); preserving contiguous interconnected water systems (including mangrove stands, spawning lagoons, upland forest and watershed systems, coastal wetlands) (Epstein *et al.* 2006); and constructing watertight containment for essential equipment (NY City DEP 2008). Although the options for adaptation in coastal and low-lying areas are many, the key is to consider the period during which these adaptations are proposed and implemented to best prepare communities. The IPCC in their 2007 Technical Summary has predicted that the costs of adaptation are *virtually certain* to be less than those of inaction (Parry *et al.* 2007).

Current government programs are in effect that assist in subsidizing protection for coastline development, including shoreline protection and beach replenishment, federal disaster assistance, and the National Flood Insurance Program (Fisher *et al.* 2000). In 2006, Maine developed and implemented shoreline regulations to address projected sea-level rise due to climate change (Frumhoff *et al.* 2007). Maine is currently the only state in the Nation with such a program.

4.5.5.2.3 Projected Global Impacts of Climate Change

Globally, coastal systems and low-lying areas are experiencing adverse effects related to climate change and sea-level rise, such as coastal inundation, erosion, ecosystem loss, coral bleaching and mortality at low latitudes, thawing of permafrost, and associated coastal retreat at high latitudes (*very high confidence*) (Nicholls *et al.* 2007). To further exacerbate the stressors, human settlement and encroachment on coastal systems and low-lying areas have been increasing with an estimated 23 percent of the world's population living within about 60 to 65 miles of the coast and no more than about 330 feet above sea level (Small and Nicholls 2003).

Although non-uniform around the world, global sea level is estimated to have risen by 0.07 plus or minus 0.02 inch per year over the past century with western Pacific and eastern Indian Ocean experiencing the greatest rise (Nicholls *et al.* 2007). Sea level is anticipated to continue to increase 0.7 to 2.0 feet or more by the end of the 21st Century (Nicholls *et al.* 2007). This sea-level rise coupled with both projected sea surface temperatures increasing 1 to 3 °C and intensified cyclonic activity could lead to larger waves and storms surges impacting coastal systems and low-lying areas across the globe (Nicholls *et al.* 2007). The loss or degradation of coastal ecosystems has a direct impact on societies that depend on coastal-related goods and services such as freshwater and fisheries with the potential to impact hundreds of millions of people (Parry *et al.* 2007).

There is variability in the projected effects from climate change and sea-level rise on an international scale. For instance, if the global mean annual temperature increases above 1980 to 1999 levels, coastal systems and low-lying areas are anticipated to sustain increased damage due to floods and storms; an additional increase of 2 °C would lead to an increase of millions of people that could experience coastal flooding each year; and an increase of 3 °C is estimated to cause a loss of 30 percent of the global coastal wetlands (*high confidence*; IPCC 2007c, Figure SPM.2). Coastal wetland ecosystems are at substantial risk from sea-level rise if they are sediment-starved or prevented from migrating inland. As sea water temperatures increase, it is *likely* that coral bleaching and mortality will rise unless corals demonstrate thermal adaptation (Nicholls et al 2007). These adverse impacts are expected to increase in severity as the global mean annual temperature increases.

Tide gauges have measured the average rate of sea-level rise to be 0.07 plus or minus 0.02 inch per year from 1961 to 2003 and 0.07 plus or minus 0.02 inches per year (National Science and Technology Council 2008) over the past century. These changes are attributed to thermal expansion associated with rising global temperature, thawing of permafrost, and loss of sea ice (Nicholls *et al.* 2007). The global ocean temperature averaged from the surface to a depth of approximately 2,300 feet has increased by 0.10 °C over the period from 1961 to 2003, contributing to an average increase in sea level of 0.02 plus or minus 0.004 inch per year (National Science and Technology Council 2008). This contribution has increased for the period 1993 to 2003 with a rate of sea-level rise of 0.06 plus or minus 0.02 inch per year. Melting of mountain glaciers, ice caps, and land ice have also contributed to the measured sea-level rise. From 1961 to 2003, the melting of land ice has contributed approximately 0.03

plus or minus 0.02 inch per year to sea-level rise with an accelerated rate of 0.05 ± plus or minus 0.02 inch per year between 1993 and 2003 (Lemke *et al.* 2007, as cited in National Science and Technology Council 2008).

Sea-level rise is non-uniform around the world. In some regions, rates of rise have been as much as several times the global mean, while other regions have experienced falling sea level. This might be the result of variations in thermal expansion and exchanges of water between oceans and other reservoirs, ocean and atmospheric circulation, and geologic processes (Bindoff *et al.* 2007, as cited in National Science Technology Council 2008). Satellite measurements provide unambiguous evidence of regional variability of sea level change for the period 1993 to 2003 with the largest sea-level rise occurring in the western Pacific and eastern Indian oceans (National Science and Technology Council 2008).

Sea level is projected to increase from 0.7 to 2.0 feet or more by the end of the 21^{st} Century (Nicholls *et al.* 2007) with the possibility of additional sea-level rise occurring as a result of the breakdown of West Antarctic and Greenland ice sheets. A temperature increase of 1.1 to 3.8 °C would trigger the breakdown of the Greenland ice sheet, and is *likely* to occur by 2100 (Parry *et al.* 2007). An additional sea-level rise of about 21 to 24 feet would result in the complete disappearance of the Greenland ice sheet (IPCC 2007a, Table 4.1, Epstein *et al.* 2006). This scenario raises concern regarding the viability of coastal communities, salt marshes, corals, and mangroves. A sea-level rise of about 14 inches from 2000 to 2080 is projected to reduce coastal wetlands by 33 percent with the largest impact on the Atlantic and Gulf of Mexico coasts of the Americas, the Mediterranean, the Baltic, and small-islands (Nicholls *et al.* 2007).

IPCC SRES estimated that the coastal population could grow from 1.2 billion people in 1990 to between 1.8 billion and 5.2 billion people by the 2080s with this range dependent on coastal migration. Although the impact of sea-level rise on a specific region can be difficult to quantify given regional and local variations (Parry *et al.* 2007), the IPCC describes the following coastal regions as the most vulnerable to the impact of climate change: South Asia, Southeast Asia, East Asia, Africa, and small islands (Nicholls *et al.* 2007).

Many of the coastal cities that are most vulnerable to adverse impacts of climate change are at further risk due to human activities such as agriculture, aquaculture, silviculture, industrial uses, and residential uses that have degraded the natural protective qualities of the coastal systems (Nicholls *et al.* 2007). Coastal countries at risk for shoreline retreat and flooding due to degradation associated with human activity include Thailand (Durongdej, 2001, Saito 2001, both as cited in National Science and Technology Council 2008); India (Mohanti 2000, as cited in National Science and Technology Council 2008); Vietnam (Thanh *et al.* 2004, as cited in National Science and Technology Council 2008); and the United States (Scavia *et al.* 2002, as cited in National Science and Technology Council 2008), with emphasis on the seven Asian megadeltas that have a combined population greater than 200 million (Nicholls *et al.* 2007). Of particular concern are those highly coastal populated regions within countries with limited financial resources to protect or relocate its populations (Nicholls *et al.* 2007).

Small islands are particularly vulnerable to climate change and sea-level rise, especially those islands prone to subsidence (Parry *et al.* 2007). Beach erosion is projected to increase as sea level rises and sea water temperature increases. Arctic islands could experience increased erosion and volume loss as permafrost and ground ice warms in response to rising global temperatures (Mimura *et al.* 2007).

Positive impacts anticipated to be experienced in high latitudes include a longer tourist season and better navigability (Mimura *et al.* 2007). Without adaptation, IPCC model results suggest more than 100 million people could endure coastal flooding due to sea-level rise every year by 2080 (Nicholls *et al.* 2007).

4.5.5.2.4 Adaptation to Climate Change

In some circumstances, the potential effects from climate change and sea-level rise on coastal systems and low-lying areas can be reduced through widespread adaptation (Nicholls *et al.* 2007). The IPCC modeled results of flood risk associated with rising sea level and storm surges projected to 2080 found substantial benefit associated with upgrading coastline defenses (Nicholls *et al.* 2007). In addition, curtailing the current degradation in coastal systems by anthropogenic activities such as deforestation, fertilizer use, sewage dredging, sand mining, fish harvesting, and sea wall construction would provide a more robust coastal system resistant to extreme water levels during storms.

Small islands in the Indian Pacific Oceans and the Caribbean have much of their infrastructure in coastal locations (Parry *et al.* 2007). Under projected levels of sea-level rise, some infrastructure is *likely* to be at risk from inundation and flooding (Mimura *et al.* 2007). Small islands have limited choices in adaptation to sea-level rise and climate change impact on coastal sections.

4.5.6 Food, Fiber, and Forest Products

This section defines these food, fiber, and product resources and the existing conditions and potential vulnerability of each to climate change impacts. The primary source of information presented in this section is the IPCC Fourth Assessment Report (Easterling *et al.* 2007), specifically, Chapter 5 for food, fiber, and forest products.

The food, fiber, and forest sector is a substantial source of livelihood and food for large numbers of the world's population and a major land cover type at a global level. Cropland, pasture, or natural forests account for approximately 70 percent of the world's land cover. The United Nations Food and Agriculture Organization (FAO) estimates that approximately 450 million of the world's poorest people depend entirely on this sector for their livelihood (Easterling *et al.* 2007).

According to IPCC, this sector includes agriculture, forestry, and fisheries. It also includes subsistence and smallholder agriculture, defined as rural producers who farm or fish primarily with family labor and for whom this activity provides the primary source of income (Easterling *et al.* 2007).

4.5.6.1 Affected Environment

An estimated 40 percent of Earth's land surface is used for cropland and pasture (Foley *et al.* 2005, as cited in Easterling *et al.* 2007). The FAO estimates that natural forests cover another 30 percent of the land surface, and that 5 percent of that natural forest area generates 35 percent of global timber production (FAO 2000, as cited in Easterling *et al.* 2007). Nearly 70 percent of people in lower income countries around the world live in rural areas where agriculture is the primary source of livelihood. Growth in agricultural incomes in developing countries fuels the demand for non-basic goods and services fundamental to human development. The FAO estimates that the livelihoods of roughly 450 million of the world's poorest people depend entirely on managed ecosystem services. Fish provide more than 2.6 billion people with at least 20 percent of their average per-capita animal protein intake, but 75 percent of global fisheries are currently fully exploited, overexploited, or depleted (FAO 2004, as cited in Easterling *et al.* 2007).

4.5.6.1.1 Terrestrial Systems

The distribution of crop, pasture, and forest species between the polar and equatorial latitudes is a function of current climatic and atmospheric conditions, as well as photoperiod. Agricultural, pastoral, and forestry systems depend on total seasonal precipitation and its pattern of variability, as well as wind and humidity. Crops exhibit threshold responses to their climatic environment, which affect their growth, development, and yield (Porter and Semenov 2005, as cited in Easterling *et al.* 2007). Short-term natural extremes, such as storms and floods, interannual and decadal climate variations, and large-scale circulation changes, such as ENSO, all have important effects on crop, pasture, and forest production (Tubiello 2005, as cited in Easterling *et al.* 2007).

For example, Europe experienced a particularly extreme climate event during the summer of 2003, with temperatures up to 6 °C above long-term means, and precipitation deficits up to 12 inches (Trenberth *et al.* 2007, as cited in Easterling *et al.* 2007). Associated with this extreme climate event was a decline in corn yield of 36 percent in the Po River valley in Italy and 30 percent in France. In addition, French fruit harvests declined by 25 percent, winter wheat yields declined by 21 percent, and hay and other forage production declined on average by 30 percent (Ciais *et al.* 2005, as cited in Easterling *et al.* 2007). Moreover, African droughts between 1981 and 1999 caused livestock mortality from 20 percent to more than 60 percent in countries such as Botswana, Niger, Ethiopia, and Kenya (Easterling *et al.* 2007).

Overall, climate change might benefit crop and pasture yields in mid- to high-latitude regions, while decreasing yields in dry and low-latitude regions. Total forest productivity might rise modestly, with considerable global variation. Local extinctions of fish species are expected, particularly at the edges of habitat ranges (Easterling *et al.* 2007).

Agricultural and forest lands are experiencing multiple stresses that increase their vulnerability to climate change impacts. Examples include soil erosion, salinization of irrigated areas, overgrazing, over-extraction of groundwater, loss of biodiversity, and erosion of the genetic resource base in agricultural, forest, and pasture areas. Overfishing, loss of biodiversity, and water pollution in aquatic areas are stresses that increase vulnerability to climate change to fishery resources (Easterling *et al.* 2007).

The vulnerability of these resources depends on both the exposure to climate conditions and capacity to cope with changing conditions. Exposure to conditions highly depends on local geography and environment. Adaptive capacity is dynamic and depends on wealth, human capital, information and technology, material resources and infrastructure, and institutions and entitlements (Easterling *et al.* 2007).

Sub-Saharan Africa offers one example of a region that is currently highly vulnerable to food insecurity (Vogel 2005, as cited in Easterling *et al.* 2007). Drought conditions, flooding, and pest outbreaks are some of the current stressors on food security that could be influenced by future climate change. Options for addressing food insecurity in this region (and overall development initiatives related to agriculture, fisheries, and forestry) could be constrained by health status, lack of information, and ineffective institutional structures. These constraints could limit future adaptations to periods of heightened climate stress (Reid and Vogel 2006, as cited in Easterling *et al.* 2007).

4.5.6.1.2 Aquatic Systems

Spatial adaptation of marine ecosystems to climate change is in some ways less geographically constrained than for terrestrial systems. The rates at which planktonic ecosystems have shifted their distribution have been very rapid over the past three decades, which can be regarded as natural adaptation to a changing physical environment (Beaugrand *et al.* 2002, as cited in Easterling *et al.* 2007). Most fishing communities use stocks that fluctuate due to interannual and decadal climate variability, and consequently have developed considerable coping capacity (King 2005, as cited in Easterling *et al.* 2007).

Research on the relationship between water temperature and the health of freshwater fishes indicates different impacts in summer and winter. Although temperature increases might cause seasonal increases in growth in the winter, mortality risks to fish populations occur at the upper end of their thermal tolerance zone in the summer.

World capture production of finfish and shellfish in 2004 was more than twice that of aquaculture, but since 1997 capture production decreased by 1 percent, whereas aquaculture increased by 59 percent (Easterling *et al.* 2007). The increasingly important aquaculture sector allows for the application of similar types of management adaptations to climate change suggested for crop, livestock, and forestry sectors. This is not the case, however, for marine capture fisheries, which are shared resources subject to varying degrees of effective governance. Adaptation options for marine capture fisheries include altering catch size and effort. Three-quarters of world marine fish stocks are currently exploited at levels close to or above their productive capacity (Bruinsma 2003, as cited in Easterling *et al.* 2007). Reductions in the level of effort and harvest are required to sustain yields. Such a course of action might also benefit fish stocks that are sensitive to climate variability when their population age-structure and geographic sub-structure are reduced (Brander 2005, as cited in Easterling *et al.* 2007).

4.5.6.2 Environmental Consequences

Earth's land surface is composed mostly of managed cropland and pasture (40 percent) and natural forests (30 percent) (Foley *et al.* 2005, as cited in Easterling *et al.* 2007). These sectors provide important commodities that are produced in a variety of geographic and climatic regions (CCSP 2008c). The continued growth and productivity of the world's agriculture and forests is necessary to sustain human economic and social development.

The discussion below is focused on impacts on food and industrial crops, fisheries, agricultural pastures, commercial forestry, and subsistence farming (Easterling *et al.* 2007). The key drivers for climate impacts in this sector are higher temperatures, changed precipitation and transpiration dynamics, the effects of increased CO_2 concentrations on vegetative growth and yield, greater frequency in extreme weather events, and increased stressors to forests and agriculture in the form of pests and weeds (Easterling *et al.* 2007).

The world's food crops, forests, and fisheries have evolved to be in tune with the present climatic environment. The productivity of these systems ultimately relies on the interaction of various climate factors including temperature, radiation, precipitation, wind speed, and water vapor pressure (Easterling *et al.* 2007). Threshold climatic conditions for crops and forests affect their growth and yield, and climatic conditions and their interaction influence the global distribution of agricultural and forest species (Porter and Semenov 2005, as cited in Easterling *et al.* 2007).

The sensitivity to climate change and exposure to various other stressors increases the vulnerability of the forest, food, and fiber systems (Easterling *et al.* 2007). Non-climate stressors such as soil erosion, overgrazing, loss of biodiversity, decreased availability of water resources, increased economic competition among regions, and the adaptive capacity of various species increase overall sensitivity to the climate and thus exacerbate the adverse effects of climate change (CCSP 2008b).

Climate change could also benefit agriculture and silviculture through the CO_2 fertilization effect. CO_2 is essential for plant growth; some research suggests that higher atmospheric concentrations lead to higher productivity of some food, fiber, and forest crops. Milder winters and longer growing seasons could also increase productivity in some regions.

Important examples that highlight the link between large-scale climate changes and the sensitivity of the food, fiber, and forest systems include the effects of ENSO, a relatively well-known phenomenon, on crop yield. In Australia, during ENSO years there is increased probability of a decline in farmers' incomes by as much as 75 percent below the median income as compared to non-ENSO years (Tubiello 2005, as cited in Easterling *et al.* 2007). Another example is the extreme heat wave that occurred in Europe in 2003, which lowered maize yield by 36 percent in Italy and 30 percent in France (Ciais *et al.* 2005, as cited in Easterling *et al.* 2007). Uninsured losses for the entire European Union agriculture sector were estimated at 13 billion euros; 4 billion euros was lost in France alone (Sénat 2004, as cited in Easterling *et al.* 2007).

The most recent comprehensive and peer-reviewed literature on global climate impacts on the food and forestry sectors is from the IPCC Fourth Assessment Report. The SAP 4.3 Report provides an additional source of information on the impacts of climate change on agriculture, land resources, and biodiversity in the United States. Most of the evidence cited in this chapter focuses on the results of the IPCC report and SAP 4.3. However, because new evidence is continuously emerging on the subject of climate change impacts on the agriculture and forest systems, the discussion below also draws on results reported in more recent studies.

4.5.6.2.1 Projected Impacts of Climate Change for the United States

Forests

In the United States, the combination of human management and temperate climate has resulted in a productive and healthy forest system, as exemplified by the southern pine plantations (CCSP 2000). Forests are generally considered the most productive of the terrestrial ecosystems and provide important commodities like timber products. They are also key biodiversity sanctuaries and providers of ecosystem services. Currently, forests cover roughly one third of the land in the United States. Net growth of these forests (growth minus removals minus decomposition) accounts for removing about 883.7 $MMTCO_2$ per year, about 12.5 percent of gross national GHG emissions (EPA 2008b). Globally, forests account for the largest fraction of terrestrial ecosystem sequestered carbon, estimated to be roughly 1,640 petagrams of carbon (Sabine *et al.* 2004, as cited in CCSP 2008b). Climate change could directly affect the ability of forests to provide these key services and commodities in several ways.

One key impact of climate change is the extended risk and increased burn area of forest fires coupled with pathogenic stressors that damage fragile forest systems (Easterling *et al.* 2007). These impacts (forest fires, diseases, and pathogens) might be greatest between 2050 and 2100. It is projected that the forest fire season (summer) could be extended by 10 to 30 percent as a result of warmer temperatures (Parry *et al.* 2007). In the western states, the anticipated warmer spring and summer temperatures are expected to reinforce longer fire seasons and increased frequency of large wildfires. In turn, the carbon pools within forests are expected to be affected by changes in forest composition and reduced tree densities (Westerling 2006). More specifically, the Hadley and Canadian climate and ecological models project an increase in the fire season hazard by 10 percent in the 21st Century in the United States, with small regional decreases in the Great Plains and a 30-percent increase in Alaska and the Southeast (CCSP 2000). Highlighting the geographic differences even within a state, two climate models including the Geophysical Fluid Dynamics Laboratory and the Parallel Climate Model were run using “business as usual” (A2) and “transition to a low GHG emissions” (B1) IPCC SRES emissions scenarios. The results showed increases in fire risk in Northern California (15 to 90 percent), increasing with temperature, whereas, in Southern California, the change in fire risks ranged from a decrease of 29 percent to an increase of 28 percent. These results were largely driven by differences in precipitation between the different scenarios. In Southern California the drier conditions simulated in both the Geophysical Fluid Dynamics Laboratory model scenarios led to reduced fire risks in large parts of southern California, with fire risks increased in parts of the San Bernardino Mountains (Westerling and Bryant 2006).

Historical evidence indicates that the warmer periods in the past millennium correlated with increased frequency in wildfires, particularly in western forests (CCSP 2008b). General circulation models project increased wildfire activity in the western states, particularly from 2010 through 2029 (Flannigan *et al.* 2000, Brown *et al.* 2004, both as cited in CCSP 2008b). In 2060, models have projected forest fire severity increases of 10 to 30 percent in the southeastern states and 10 to 20 percent in the northeastern states (Flannigan *et al.* 2000, as cited in CCSP 2008b). Some models have projected even larger increases in wildfire activity, particularly in the southeastern region of the United States (Bachelet *et al.* 2001, as cited in CCSP 2008b). Potential losses to North American producers from increased disturbances (including wildfires, insects, and diseases) coupled with climate change impacts have been estimated to range from $1 to $2 billion per year averaged throughout the 21st Century (Sohngen and Sedjo 2005, as cited in Field *et al.* 2007).

Ancillary consequences of the projected increase in wildfire frequency across the United States include an increase in emissions expected to affect air quality and continue to be a source of GHGs. Although the GHGs that are released through wildfires could eventually be sequestered by forest regrowth, this carbon release might not be fully recovered in the short term and thus might be an important source of CO_2 in the atmosphere (Kashian *et al.* 2006, as cited in CCSP 2008b). Particularly in forests in the western United States, "If wildfire trends continue, at least initially this biomass burning will result in carbon release, suggesting that the forests of the western United States could become a source of increased atmospheric carbon dioxide rather than a sink, even under a relatively modest temperature increase scenario" (Westerling *et al.* 2006).

Invasive Species

The increasing occurrence of forest fires, which is likely to continue with projected warming temperatures, would impact ecosystem services, reduce the potential for carbon storage via forest management, and provide increased potential habitat for invasive species and insect outbreaks (Parry *et al.* 2007).

Since invasive species and pests are not constrained by the need for pollinators or seed spreaders, these species are more adaptable to the warming climate (Vila *et al.* 2007, as cited in CCSP 2008b). The northward movement of weed species, especially invasive weeds, is likely to be a result of higher projected temperatures and increased CO_2 concentration. This movement northward could further be accelerated, as some studies that have shown that the responsiveness of weeds to glyphosate, an important herbicide used in the United States, diminishes with increases in CO_2 concentration levels (Ziska *et al.* 1999, as cited in CCSP 2008b).

Disease and Pathogens

Warming temperatures might be allowing for the migration of diseases and pathogens (CCSP 2008b). More specifically, the increases in temperature are influencing the development of insect lifecycles, reducing winter mortality rates and "influence[ing] synchronization of mass attacks required to overcome tree defenses" (Ryan *et al.* 2008, as cited in CCSP 2008b).

The warming trends in the United States have already allowed for earlier spring insect activity and the increased proliferation of certain species (CCSP 2008b). These warming trends have also allowed for an increase in the survival rates of diseases and pathogens that affect crops, as well as plant and animal species. Recent research has linked the rising temperatures to increased outbreaks of the mountain pine beetle, the southern pine beetle, and the spruce beetle. Rising temperatures have also been correlated with the expansion of suitable range for the hemlock wooly adelgid and the gypsy moth (Ryan *et al.* 2008, as cited in CCSP 2008b). Not only are the boundaries of insects being shifted by climate change but "tree physiology and tree defense mechanisms" are being altered as well (Kirilenko and Sedjo 2007). The damage to forests is expected to depend on seasonal warming: winter and spring increases in temperature might increase losses to insects such as the southern pine beetle (Gan 2004, as cited in Field *et al.* 2007). In the western United States, particularly in Colorado, a recent measurable decline in aspen trees has been linked to global warming. Unlike earlier episodes of aspen tree dieback, the current decline is occurring more rapidly and over larger areas. The dieback is caused by bark beetles that were not known to have existed in the area (Saunders *et al.* 2008). In effect, "the hotter, drier conditions recently present in Colorado's mountains have enabled these unexpected agents to so quickly kill so many aspen" (Saunders *et al.* 2008). The forest disturbances such as insect outbreaks "are increasing and are likely to intensify in a warmer future with drier soils and longer growing seasons" (Field *et al.* 2007, as cited in Saunders *et al.* 2008). The control of increased insect populations, especially in the projected warmer winters and in the southern regions, might require increased applications of insecticides. It is important to control these insect populations because of their ability to spread other pathogens, especially the flea beetle, which is known to be a conduit for the corn damaging bacteria Stewart's Wilt (CCSP 2008b).

Migration

Under future climate warming scenarios, plant and animal species are expected to shift northward and to migrate to higher elevations, thus redistributing North American ecosystems (Parry *et al.* 2007). The southeast and northwest forests could experience carbon losses as a result of increased drought (CCSP 2000). However, the projected increases in precipitation over dry regions might encourage forest growth and displace some grasslands (CCSP 2008b).

A marked change in forest composition and distribution has been noted in Alaska, as indicated by a northward migration of the subarctic boundary tree line by 6 miles, and the displacement of 2 percent of the Alaskan tundra in the past 50 years (Anisimov *et al.* 2007, as cited in CCSP 2008b). Also, as evidenced by remote sensing analysis, the growing season is increasing in length by roughly 3 days per decade (CCSP 2008b). Arctic vegetation is expected to shift northward and cause forests to overtake tundra (ACIA 2004, as cited in CCSP 2008b).

Crops and Agriculture

In the early part of the 21st century, moderate climate change will increase crop yields on agricultural land by 5 to 20 percent (Easterling *et al.* 2007). However, this is dependent on regional differences and for crops that rely on highly utilized water resources (Parry *et al.* 2007). Crops that are near the threshold of their productive temperature range (*i.e.*, crops that are "near the warm end of their suitable range"), such as wine grapes in California, are expected to decrease in yield or quality based on moderate climate change scenarios (Easterling *et al.* 2007).

Grain crops in the United States are likely to initially benefit from the increased temperature and CO_2 levels. However, as temperatures continue to rise, sensitivity of these grain crops could increase. This sensitivity is expected to an even greater extent for horticultural crops such as tomatoes and onions, compromising their productive yield (CCSP 2008b). Various studies have found differing thresholds for maize production in the United States, with one in particular showing a 17 percent reduction of maize yield per 1 degree Celsius increase in temperature (Lobell and Asner 2003, as cited, in CCSP 2008b). Other crops such as wheat are regionally and temporally dependent. Studies show that wheat yield in the Great Plains "is estimated to decline 7 percent per 1 degree Celsius increase in air temperature between 18 and 21 degrees Celsius and about 4 percent per 1 degree Celsius increase in air temperature above 21 degrees C" (Lobell and Field 2007, as cited in CCSP 2008b). Similarly, rice yields are projected to decline about 10 percent per 1 degree Celsius increase for temperature profiles that are above current summer mean air temperatures (CCSP 2008b).

In the Great Lakes region, fruit production might benefit from climate change although there might be increased risk of winter thaws and spring frost (Bélanger *et al.* 2002 and Winkler *et al.* 2002, both as cited in Field *et al.* 2007). In New Jersey, higher summer temperatures are expected to depress the yields of a number of other economically important crops adapted to cooler conditions (*e.g.*, spinach, lettuce) by mid-century, while rising winter temperatures are expected to drive the continued northward expansion of agricultural pests and weeds (such as kudzu) (Frumhoff *et al.* 2007) . Cranberries are especially susceptible because of their requirement to be subjected to long periods of cold winter temperatures for development (Frumhoff *et al.* 2007).

Extreme Weather Events

The negative impacts of increased frequency of extreme weather events on crop yield might temper the beneficial effects of increased CO_2 concentrations with associated temperature increases and longer growing seasons on crop growth (CCSP 2008b).

In the United States, particularly in the north, the average increase in temperature is expected to lead to a longer growing season. However, temperature increases could also lead to increased climate sensitivity in the southeast and the Corn Belt (Carbone *et al.* 2003, as cited in CCSP 2008b). The Great Plains region is not expected to experience increased climate sensitivity (Mearns *et al.* 2003, as cited in CCSP 2008b). In terms of species migration as a result of climate change, the United States has experienced an incursion of perennial herbaceous species that limit the soil moisture available for other crops throughout the growing season (CCSP 2008b). The invasion of these nonnative species could impact how these regions adapt to climate change and could lead to the potential for more frequent wildfires by increasing vegetation density (Fenn *et al.* 2003 and Wisdom *et al.* 2005, both as cited in CCSP 2008b).

Multiyear droughts, which might have been a result of increased temperature conditions in lower-elevation forests in the southwestern region, have had a large impact on forest mortality rates (Breshears *et al.* 2005, as cited in CCSP 2008b). The mortality rate continued to increase even though growth at the forest tree line had been increasing previously (Swetnam and Betancourt 1998, as cited in CCSP 2008b). Forest productivity has decreased from climate change-induced warming in drought-prone regions (McKenzie *et al.* 2001, as cited in CCSP 2008b) and in subalpine regions (Monson *et al.* 2005 and Sacks *et al.* 2007, both as cited in CCSP 2008b).

Livestock

The livestock production infrastructure in the United States is likely to be influenced by the climate change-induced distributional and productivity changes to plant species. Livestock production during the summer season would *very likely* be reduced due to higher temperatures, but livestock production during the winter months could increase, again due to the projected increase in temperatures (CCSP 2008b).

The expected elevated CO_2 concentrations could diminish the grass feed quality. An increase in the carbon to nitrogen ratio would decrease the nutritional value of feed. In turn, grazing livestock that feed on lower quality grasses might be affected in terms of decreased weight and health (CCSP 2008b). Expected future average climate-change conditions could have less effect on livestock productivity and potential livestock loss than the effects of increased climate variability (*e.g.*, droughts and heat waves) (CCSP 2008b).

Climate models have projected decreases in livestock productivity in the United States simply due to projected temperature increases. In 2050, climate models project an average decrease in swine, beef, and milk production of 0.9 to 1.2 percent, 0.7 to 2.0 percent, and 2.1 to 2.2 percent, respectively (Frank *et al.* 2001, as cited in CCSP 2008b). Indeed, higher temperatures directly affect animals' ability to maintain homeostasis and consequently livestock must engage in altered metabolic thermoregulatory processes (Mader *et al.* 1997 and Davis *et al.* 2003, both as cited in CCSP 2008b). The induced thermal stress on livestock often results in a reduction in physical activity and ultimately diminishes feed intake. Livestock production losses and associated economic losses might be attributed to increasing temperatures that are "beyond the ability of the animal to dissipate [and] result in reduced performance (*i.e.*, production and reproduction), health, and well-being" (Hahn *et al.* 1992 and Mader, 2003, both as cited in National Science and Technology Council 2008).

The increased temperature expected as a result of climate change could allow for easier migration of animal pathogens and diseases, especially in the northward transition from the low to mid-latitudes, which would adversely affect livestock well-being in the United States (White *et al.* 2003, Anon 2006, van Wuijckhuise *et al.* 2006, all as cited in CCSP 2008b).

Fisheries

Although fisheries in cold freshwater regions are expected to be adversely affected, fisheries in warm freshwater regions could benefit from climate change. The effects of temperature increases have caused northward shifts of fisheries systems and this is expected to continue in the future (CCSP 2008b). According to IPCC, "many warm-water and cool-water species will shift their ranges northward or to higher altitudes" (Clark *et al.* 2001 and Mohseni *et al.* 2003, as cited in Field *et al.* 2007).

An example of negative impacts that result from large-scale species migration is the recent migration of two protozoan parasites from the Gulf of Mexico northward into the Delaware Bay. This parasitic incursion, possibly as a result of climate change, has led to a substantially increased mortality rate of oysters in the region (Hofmann *et al.* 2001, as cited in CCSP 2008b).

According to IPCC, the survival of brook trout in the United States is directly correlated to its preferred cold groundwater seeps habitat. As temperatures increase, mortality rates also increase for certain species of trout (CCSP 2008b). The salmonid species are likely also to be negatively affected by rising temperatures as they, too, are cold-water species (Gallagher and Wood 2003, as cited in Field *et al.* 2007). It is *likely* that other coldwater marine species could "disappear from all but the deeper lakes; cool-water species will be lost mainly from shallow lakes; and warm-water species will thrive, except in the far south, where temperatures in shallow lakes will exceed survival thresholds" (CCSP 2008b). Stocks of the river-spawning walleye will likely decline due to lower lake levels and climate change impacts in Lake Erie (Jones *et al.* 2006, as cited in Field *et al.* 2007). Coastal fisheries are also expected to experience the negative impacts of climate change, including coral reef bleaching, due to increased ocean temperatures (CCSP 2008b). In Alaska, the spawning and migration behaviors of commercially fished species could be affected and increasing temperatures might cause an increase in the cooling needs for storage and processing of catch (CIER 2007).

Adaptation

Motivation to engage in specific adaptation strategies because of the impacts of climate change on the forest, fiber, and food systems of the United States is expected. Adaptive practices in the forestry sector include cultivar selection, replanting tree species that are appropriate for the new climate regime, and utilizing dying timber (CCSP 2000). These and other potential strategies should be taken in the context of overall demand, population, and economic growth. Adaptive measures could be especially important to ensure the survival of forest, fisheries, and agriculture systems that are rich in biodiversity and productive value (CCSP 2000). It is possible that the current pace of climate change will make it difficult for many tree species to adapt as readily via migration as they have in previous periods of climate changes (Davis and Shaw 2001). It has been documented via pollen records that tree migration rates in the past have been roughly 20 to 40 km per century. In order to keep up with the projected climate changes in the future, tree migration rates would require migration patterns of roughly 300 to 500 km per century. Due to the projected pace of climate change, it is possible that “taxa that fail to adapt rapidly enough to tolerate these new and rapidly changing climate regimes will go extinct” (Davis and Shaw 2001). It is also possible that climate change could result in extinctions of many tree species (Davis and Shaw 2001).

4.5.6.2.2 Projected Global Impacts of Climate Change

Although the preceding section highlights anticipated climate change impacts in the United States, there are additional impacts that could affect forest and agriculture systems elsewhere in the world.

Crops

Globally, the agriculture and forest infrastructure will be affected by climate change. A recent Harvard report on Climate Change Futures states that a “changing climate will alter the hydrological regime, the timing of seasons, the arrival of pollinators and the prevalence, extent, and type of crop diseases and pests” (Anderson *et al.* 2005). Throughout the mid- to high-latitudinal regions, crop-specific productivity increases are projected for global mean temperature increases of 1 to 3 degrees Celsius. Beyond a 3-degrees Celsius increase in global mean temperature, crop productivity is expected to decrease in some regions (Easterling *et al.* 2007). Depending on the crop type, experiments on the effects of increased CO_2 concentrations, namely 550 parts per million as opposed to current levels of roughly 380 parts per million, suggest that crop yields could increase by 0 to 20 percent (Parry *et al.* 2007).

In a modest warming climate scenario, adaptive practices such as using various cultivars and altering planting and harvesting times might maintain cereal crop yields and possibly allow for an increase in productivity in the high latitudinal and temperate regions (Easterling *et al.* 2007). The adaptive practice in regions with 1 to 2 degrees Celsius increases in temperatures corresponds to an avoidance of a 10 to 15 percent reduction in yield for cereal crops (Parry *et al.* 2007). However, in the lower latitude dry regions, cereal crop productivity is projected to decrease for 1 to 2 degrees Celsius temperature increases, thereby exacerbating hunger issues for the population living in these regions (Parry *et al.* 2007).

According to IPCC the, “projected changes in the frequency and severity of extreme climate events will have more serious consequences for food and forestry production, and food insecurity, than will changes in projected means of temperature and precipitation” (Easterling *et al.* 2007). The low latitudinal regions might experience an increase in the frequency of extreme weather events like floods and droughts, which could adversely affect crop production, especially in the subsistence farming regions (Easterling *et al.* 2007). Extreme weather events, “reduce crop yield and livestock productivity beyond the impacts due to changes in mean variables alone, creating the possibility for surprises” (Parry *et al.* 2007). The reduced adaptive capacity of small-scale farmers such as subsistence and artisanal fisherfolk could result in increased vulnerability to extreme weather events, sea-level rise, and the spread of human disease, which could negatively affect agricultural and fish yields (Parry *et al.* 2007). Current climate change models do not yet include recent findings on precipitation extremes that are expected to impact agricultural production in areas such as southern Asia, northern Europe, and eastern Australia. These areas are expected to experience an impact on agricultural productivity as a result of projected increased precipitation extremes such as floods and droughts (Christensen *et al.* 2007, as cited in Easterling *et al.* 2007). Certain crops, such as wheat, are impacted by high precipitation events because wheat is, "susceptible to insects and diseases (especially fungal diseases) under rainy conditions" (Rosenzweig and Hillel 1998, as cited in Anderson *et al.* 2005). On the other hand, during droughts, certain fungi, such as *Aspergillus flavus*, are stimulated and will feed on drought-weakened crops (Anderson *et al.* 2005).

Decreases in crop and forest yields in moderate warming scenarios for the low latitudes will likely result in increased dependence on food imports in these typically the developing countries. As such, agricultural exports to lower latitude countries are likely to increase in the short term (Parry *et al.* 2007).

There could be a marginal increase in the population at risk of hunger due to climate change, but this would occur in the context of an overall decrease in the global population at risk of hunger as a result of anticipated economic development (Parry *et al.* 2007).

Forests

Globally, commercially grown forests for use in timber production are expected to increase modestly in the short term, depending on geographic region (Easterling *et al.* 2007). Large regional and local differences are anticipated as is a shift in terms of production increase from the lower latitudes to the higher latitudes (Parry *et al.* 2007). This poleward shift of forests and vegetation is estimated at roughly 500 km or more for the boreal zones for climate scenarios with CO_2 concentrations of double the current levels (Kirilenko and Sedjo 2007). In terms of distributional production, net benefits will accrue to regions experiencing increased forest production, whereas regions with declining activity will likely face net losses (Kirilenko and Sedjo 2007).

Due to increases in CO_2 concentration, there is potential for a carbon fertilization effect on the growth of trees with some experiments showing up to an 80 percent increase in wood production for orange trees (Kirilenko and Sedjo 2007). There is evidence to support elevated growth for young, immature forests in response to higher CO_2 concentration levels (Parry *et al.* 2007). However, free-air CO_2 enrichment experiments indicate that mature forests show no appreciable response to elevated CO_2 concentrations. However, young, immature forests show elevated growth in response to higher CO_2 concentrations (Parry *et al.* 2007). It should be noted that there has been only one feasibility study regarding forest free air CO_2 enrichment (FACE) of 100-year-old tree stands in which little to no stem growth was recorded, but that this lack of growth might be explained by the relative difficulty of controlling for constant CO_2 levels (Kirilenko and Sedjo 2007). Many GCMs have projected increases in forest production in certain geographic regions with notable exceptions. For example, the Terrestrial Ecosystem Model and the Center for International Trade in Forest Products Global Trade Model have simulated a future harvest increase of 2 to 11 percent in western North America, a 10 to 12 percent increase in New Zealand, a 10 to 13 percent increase in South America and a harvest decrease in Canada (Kirilenko and Sedjo 2007).

It is important to contrast these possible short term benefits with the negative implications of a warming climate since, "continued warming favors more fungal and insect of forests, and more harsh weather will further weaken tree defenses against pests" (Anderson *et al.* 2005) The ability of forests to continue to function as providers of agriculture and energy as well as sequester carbon will be affected by climate change (Anderson *et al.* 2005). Overall, the "effects of future drought and decreased soil moisture on agriculture and natural vegetation (such as forests) are uncertain and may, at least in part, be temporarily offset by fertilization effects of higher atmospheric concentrations of CO_2" (Triggs *et al.* 2004, as cited in CIER 2007). These extreme weather events, in concert with increased damage from insect and pathogen outbreaks and wildfires, might result in large-scale deforestation, as evidenced by recent trends in the Amazon basin (Kirilenko and Sedjo 2007). Climate-vegetation models have indicated that at CO_2 concentration levels of roughly three times current levels, the Amazon rainforests will eventually be lost due to climate change (Cox *et al.* 2004, as cited in Kirilenko and Sedjo 2007).

Fisheries

The aquaculture and fisheries sector are expected to incur negative development impacts as a result of the regional changes in the distribution and proliferation of various marine species (Easterling *et al.* 2007). As the distribution of certain fish species continues to be regionally rearranged, there is the potential for notable extinctions in the fisheries system, especially in freshwater species, in temperature ranges at the margin (Parry *et al.* 2007). Recent evidence indicates that the Meridional Overturning Circulation, which supplies nutrients to the upper layers of the Pacific and Atlantic Oceans, is slowing and thus adversely affecting regional production of primary food supply for fisheries systems (McPhaden and Zhang 2002, Curry and Mauritzen 2005, Gregg *et al.* 2003, Lehodey *et al.* 2003, all as cited in Easterling *et al.* 2007). In the North Sea, a shift in the distribution of warm water species such as zooplankton has resulted in a shift of fish species from whiting to sprat (Beaugrand 2004, as cited in CCSP 2008b).

The largest economic impacts associated with the fisheries sector as a result of climate change are expected to occur in coastal regions of Asia and South America (Allison *et al.* 2005, as cited in CCSP 2008b). Specifically, regional climate change could most affect species such as tuna and Peruvian anchovy (Barber 2001 and Lehodey *et al.* 2003, both as cited in CCSP 2008b).

Earlier spring ice melts in the Arctic and diminishing sea ice are affecting the distribution and productivity of marine species, particularly the upper-level sea organisms. In turn, fish harvests in the Arctic region are expected to change in the warming future. The freshwater species in the Arctic region are expected to be most affected by the increasing temperatures (Wrona *et al.* 2005, as cited in Field *et al.* 2007).

4.5.7 Industries, Settlements, and Society

This section defines these resources and describes the existing conditions and potential vulnerability of each to climate change impacts. In addition, this section briefly describes the potential vulnerability of cultural resources, including archaeological resources and buildings of historic significance to climate change impacts. The primary resource used in this section is the IPCC Fourth Assessment Report (Wilbanks *et al.* 2007); specifically, Chapter 7 for industry, settlement, and society.

The industries, settlements, and society sector encompasses resources and activities that describe how people produce and consume goods and services, deliver and receive public services, and live and relate to each other in society.

As defined by IPCC, this sector includes the following:

- Industry: manufacturing, transport, energy supply and demand, mining, construction, and related informal production activities (Wilbanks *et al.* 2007)
- Services: trade, retail, and commercial services, tourism, risk financing/insurance (IPCC 2007a)
- Utilities/Infrastructure: systems designed to meet relatively general human needs, often through largely or entirely public utility-type institutions (Wilbanks *et al.* 2007)

- Human Settlement: urbanization, urban design, planning, rural settlements (Wilbanks *et al.* 2007)
- Social Issues: demography, migration, employment, livelihood, and culture (Wilbanks *et al.* 2007)

4.5.7.1 Affected Environment

The industry, settlements, and society sector covers a very broad range of human institutions and systems, including the industrial and services sectors, large and small urban areas and rural communities, transportation systems, energy production, and financial, cultural, and social institutions.

A principal objective of human societies is to reduce their sensitivity to weather and climate. Recent experience with storms such as Hurricane Katrina reveals the limits to human control over climate-related impacts on industries, settlements, and society. Systems that are sensitive to climate change include air and water quality, linkage systems (transportation and transmission networks), building structures, resource supplies, social networks, and economic systems (Wilbanks *et al.* 2007).

This sector normally experiences and is generally resilient to variability in environmental conditions. Industries, settlements, and human society, however, can be vulnerable to extreme or persistent changes. Vulnerability increases when changes are unexpected or if resources or other factors inhibit the ability of this sector to respond to changes (Wilbanks *et al.* 2007).

Together, industry and economic services account for more than 95 percent of gross domestic product in highly developed economies and between 50 and 80 percent of gross domestic product in less developed economies (World Bank 2006, as cited in Wilbanks *et al.* 2007). Industrial activities are vulnerable to temperature and precipitation changes. For example, in Canada weather-related road accidents translate into annual losses of at least $1 billion Canadian annually, while more than a quarter of air travel delays in the United States are weather related (Andrey and Mills 2003, as cited in Wilbanks *et al.* 2007). Buildings, linking systems, and other infrastructure are often located in areas vulnerable to extreme weather events (flooding, drought, high winds). Trapp *et al.* (2007) found a net increase in the number of days in which severe thunderstorm environmental conditions could occur during the late 21st century using global and high-resolution regional climate models. The analysis suggests a future increase in these conditions of 100 percent or more in Atlanta, Georgia, and New York, New York. Such extreme events that can threaten linkage infrastructures such as bridges, roads, pipelines or transportation networks could cause industry to experience substantial economic losses (Wilbanks *et al.* 2007).

Institutional infrastructure is generally considered to be less vulnerable to weather and climate variation, as it embodies less fixed investment and is more readily adapted within the time scale of climate change. In some cases, experience with climatic variability can enhance the resilience of institutional infrastructure by triggering adaptive responses (Wilbanks *et al.* 2007).

Vulnerability to climate change impacts is determined by local geography and social context rather than large scale or aggregate factors (Wilbanks *et al.* 2007). Risk factors associated with local geography and social context are briefly described below.

4.5.7.1.1 Geography

Extreme weather events are more likely to pose risks to industry, settlements, and society than gradual climate change (Wilbanks *et al.* 2007). Resources and activities that are located in areas with higher susceptibility to extreme weather events (high temperatures, high winds, and flooding) are more vulnerable to the impacts of climate change. Extreme weather events can damage transportation routes and other infrastructure, damage property, dislocate settlement patterns, and disrupt economic activity. Gradual climate change can change patterns of consumption, decrease or increase the availability of inputs for production, and affect public health needs. Such impacts are experienced locally, but can be linked to impacts on national and global systems (Wilbanks *et al.* 2007).

Archaeological resources and buildings of historic significance are fixed in location and are therefore vulnerable to the effects of extreme weather events and gradual changes associated with local geography. Extreme weather events can expose archaeological resources and damage structures. Over time, gradual changes to weather patterns can also erode protective cover around archaeological resources and increase the rate of deterioration of historic buildings. Vulnerability of these resources to climate change impacts is tied to the susceptibility of location and local geography to extreme and gradual changes to weather.

4.5.7.1.2 Social Context

Worldwide, many of the places where people live are under pressure from a combination of growth, social inequity, jurisdictional fragmentation, fiscal shortfalls, and aging infrastructure. These stresses can include scarcity of water, poor sanitation, inadequate governance structures, unmet resource requirements, economic inequities, and political instability. While these types of stresses vary greatly across localities, they can combine with climate change impacts to result in substantial additional stress at local, national, and global levels (Wilbanks *et al.* 2007).

The social impacts associated with climate change will be mainly determined by how the changes interact with economic, social, and institutional processes to minimize or magnify the stresses. From an environmental justice perspective, the most vulnerable populations include the poor, the very old and very young, the disabled, and other populations that have limited resources and ability to adapt to changes (Wilbanks *et al.* 2007).

4.5.7.1.3 Urbanization

It is estimated that one third of the world's urban population (nearly 1 billion people) lives in overcrowded and unserviced slums, and 43 percent of the urban population is in developing countries. More generally, human settlements are often situated in risk-prone regions such as steep slopes, ravines, and coastal areas. These risk-prone settlements are expected to experience an increase in population, urbanized area, and economic activity. The population in the near-coastal zone (*i.e.*, within 330 feet elevation and 60 to 65 miles distance from the coast) has been estimated to be between 600 million and 1.2 billion, or 10 to 23 percent of the world's population (Adger *et al.* 2005, McGranahan *et al.* 2006, both as cited in Wilbanks *et al.* 2007). Migration from rural to urban areas is a common response to calamities such as floods and famines (Wilbanks *et al.* 2007).

4.5.7.2 Environmental Consequences

Key climate change impacts on this set of human systems are likely to vary widely and depend on a range of location-specific characteristics and circumstances. Moreover, potential climate change impacts on this sector could be particularly challenging to determine because effects tend to be indirect rather than direct, for example changes in temperature—a direct effect of climate change—affect air pollution concentrations in urban areas thereby affecting human health and health care systems, which are all indirect effects (Wilbanks *et al.* 2007).

The human institutions and systems that comprise the industry, settlements, and society sector tend to be quite resilient to fluctuations in environmental conditions that are within the range of normal occurrence. However, when environmental changes are more extreme or persistent, these systems can exhibit a range of vulnerabilities "especially if the changes are not foreseen and/or if capacities for adaptation are limited" (Wilbanks *et al.* 2007). For this reason industry, settlements, and society in developing countries are expected to be more vulnerable to direct and indirect climate change impacts than they are in industrialized countries (Wilbanks *et al.* 2007).

Climate change is expected to affect industry, settlements, and society via a range of physical effects, including the frequency and intensity of tropical cyclones and storms, extreme rainfall and floods, heat and cold waves, drought, temperature extremes, precipitation, and sea-level rise. Following the approach in Wilbanks *et al.* 2007, the categories of human systems addressed in this section include industry, services, utilities and infrastructure, settlements, and social issues. Each category is described below, and potential climate impacts on each category are discussed. Key systems within these categories that are expected to experience impacts associated with climate change are then discussed in greater detail in subsequent sections.

Industry includes manufacturing, transport, energy supply and demand, mining, construction, and related informal production activities (Wilbanks *et al.* 2007). These activities can be vulnerable to climate change when (a) facilities are located in climate-sensitive areas such as coasts and floodplains, (b) the sector is dependent on climate-sensitive inputs such as food processing, or (c) the sector has long-lived capital assets (Ruth *et al.* 2004, as cited in Wilbanks *et al.* 2007). For the energy sector, in addition to possible infrastructure damage or destruction from the effects of climate change (*e.g.*, as could happen due to extreme weather events) effects could also include climate-driven changes in demands for energy. For example, demand for heating could decline in winter months while demand for cooling could rise in summer months (CCSP 2008f).

Services include trade, retail and commercial services, tourism, and risk financing or insurance (Wilbanks *et al.* 2007). Possible climate change impacts on trade include impacts on transportation from extreme weather events like snow and ice storms that could impede the ability to transport goods, or impacts on comparative advantage of a region or country due to temperature shifts that affect production. Climate change impacts on transportation could also affect retail and commercial services. Retail and commercial services could also be affected by climatic conditions that affect prices of raw materials and by potential damage to infrastructure such as facilities existing in climate sensitive areas like coastal regions. Extreme events such as hurricanes can also affect tourism infrastructure. Tourism services could also be affected by climate change impacts through temperature shifts and changes that affect the natural landscape of tourist destinations. Potential indirect effects of climate change on tourism include changes in availability of water and energy prices. With respect to the insurance sector, climate change impacts could lead to increasing risk, which could trigger higher premiums and more conservative coverage. A reduction in availability of or ability to afford insurance could in turn lead to impacts on local and regional economies.

Utilities and infrastructure includes systems that are "designed to meet relatively general human needs, often through largely or entirely public utility-type institutions" (Wilbanks *et al.* 2007). This includes physical infrastructure such as water, transportation, energy, and communication systems, as well as institutional infrastructure such as shelters, public health care systems, and police, fire, and emergency services. "These infrastructures are vulnerable to climate change in different ways and to different degrees depending on their state of development, their resilience, and their adaptability" (Wilbanks *et al.* 2007). In general, institutional infrastructure tends to be less vulnerable to climate change than physical infrastructure because it typically involves less investment in fixed assets and is more flexible over timeframes that are relevant to climate change. There are numerous points where impacts on different infrastructures interact and the failure of one system can put pressure on others. At the same time, however, "this means that measures to protect one sector can also help to safeguard the others" (Wilbanks *et al.* 2007).

Human Settlement - Climate change interacts with other stresses in its impact on human settlements (Wilbanks *et al.* 2007). Potential impacts on human settlements could be experienced through several pathways. Sea-level rise threatens populations in coastal areas by accelerating the inundation of coastal wetlands, threatening vital infrastructure and water supplies, augmenting summertime energy demand, and affecting public health (Wilbanks *et al.* 2007). Changes in precipitation patterns could alter the availability of potable water while changes in temperature could affect air quality and contribute to an increase in incidents of heat stress and respiratory illnesses (Wilbanks *et al.* 2007). In urban areas, the Urban Heat Island effect (Wilbanks *et al.* 2007), which relates to the "degree to which built and paved areas are associated with higher temperatures than surrounding rural areas" (National Science and Technology Council 2008) might affect the manner in which climate change affects these areas.

Social Issues - Within human settlements, society could also experience a variety of effects associated with climate change. For example, communities could experience increasing stress on management and budget requirements for public services, if demands on public health care and disaster risk reduction grow (CCSP 2008f). There could be a loss of cultural and traditional groups of people, *e.g.* "indigenous societies in polar regions" (Wilbanks *et al.* 2007). Societal concerns that might be affected by the impacts of climate change include socioeconomic issues relating to developed versus developing areas and rich versus poor. Because the developing countries and poorer populations tend to have weaker infrastructure in place to begin with, their vulnerability to climate change effects is expected to be higher and their capacity to cope or adapt are expected to be lower than developed countries and wealthier populations (Wilbanks *et al.* 2007).

4.5.7.2.1 Projected Impacts of Climate Change for the United States

The research literature on climate impacts on United States industry, settlements, and society is relatively sparse. "At the current state of knowledge, vulnerabilities to possible impacts are easier to project than actual impacts because they estimate risks or opportunities associated with possible consequences rather than estimating the consequences themselves" (CCSP 2008f). In general, "climate change effects on human settlements in the United States are expected to occur as a result of interaction with other processes" (National Science and Technology Council 2008). These effects include those on health, water resources, physical infrastructure (notably transportation systems), energy systems, human settlements, and economic opportunities.

Impacts on human health and human health care systems are expected to arise because of temperature-related stress. Increases in cases of respiratory illness associated with high concentrations of ground-level ozone; water-, food-, and vector-borne diseases; and allergies related to higher concentrations of plant species are expected.

Effects on water are expected to include reductions in snowpack, river flows, and groundwater levels, saline intrusion in rivers and groundwater, an increase in water demand due to increasing temperatures, and impacts on sanitation, transportation, food and energy, and communication infrastructures from severe weather events.

The United States coastline, deltas, and coastal cities such as the Mississippi Delta and surrounding cities, are vulnerable to sea-level rise. "Rapid development, including an additional 25 million people in the coastal United States over the next 25 years will further reduce the resilience of coastal areas to rising sea levels and increase the economic resources and infrastructure vulnerable to impacts" (Field *et al.* 2007, as cited in National Science and Technology Council 2008).

Effects on other key human systems are discussed in greater detail below. Because this section deals with such a broad set of human systems, the potential impacts of climate change and potential adaptations available to key human systems are discussed together. Given the enormous range of human systems that could be affected by climate change, the discussion here is focused on a few key systems where impacts can best be characterized or supported by sufficient information.

Impacts on Transportation Infrastructure

Climate affects the design, construction, operation, safety, reliability, and maintenance of transportation infrastructure, services, and systems. The potential for climate change raises critical questions about how changes in temperature, precipitation, storm events, sea-level rise, and other climate variables could affect the system of roads, airports, rail, public transit, pipelines, ports, waterways, and other elements of the nation's and the world's complex transportation systems.

Climate changes anticipated during the next 50 to 100 years include higher temperatures, changes in precipitation patterns, increased storm frequency and intensity, and rising sea levels globally, resulting from the warming of the world's oceans and decline in polar ice sheets. These changes could affect the transportation system in a wide variety of ways. Those of greatest relevance for the United States are summarized below.

- *Increases in very hot days and heat waves.* It is very likely that heat extremes and heat waves will continue to become more frequent, more intense, and last longer in most regions during the 21st century. This could increase the cost of transportation construction, operations, and maintenance.

- *Increases in Arctic temperatures.* Arctic warming is virtually certain as temperature increases are expected to be greatest over land and at most high northern latitudes. As much as 90 percent of the upper layer of permafrost could thaw under more pessimistic emission scenarios.

- *Rising sea levels.* It is virtually certain that sea levels will continue to rise in the 21st century as a result of thermal expansion and loss of mass from ice sheets. This could make much of the existing transportation infrastructure in coastal areas prone to frequent, severe, and/or permanent inundation.

- *Increases in intense precipitation events.* It is very likely that intense precipitation events will continue to become more frequent in widespread areas of the United States. Transportation networks, safety, and reliability could be disrupted by visibility problems for drivers, and by flooding, which could result in substantial damage to the transportation system.

- *Increases in hurricane intensity.* Increased tropical storm intensities, with larger peak wind speeds and more intense precipitation are likely, which could result in increased travel disruption, impacts on the safety and reliability of transportation services and facilities, and increased costs for construction, maintenance, and repair (Transportation Research Board 2008).

Numerous studies have examined ways of mitigating the transportation sector's contribution to global warming from GHG emissions. However, far less attention has been paid to the potential impacts of climate change on United States transportation and on how transportation professionals can best adapt to climate changes that are already occurring, and will continue to occur into the foreseeable future even if drastic mitigation measures were taken today. Since GHGs have long life spans they continue to impact global climate change for decades (Transportation Research Board 2008).

Scientific evidence confirms that climate change is occurring, and that it will trigger new, extreme weather events and could possibly lead to surprises, such as more rapid than expected rises in sea levels or temperature changes. Every mode of transportation will be affected as climate change poses new and often unfamiliar challenges to infrastructure providers (Transportation Research Board 2008).

Consideration of climate change-related factors in transportation planning and investment decisions should lead to a more resilient, reliable, and cost-effective transportation system in the coming decades. When decisionmakers better understand the risks associated with climate change, they can make better decisions about potential adaptation strategies and the tradeoffs involved in planning, designing, constructing, operating, and maintaining transportation systems (Transportation Research Board 2008).

Projected climate changes have profound implications for transportation in the United States (Transportation Research Board 2008). Climate change is likely to increase costs for the construction and maintenance of transportation infrastructure, impact safety through reduced visibility during storms and destruction of elements of the transportation system during extreme weather events, disrupt transportation networks with flooding and visibility problems, inundate substantial portions of the transportation system in low lying coastal areas, increase the length and frequency of disruptions in transportation service, cause substantial damage and incur costly repairs to transportation infrastructure, and impact the overall safety and reliability of the nation's transportation system (Transportation Research Board 2008).

Transportation systems across the United States are projected to experience both positive and negative impacts from climate change over the next century; the degree of impacts will be determined, in part, by the geographic region (Transportation Research Board 2008). Coastal communities are especially vulnerable to impacts associated with sea-level rise, increased frequency or intensity of storms, and damage to the transportation system due to storm surges and flooding. The literature indicates that the intensity of major storms could increase by 10 percent or more, which could result in more frequent Category 3 (or higher) storms in the Gulf Coast and along the Atlantic coast (Transportation Research Board 2008).Warming temperatures might require changes in the kinds of materials used for construction of transportation facilities, and in the operation and maintenance of transportation facilities and services. Higher temperatures could require the development and use of more heat-tolerant materials (Transportation Research Board 2008). Restrictions on work rules could increase the time and costs for labor for construction and maintenance of transportation facilities. Rail lines could be affected by higher temperatures and more frequent rail buckling, which would affect service reliability, safety and overall system costs and performance. Costs could increase for ports, maintenance facilities, and transportation terminals if higher temperatures require an increase in refrigeration and cooling (Transportation Research Board 2008); and higher temperatures could affect aircraft performance and the runway lengths required for safe operation (Transportation Research Board 2008). On the positive side, higher temperatures might open up northern transportation routes for longer periods of time and allow more direct routing for marine transportation (Transportation Research Board 2008).

Changes in precipitation patterns could increase short-term flooding, resulting in decreased safety, disruptions in transportation services, and costly damage to transportation infrastructure. Hotter climates could exhibit reduced soil moisture and average runoff, which might require changes in the management and maintenance of publicly owned right-of-way. The potential increase in heavy rainfall might exceed the capacity of existing drainage systems, resulting in more frequent flooding and associated disruptions in transportation system reliability and service, increased costs for maintenance of existing facilities, and increased costs for construction of new facilities (Transportation Research Board 2008).

Relative sea-level rise might inundate existing transportation infrastructure and substantially increase the cost of provision of new transportation facilities and services. Some portions of the transportation infrastructure in coastal areas, or in areas prone to flooding, might have to be protected with dikes or levees – increasing the cost for construction and maintenance, and the potential for more serious flooding incidents associated with the failure of such dikes and levees (Transportation Research Board 2008).

Increased storm frequency and intensity might lead to greater transportation service disruption, and damage to transportation infrastructure in coastal and inland areas. Model results for the study of the Gulf Coast conservatively estimated a 22- to 24-foot potential surge for major hurricanes (Transportation Research Board 2008). During Hurricane Katrina (a Category 3 storm at landfall) surges exceeded these heights in some locations (Transportation Research Board 2008). While the specific location and strength of storm surges are difficult to predict due to the variation of the scale and trajectory of individual tropical storms, substantial portions of the coastal infrastructure across the United States are vulnerable to increased damage resulting from the impacts of climate change (Transportation Research Board 2008).

Disruptions in transportation system availability could result in substantial economic impacts associated with increased costs to construct or repair transportation infrastructure, and costs associated with disruptions in transportation for goods and services. Increasing fuel costs and delays in transportation service result in increased transport costs, which are then passed on to consumers. A substantial disruption in transportation (*e.g.,* destruction of a major transportation facility by hurricane, flood, or other extreme weather event) could affect the regional economy in many different ways. Communities are likely to require long periods of time to recover from these events, and some communities could be permanently affected (Transportation Research Board 2008).

The analysis to date raises clear cause for concern regarding the vulnerability of transportation infrastructure and services in coastal areas, and across the United States. Addressing the risks associated with a changing climate in the planning and design of transportation facilities and services can help public agencies and private investors to minimize disruptions to the smooth and safe provision of transportation services; and can protect the substantial investments made in the nation's transportation infrastructure now and in the future (Transportation Research Board 2008).

According to the USCCSP's *Impacts of Climate Change and Variability on Transportation Systems and Infrastructure Report* (Transportation Research Board 2008), four key factors are critical to understanding how climate change might affect transportation:

- *Exposure.* What is the magnitude of stress associated with a climate factor (sea-level rise, temperature change, severe storms, and precipitation) and the probability that this stress will affect a transportation segment or facility?

- *Vulnerability.* Based on the structural strength and integrity of the infrastructure, what is the potential for damage and disruption in transportation services from this exposure?

- *Resilience.* What is the current capacity of a system to absorb disturbances and retain transportation performance?

- *Adaptation.* What response(s) can be taken to increase resilience at both the facility (e.g., a specific bridge) and system levels?

New approaches to address climate change factors in transportation planning and decisionmaking could include:

- *Extending planning timeframes.* To address the long timeframe over which climate changes and environmental processes occur, planning time frames might need to be extended beyond the typical 20- to 30-year planning horizon. The fact that transportation infrastructure can last for many decades (or even more than 100 years) argues for planning for much longer time frames to examine the potential impacts of climate change and other elements of the natural environment on the location, construction techniques, and costs for transportation infrastructure investments that are expected to last for many decades (Transportation Research Board 2008).

- *Conducting risk assessment analysis for transportation investments.* Transportation investments face many uncertainties, including the potential impacts of climate change on construction, operation, and maintenance. Planners and decisionmakers can use iterative risk management analysis to evaluate potential risks of all types, and to identify potential ways to minimize the risks and increase the resiliency of transportation infrastructure. Transportation structures and facilities can be hardened, raised, or even relocated if needed. Where it is critical to safety, reliability and mobility, redundant systems might be necessary for the most critical elements of the transportation system (Transportation Research Board 2008).

Impacts on Energy Systems

Although the energy sector has been seen as a driver of climate change, the energy sector is also subject to the effects of climate change (Wilbanks *et al.* 2007). All major energy sources are subject to a variety of climate change effects, including temperature, wind, humidity, precipitation, and extreme weather events (Bhatt *et al.* 2007). The most direct climate change impacts for fossil fuel and nuclear power plants, for example, are related to power plant cooling and water availability (Bhatt *et al.* 2007). Each kilowatt of electricity generated by thermoelectric generation requires about 25 gallons of water. Power plants rank only slightly behind irrigation in terms of freshwater withdrawals in the United States (USGS 2004, as cited in Bhatt *et al.* 2007). In addition, about 10 percent of all United States coal shipments were delivered by barge in 2003, and consequently low river flows can create shortfalls in coal supplies at power plants (Bhatt *et al.* 2007).

USCCSP identified potential effects of climate change on energy production and use in the United States, which are stated in terms of likelihood (Wilbanks *et al.* 2007). Principal impacts and their likelihood are listed below:

- Climate change will reduce total energy demand for space heating; effects will differ by region (*virtually certain*).

- Climate change will increase total energy demand for space cooling; effects will differ by region (*virtually certain*).

- Net effects on energy use will differ by region. Overall impacts will be affected by patterns of interregional migration – which are likely to be in the direction of net cooling load regions – and investments in new building stock (*virtually certain*).

- Temperature increases will increase peak demands for electricity (*very likely*).
- Changes in the distribution of water availability will affect power plants; in areas with decreased water availability, competition for water supplies between energy and other sectors will increase (*virtually certain*).
- Temperature increases will reduce overall thermoelectric power generation efficiency (*virtually certain*).
- In some regions, energy resource production and delivery systems will be vulnerable to the effects of sea-level rise and extreme weather events, especially the Gulf Coast and the East Coast (*virtually certain*).
- Hydropower production will be directly and substantially affected by climate change, especially in the West and Northwest (*very likely*).
- Climate change concerns will affect perceptions and practices related to risk management behavior in investment by energy institutions (*very likely*).
- Climate change concerns are almost certain to affect public and private sector energy technology research and development investments and energy resource and technology choices by energy institutions, along with associated emissions (*virtually certain*).

USCCSP concluded that there is very little literature on adaptation of the energy sector to effects of climate change, and their following discussion is therefore largely speculative (Wilbanks *et al.* 2007). Both energy users and providers are accustomed to changing conditions that affect their decisions. The energy sector is among the most resilient of all economic sectors in terms of responding to changes within the range of historical experience (Wilbanks *et al.* 2007). Adaptations to the effects of climate change on energy use could focus on increased demands and rising costs for space cooling; likely responses include investing in more efficient cooling equipment and building envelopes. Increased demands for both peak and average electricity demands could lead to contingency planning for load-leveling, more efficient and expanded generation capacity, expanded inter-ties, and increased storage capacity (Wilbanks *et al.* 2007).

In terms of energy production and supply, the most likely near-term adaptation is expected to be an increase in perceptions of uncertainty and risk in long-term strategic planning and investment; with investors seeking to reduce risks through such approaches as diversifying supply sources and technologies, and risk-sharing arrangements (Wilbanks *et al.* 2007).

Impacts on Human Settlements

The impacts of climate change on human settlements are expected to be substantial in a number of ways. "Settlements are important because they are where most of the [United States] population lives, often in concentrations that imply vulnerabilities to location-specific events and processes" (Wilbanks *et al.* 2007). Among the general effects of climate change are increased stress on human settlements due to higher summer temperatures and decreased stress associated with warmer winter weather. Changes in precipitation and water availability, rising sea levels in coastal regions, and greater risks from extreme weather events such as storms, flooding, and droughts are also expected to affect human settlements to various degrees. At the same time, stresses due to cold weather extreme events, such as blizzards and ice storms, are expected to decrease (Wilbanks et al 2007).

Predicting climate change impacts on United States settlements is difficult because climate change is not forecast on a scale that is appropriate for local decisionmaking, and because climate is not the only change that settlements are confronting. A key example is the continuing population shift, particularly among persons who have reached retirement, toward the Sun Belt and coastal areas. This means an ever larger elderly population could be at risk especially from extreme weather events such as tropical storms, as well as some types of vector-borne diseases and heat related illnesses (CCSP 2008f).

Anticipated human impacts include the following:

- Increased respiratory and cardiovascular problems (Patz and Baldus 2001, as cited in CCSP 2008f).
- Changes in mortality rates caused by temperature extremes (Rozenzweig and Solecki 2001, as cited in CCSP 2008f).
- Increased water demands associated with warming accompanied by changes in precipitation that alters access to water (Gleick 2000, Kirshen 2002, Ruth *et al.* 2007, all as cited in CCSP 2008f).
- Damages or disruptions to services associated with urban infrastructure such as sanitation systems, electricity transmission networks, communication systems, and the like could occur as a result of storms, floods, and fires (CCSP 2008f).
- Sea-level rise could jeopardize many of the 673 coastal counties and threaten population centers (Neumann *et al.* 2000, Kirshen *et al.* 2004, both as cited in CCSP 2008f).
- Vulnerable populations such as the poor, elderly, those in ill health, the disabled, persons living alone, and individuals with limited rights (*e.g.*, recent migrants) are expected to be at greater risk from climate change (CCSP 2008f).

As a specific example with respect to urban infrastructure, the New York City Department of Environmental Protection assessed potential climate change impacts on the city's drainage and wastewater collection systems, noting that if rainfall becomes more intense, sewer system capacities could be exceeded leading to street and basement flooding (NY City DEP 2008). Additionally, extreme precipitation events could lead to an inundation of the Water Pollution Control Plants' (WPCPs) influent wells. Sea-level rise could threaten hydraulic capacity of WPCP outfalls by making peak flow discharges more difficult and also increase the salinity of influent to the WPCP which would upset biological treatment processes and lead to corrosion of equipment (NY City DEP 2008).

The vulnerability of human settlements and infrastructure in coastal areas to natural disasters such as hurricanes and tropical storms was demonstrated through the damages incurred by Hurricanes Katrina and Rita in the Southeastern region of the United States After Hurricane Katrina struck, a total of 90,000 square miles was declared a Federal disaster area, 80 percent of New Orleans was flooded, more than 1,700 lives were lost, 850,791 housing units were damaged, 2,100 oil platforms and over 15,000 miles of pipeline were damaged (Petterson *et al.* 2006, as cited in CIER 2007).

There are various possible adaptation strategies for human settlements. Assuring effective governance, increasing the resilience of physical and linkage infrastructures, changing settlement locations over a period of time, changing settlement form, reducing heat-island effects, reducing emissions and industry effluents, improving waste handling, providing financial mechanisms for increasing resiliency, targeting assistance programs for especially impacted segments of the population, and adopting sustainable community development practices are some of them (Wilbanks *et al.* 2005, as cited in Wilbanks *et al.* 2007). Land use choices, specifically the discouragement of housing development in flood prone areas including areas below sea level and in deep flow plains, can help protect human settlements and preserve management flexibility for these areas (Isenberg *et al.*, 2008). The choice of strategies and policies for adaptation depend on their relationships with other social and ecological processes and level of economic development (O'Brien and Leichenko 2000, as cited in Wilbanks *et al.* 2007).

Impacts on Economic Opportunities and Risks

Communities or regions that are dependent on climate-sensitive resources or goods or whose comparative advantage could be affected are expected to be particularly vulnerable to climate change. The insurance sector is an example of an industry that could be highly vulnerable to climate impacts. If increasing trends of adverse weather events continue, claims made to private and public insurers are expected to climb (NAST 2001, as cited in CIER 2007). Overall risk exposure of insurers' has grown considerably, *e.g.*, the National Flood Insurance Program's exposure increased four-fold since 1980 to $1 trillion in 2005 and the Federal Crop Insurance Corporation's exposure grew up to $44 billion (U.S. GAO 2007, as cited in CIER 2007). To the extent that climate change increases costs for insurers or increases the difficulty in forecasting risks, the insurance sector might "withdraw (or make much more expensive) private insurance coverage from areas vulnerable to climate change impacts" (National Science and Technology Council 2008).

Trade, retail, and commercial services, and tourism are other economic areas that are expected to be affected by climate change impacts, largely as a result of impacts on the transportation and energy sectors. For example, impacts on transportation will affect distribution and receipt of goods for retail services. This could have a particular effect on the Midwest which is a heavy domestic freight and shipping route area. Approximately "$3.4 billion and 60,000 jobs rely on the movement of goods within the Great Lakes-St. Lawrence shipping route annually" (Easterling and Karl 2001, as cited in CIER 2007). A decline in water levels could jeopardize this mode of transporting manufacturing. In fact, "system connectivity is predicted to be come 25 percent impaired causing a loss of $850 million annually" (Easterling and Karl 2001, as cited in CIER 2007). Dredging 7.5 to 12.5 million cubic yards, costing $85-142 million, might be the only alternative to salvage this system if water levels decline substantially (Great Lakes Regional Assessment Group 2000, as cited in CIER 2007).

Tourism could be affected by "changes in the landscape of areas of tourist interest" as well as by changes in the availability of resources and energy costs (Wilbanks *et al.* 2007). In the United States, climate change impacts could affect winter recreation and tourism in the Northeast. Warmer winters would "shorten the average ski and snowboard seasons, increase snow making requirements, and drive up operating costs," possibly "prompting further closures and consolidation of ski areas northward toward the Canadian border" (Frumhoff *et al.* 2007).

Historical and Cultural Resources

A variety of cultural and historical resources are at risk from climate change. According to a recent study by UNESCO "The adverse impacts of climate change will have consequences for humanity as a whole including the products of human creativity...these consequences will be manifest in at least two principal ways: (1) the direct physical effects on the buildings or structures and (2) the effects on social structures and habitats" (Colette *et al.* 2007).

Alaska is the region expected to be most affected by climate change largely because of location (warming is more pronounced closer to the poles) and way of life (settlement and economic activities based around Arctic conditions) (CCSP 2008f). Indigenous communities in Alaska are facing major economic and cultural impacts because they depend for subsistence on various climate-sensitive animals such as polar bears, walruses, seals, and caribou (National Science and Technology Council 2008). "Changes in species' ranges and availability, access to these species, a perceived reduction in weather predictability, and travel safety in changing ice and weather conditions present serious challenges to human health and food security, and possibly even the survival of some cultures" (ACIA 2004, as cited in National Science and Technology Council 2008).

In discussing the impacts of climate change on historic cities and settlements around the world, Colette *et al.* 2007 lists the following potential threats associated with climate change:

- Increased salt mobilization with resulting damage to surfaces and decoration as a result of increasing rate of heavy rainfall
- Changes in the amplitude of temperature and humidity can cause splitting, cracking, flaking and other damage to exposed surfaces
- Organic building materials such as wood could be subject to increase infestation as a result of migration of pests
- An increase in flooding can directly damage structures and promote growth of damaging micro-organisms such as molds and fungi
- In arid regions, desertification, salt weathering and erosion could threaten cultural and historic sites

Climate change could also create pressures that result in migration of populations, which in turn could result in the breakdown of communities and the loss of "rituals and cultural memory" (Colette *et al.* 2007).

4.5.7.2.2 Projected Global Impacts of Climate Change

As the discussion above suggests, the three major ways in which industry, settlements, and society are vulnerable to climate change are through impacts on economics, infrastructure, and health. The magnitude of impacts on industry, settlements, and society largely depends on location and the level of development of the area or region. The discussion below highlights anticipated impacts on key human systems at the global level.

Global Energy Sector Impacts

In terms of energy production and use, the expected global impacts will likely be similar to those discussed above for the United States. When the climate warms, less heating will be needed for industrial, commercial, and residential buildings, with changes varying by region and by season (Wilbanks *et al.* 2007). Electricity is used in areas around the world for cooling; coal, oil, gas, biomass, and electricity provide energy for heating. Regions with substantial requirements for both cooling and heating could see net increases in electricity demands while demands for other energy sources decline (Hadley *et al.* 2006, as cited in Wilbanks *et al.* 2007).

According to one study, by 2100 the benefits (reduced heating) will be about 0.75 percent of gross domestic product, and impacts (increased cooling) will be approximately 0.45 percent (Tol 2002a, 2002b, both as cited in Wilbanks *et al.* 2007). These percentages could be affected by migration from heating-intensive regions to cooling-intensive regions (Wilbanks *et al.* 2007).

Climate change could also affect global energy production and distribution if extreme weather events become more frequent or intense; and in regions dependent upon water supplies for hydropower or thermoelectric generation if there are substantial changes in rainfall/snowfall locations and seasonality. Reduced stream flows are expected to jeopardize hydropower production in some areas, but higher precipitation rates resulting in greater or more sustained stream flows could be beneficial (Casola *et al.* 2005, Viosin *et al.* 2006, both as cited in Wilbanks *et al.* 2007). More frequent or intense extreme weather events could threaten coastal energy infrastructures including electricity transmission and distribution facilities (Bull *et al.* 2007).

Warming temperatures resulting in melting of permafrost threaten petroleum production facilities and pipelines, electrical transmission towers, and nuclear power plants in the Arctic region (Nelson *et al.* 2001, as cited in Wilbanks *et al.* 2007). As with Alaska's North Slope facilities, structural failures in transportation and industrial infrastructure are becoming more common in northern Russia due to melting permafrost (Wilbanks *et al.* 2007).

Global Transportation Sector Impacts

The IPCC concludes, with *very high confidence*, that data since 1970 have demonstrated anthropogenic temperature rises have visibly altered ecosystems (Parry *et al.* 2007). Other stressors on the built environment and the ability of cities and countries to adapt to a changing climate make it difficult to discern the exact impacts of climate change on transportation systems around the world. Additional factors, such as projected population growth, are expected to exacerbate the effects of climate change. Development typically occurs in the coastal regions, especially in the newly developing third world countries. These areas are particularly vulnerable to the impacts of projected increases in extreme weather events such as hurricanes, cyclones, unusually heavy precipitation, and flooding. In addition these developing countries are less able to adapt to expected changes due to their limited resources and other pressing needs (Wilbanks *et al.* 2007).

Transportation system vulnerabilities in more developed countries often focus on physical assets and infrastructures and their economic value and replacement costs, along with linkages to global markets. Vulnerabilities in less developed countries often focus on human populations and institutions that are likely to have very different transportation needs and resources (Wilbanks *et al.* 2007). A warmer, drier climate could exacerbate many of the problems of developing countries, including drought and decreases in food production in areas of Africa and Asia (Wilbanks *et al.* 2007).

At a national scale, industrialized countries such as the United Kingdom and Norway can cope with most kinds of gradual climate change, but localized differences can show considerable variability in stresses and capacities to adapt (Environment Canada 1997; Kates and Wilbanks 2003, as cited in National Science and Technology Council 2008; London Climate Change Partnership 2004; O'Brien *et al.* 2004; Kirshen *et al.* 2006).

The impacts on the United States transportation systems described above apply in other countries as well. Based on information developed by the Transportation Research Board (2008) the potential impacts of climate change on transportation fall into the two major categories described below.

- Climate change will affect transportation primarily through increases in several types of weather and climate extremes, such as very hot days, intense precipitation events, intense hurricanes, drought, and rising sea levels, coupled with storm surges and land subsidence.

The impacts will vary by mode of transportation and region, but they will be widespread and costly in both human and economic terms and will require substantial changes in the planning, design, construction, operation, and maintenance of transportation systems.

- Potentially, the greatest impact of climate change on global transportation systems will be flooding of coastal roads, railways, transit systems, and runways because of rising sea levels coupled with storm surges, and exacerbated in some locations by land subsidence (National Science and Technology Council 2008).

Given the global nature of the impacts of climate change and the world economy, coordination within and among nations will become increasingly important (Wilbanks *et al.* 2007). Strong and complex global linkages and interactions occur throughout the world today and are likely to increase in the future. Climate-change effects cascade through interlinked systems for international trade, migration, and communication patterns producing a variety of direct and indirect effects. Some of these impacts might be anticipated. However, many might not, especially if the globalized economy becomes less resilient and more interdependent (Wilbanks *et al.* 2007).

The impacts of an extreme weather event in one location (*e.g.*, Hurricane Katrina in Louisiana) causes ripple effects throughout the transportation system in the United States and in areas around the world linked to the United States through the ports in the affected area (Transportation Research Board 2008).

There are now incidences in Europe, North America, and Japan, of new transportation infrastructure being designed and constructed with potential climate change in mind. For example, bridges and other infrastructure designed at higher elevations in anticipation of sea-level rise over the life span of these transportation system elements (Wilbanks *et al.* 2007).

Global Human Settlements Impacts

Human settlements are vulnerable to the effects of climate change in three major ways: (1) through economic sectors affected by changes in input resource productivity or market demands for goods and services; (2) through impacts on certain physical infrastructure; and (3) through impacts of weather and extreme events on the health of populations. The degree of vulnerability tends to be a function of the location (coastal and riverine areas are most at risk), economy (economies most dependent on weather-related sectors are at the highest risk), and size (larger settlements are at a greater aggregate risk, but they likely have greater resources to prevent the impacts of climate change and respond to events that result from climate changes such as hurricanes, floods, or other extreme weather events) (Wilbanks *et al.* 2007).

Shifts in precipitation patterns might affect already stressed environments. For example, mean precipitation in all four seasons of the year has tended to decrease in all main arid and semi-arid regions of the world, *e.g.*, northern Chile and northeast Brazil, West Africa, and Ethiopia, drier parts of southern Africa, and western China (Folland *et al.* 2001, as cited in Wilbanks *et al.* 2007). Increasing temperature could aggravate ozone pollution in many cities, which could affect quickly growing urban areas that, especially those in developing countries, are experiencing more air pollution problems (Wilbanks *et al.* 2007). Extreme weather events affect settlements and society in developing countries just as they do developed countries, through damage and destruction of infrastructure and loss of human life, although perhaps in slightly different ways. For example, in some urban areas of developing countries, informal settlements develop. These informal settlements are especially vulnerable as they tend to be built on hazardous sites and susceptible to floods, landslides, and other climate-related disasters (Cross 2001, UN-Habitat 2003, both as cited in Wilbanks *et al.* 2007). Another example is how "[i]n developing countries, a common cause of death associated with extreme weather events in urban areas is electrocution by fallen power cables" (Few *et al.* 2004, as cited in Wilbanks *et al.* 2007).

Generally, low-income and other vulnerable populations would experience the same impacts from climate change as populations in comparable geographic areas described in this section, as well as sections 4.5.6, Food, Fiber, and Forest Products and 4.5.8, Human Health. However, as with environmental justice populations in the United States, climate change impacts would likely be differentially experienced by vulnerable populations. The magnitude of climate change impacts on residents of developing countries would be expected to be greater. For example, IPCC notes that the continent of Africa's "major economic sectors are vulnerable to current climate sensitivity, with huge economic impacts, and this vulnerability is exacerbated by existing developmental challenges such as endemic poverty, complex governance and institutional dimensions; limited access to capital, including markets, infrastructure and technology; ecosystem degradation; and complex disasters and conflicts. These in turn have contributed to Africa's weak adaptive capacity, increasing the continent's vulnerability to projected climate change" (Wilbanks *et al.* 2007).

As discussed in this section, the danger to human health from climate change will differentially affect developing countries. The IPCC states that "Adverse health impacts will be greatest in low-income countries. Those at greater risk include, in all countries, the urban poor, the elderly and children, traditional societies, subsistence farmers, and coastal populations" (Wilbanks *et al.* 2007). Section 4.5.8 describes in detail the potential health effects from climate change on developing countries; these impacts include:

- Increases in malnutrition, and related health impacts, in developing regions of the world due to declining crop yields
- Potential increases in water-related diseases, such as diarrhea-causing pathogens, due to higher temperatures
- Potential for continuation of upward trends in certain vector-borne diseases, such as malaria in Africa, which have been attributed to temperature increases
- Increases in temperature leading to increased ozone and air pollution levels in large cities with vulnerable populations

Section 4.5.6 and this section describe the effects of climate change on developing countries that would differ or be substantially more severe than similar effects experienced by developed nations. Because the developing world tends to depend more on small-scale farming and subsistence economic activities, individuals in these areas would be disproportionately affected by climate change impacts on agricultural and subsistence resources. In particular, these impacts could include:

- Decreases in precipitation in developing parts of the world, such as southern Africa and northern South America, leading to decreases in agricultural production and increased food insecurity
- Substantial potential for impacts on small-scale subsistence farmers resulting from increases in extreme weather events projected under global climate change, reducing agricultural production in some areas of the globe
- Changes in the range of fish and animals and species extinctions, affecting populations in developing nations that depend economically on these resources

- Declines in tourism, especially to coastal and tropical areas heavily affected by sea-level rise, with severe economic consequences for smaller, developing nations

- Sea-level rise and severe weather-related events affecting the long-term habitability of atolls (low coral reef-formed islands) (Barnett and Adger 2003)

Global Impacts on Economic Opportunities and Risks

Impacts vary by region and locality and cannot be generalized for all nations. Although impacts are expected to vary, a factor that developed countries have in common is that their access to material and financial resources provides them opportunities to adapt to the effects of a changing climate. By contrast, developing countries are expected to be less able to adapt to climate change because they lack both the physical and financial resources needed to bolster their resilience to the same extent that is possible in industrialized countries.

In developing countries "industry includes a greater proportion of enterprises that are small-scale, traditional, and informally organized…Impacts of climate change on these businesses are likely to depend on… location in vulnerable areas, dependence on inputs sensitive to climate, and access to resources to support adaptive actions" (Wilbanks *et al.* 2007). One specific industry that could become more vulnerable to direct and indirect impacts of climate change is the tourism industry. Impacts on this industry can be "especially significant for smaller, tourist-oriented countries often in the developing world" (Wilbanks *et al.* 2007). It seems "likely that tourism based on natural environments will see the most substantial changes due to climate change… Tropical island nations and low-lying coastal areas may be especially vulnerable as they may be affected by sea-level rise, changes in storm tracks and intensities, changes in perceived climate-related risks, and changes in transport costs…" (Wilbanks *et al.* 2007). The implications are most notable for areas in which tourism is a relatively large share of the local or regional economy, and those for which adaptation would represent a relatively substantial need and a relatively substantial cost (Wilbanks *et al.* 2007). Trade is another industry that could be affected by extreme weather events that temporarily close ports or transport routes and damage infrastructure critical to trade, both domestic and international. There could be "linkages between climate change scenarios and international trade scenarios, such as a number of regional and sub-regional free trade agreements" (Wilbanks *et al.* 2007). However, research on this topic is lacking.

4.5.7.2.3 Adaptation

People and societies have adapted to changing conditions in every phase of human history, and human societies have generally been highly adaptable (Ausubel and Landford 1977). Adaptation can be anticipatory or reactive, self-induced and decentralized, or dependent on centrally initiated policy changes and social collaboration. Adaptation measures can be gradual, occurring over long periods of time; or evolutionary based on reactions to abrupt changes in settlement patterns or economic activity, or in response to extreme weather events (Wilbanks *et al.* 2007).

Adaptation strategies vary widely depending on the exposure of a place or sector to dimensions of climate change, its sensitivity to such changes, and its capacities to cope with the changes. Some of the strategies are multisectoral, such as improving climate and weather forecasting at local and regional levels, emergency preparedness, and public education (Wilbanks *et al.* 2007). These strategies are likely to be more prominent in more fully developed countries, but are important tools to facilitate adaptation in all countries. Awareness, capabilities, and access to resources that facilitate adaptation to climate change are likely to be much less widely available in less developed countries, where industrial production and residential population often locate in areas vulnerable to flooding, coastal erosion, and extreme weather events (Wilbanks *et al.* 2007).

New warning systems and evacuation procedures are important adaptation strategies. New warning systems in areas prone to extreme weather events such as hurricanes, cyclones, tornados, and flooding can help to prevent weather-related deaths; and minimize damage to community infrastructure, including the transportation system. Adaptation strategies tend to be context-specific, within larger global markets and policy structures, although it generally takes place within the larger context of globalization (Benson and Clay 2003; Sperling and Szekely 2005).

"Adaptation strategies vary widely depending on the exposure of a place or sector to dimensions of climate change, its sensitivity to such changes, and its capacities to cope with the changes" (Wilbanks *et al.* 2007). In general, uncertainty about the distribution and timing of climate-change impacts at the local level makes judgments about the scale and timing of adaptation actions very difficult (Wilbanks *et al.* 2007).

4.5.8 Human Health

4.5.8.1 Affected Environment

Climate change has contributed to human mortality and morbidity (*very high* confidence; IPCC 2007b) with further projected increases. Climate change could increase the risk of flooding; increase incidence of heat waves; change the severity, duration, and location of extreme weather; increase surface temperature; and alter precipitation intensity and frequency. These events can affect human health either directly through temperature and weather or indirectly though changes in water, air, food quality, vector ecology, ecosystems, agriculture, industry, and settlements. Climate change can also affect health through social and economic disruption. Malnutrition, death, and disease brought on by climate-change are projected to affect millions of people (Confalonieri *et al.* 2007).

4.5.8.2 Environmental Consequences

4.5.8.2.1 Heat Waves

A heat wave is a period of abnormally high temperatures that can be accompanied by unusual humidity. This weather phenomenon is not formally specified by a time period or temperature reading. Conventionally, a heat wave lasts several days to several weeks, though a one-day event can qualify as a heat wave. The temperature to qualify as a heat wave is dependent upon what is considered unusually hot for that region, as increases in mortality can occur below temperatures considered extremely hot (Ebi *et al.* 2008). IPCC has found the number of hot days, hot nights, and heat-waves to have increased (Confalonieri *et al.*. 2007). Global warming has increased intensity of heat waves (Houghton *et al.* 2001, as cited in Epstein *et al.* 2006), due in part to the disproportionate warming at night (Easterling *et al.*1997, as cited in Epstein *et al.* 2006). Heat-wave events can trigger poor air quality and forest fires, leading to further increases in human mortality and morbidity (Bates *et al.* 2005, Goodman *et al.* 2004, Keatinge and Donaldson 2001, O'Neill *et al.* 2005a, Ren *et al.* 2006 all as cited in Ebi *et al.* 2008).

The impact of a heat wave on the affected population depends on the current health and economic status. In South Asia, those most sensitive to heat waves include the rural population, elderly, outdoor workers, very young, city-dwellers, those with less education, socially isolated, medicated people, mentally ill, and those without available air conditioning (Chaudhury et al 2000, as cited in Confalonieri *et al.*. 2007; Diaz *et al.* 2002, Klinenberg 2002, McGeehin and Mirabelli 2001, Semenza *et al.* 1996, Whitman *et al.* 1997, Basu *et al.* 2005, Gouveia *et al.* 2003, Greenberg *et al.* 1983, O'Neill *et al.* 2003a, Schwartz 2005, Jones *et al.* 1982, Kovats *et al.* 2004, Schwartz et al 2004a, Semenza *et al.* 1999, Watkins *et al.* 2001 all as cited in Ebi 2008). People in developed areas can be impacted substantially by heat waves as well. Existing electricity grids in the United States would be severely stressed by a major heat wave, leading to brownouts and blackouts further contributing to increased heat-related illnesses (Epstein *et al.*, 2006).

The urban heat island effect could increase temperatures experienced in cities by 2 to 10 degrees Fahrenheit compared to neighboring rural and suburban areas (EPA 2005 as cited in Ebi *et al.* 2008). This increase in temperature occurs, in part, as the city pavement and buildings absorb a greater amount of incoming solar radiation compared to vegetation and trees; in addition, heat is also emitted from buildings and transportation (EPA 2005, Pinho and Orgaz 2000, Vose *et al.* 2004, Xu and Chen 2004, all as cited in Ebi *et al.* 2008). However, it has been demonstrated that during a heat wave, not all urban areas experience greater heat-related mortality than the surrounding rural and suburban areas (Sheridan and Dolney, 2003, as cited in Ebi *et al.* 2008).

4.5.8.2.2 Cold Waves

Human mortality and morbidity can also be caused by cold waves. Cold waves affect human health through death, hypothermia, frostbite, damage to organs such as kidney, pancreas, and liver, with greatest risk to infants and the elderly (NOAA 2001). Cold waves can cause further complications of heavy snow, ice, coastal flooding, and stranded motorists. As with a heat wave, the classification of a cold wave varies by region, with no formal definition for the minimum temperature reached, the rate of temperature fall, or the duration of the event. Populations in temperate countries tend to be more sensitive to cold weather (Honda *et al.* 1998, as cited in Confalonieri *et al.*. 2007). The human health reaction of a population to a cold wave can vary depending on the income, (Healy 2003, as cited in Ebi *et al.* 2008), age, topography, climate, (Curriero *et al.* 2002, Hajat 2006, both as cited in Confalonieri *et al.* 2007), race, (Fallico *et al.* 2005. as cited in Ebi *et al.* 2008), sex, (Wilkinson *et al.* 2004, as cited in Ebi *et al.* 2008), health, (Wilkinson *et al.* 2004, as cited in Ebi *et al.* 2008), dress, (Donaldson *et al.* 2001, as cited in Ebi *et al.* 2008), and fuel access (Healy 2003, as cited in Ebi *et al.* 2008). Cold days, cold nights, and frost days have become less common (IPCC 2007b) with the winter season projected to continue to decrease in duration and intensity (Alley *et al.* 2007, as cited in Ebi *et al.* 2008). This could lead to a decrease in cold-related health impacts, notwithstanding external factors, such as influenza outbreaks (Ebi *et al.* 2008).

4.5.8.2.3 Extreme Weather Events

Climate change is anticipated to affect the number, severity, and duration of extreme weather events (Fowler and Hennessey 1995, as cited in Sussman *et al.* 2008). Extreme weather events include floods, tropical and extra-tropical cyclones, tornadoes, windstorms, and drought. Extreme weather can further trigger additional extreme events such as wildfires, negatively affecting infrastructure, including sanitation, human mortality and morbidity, and mental health (Confalonieri *et al.* 2007). The loss of shelter, large-scale population displacement, damage to community sanitation and health care, and reduction in food availability can extend the level of mortality and morbidity beyond the actual event (Curriero *et al.* 2001b, as cited in Sussman *et al.* 2008). Factors that influence population vulnerability to extreme weather include location, population density, land use, age, income, education, health, health care response, and disaster preparedness (Blaikie *et al.* 1994, Menne 2000, Olmos 2001, Adger *et al.* 2005, Few and Matthies 2006, all as cited in Confalonieri *et al.* 2007).

Adverse weather conditions create safety hazards and delays in the Nation's transportation systems, especially on the nation's highways. The Federal Highway Administration (FHWA) estimates that about 25 percent of highway crashes occur during adverse weather resulting in about 17 percent of highway fatalities (AMS, 2004), while the Federal Motor Carrier Safety Administration (FMCSA) found that the factor "environmental conditions" was the critical reason[22] for 3 percent of large truck crashes (FMCSA, 2007). Extreme weather events that increase adverse weather conditions on the nation's highways could potentially affect highway safety.

Floods occur with the greatest frequency compared to other extreme weather events (EM-DAT 2006, as cited in Confalonieri *et al.* 2007). The intensity of a flood is dependent on rainfall, surface runoff, evaporation, wind, sea level, and local topography (Confalonieri *et al.* 2007). Health impacts related to flood events include deaths and injuries sustained during a flood event; increased transmission and prevalence of infectious diseases; and toxic contamination of supplies and food (Greenough *et al.* 2001, Ahren *et al.* 2005, both as cited in Confalonieri *et al.* 2007; Hajat et al 2003, Kalashnikov *et al.* 2003, Tuffs and Bosch 2002 (all as cited in Epstein *et al.* 2006)).

Drought is an abnormal period of dry weather that has led to substantial decrease in water availability for a given location (Huschke 1959). The health impacts associated with a drought include mortality, malnutrition, infectious diseases, and respiratory diseases (Menne and Bertollini 2000, as cited in Confalonieri *et al.* 2007). Aggravating this situation, malnutrition increases the susceptibility of contracting an infectious disease (Confalonieri *et al.* 2007) and drought-related population displacement can reduce access to adequate and safe water, food, and shelter, leading to increased malnutrition and infectious diseases. Further health impacts can spiral, such as a change in the transmission of mosquito-borne diseases during and after the drought event (Confalonieri *et al.* 2007). Impacts on the agricultural productivity affect health through risk of under- and malnutrition (Epstein *et al.* 2006), and increased dust storm activity and frequency of forest fires. Drought conditions weaken trees' defenses against pests and can result in increased threats to human health from forest fires (Mattson and Haack 1987, Boyer 1995, Holsten *et al.*, 2000, all as cited in Epstein *et al.* 2006).

4.5.8.2.4 Air Quality

Climate change can affect air quality through altering local weather patterns and/or pollution concentrations. Ground-level ozone, particulate matter, and airborne allergens contribute to poor air quality, leading to respiratory ailments and premature mortality. Increasing exposure to these pollutants would have substantial negative health impacts (Confalonieri *et al.* 2007).

Ground-level ozone contributes to urban smog, and occurs both naturally and as a secondary pollutant formed through photochemical reactions of nitrogen oxides and volatile organic compounds.[23] These reactions are accelerated with increasing sunlight and temperatures; thus ozone concentrations tend to peak during late afternoon and early evening in the warmer season; however, some locations demonstrate no such seasonality in ozone concentration (Bates 2005, as cited in Confalonieri *et al.* 2007). The concentration of ground-level ozone for a particular location varies as a function of temperature, wind, solar radiation, atmospheric moisture, atmospheric mixing, and cloud cover. Studies have found increasing levels of ground-level ozone in most regions (Wu and Chan 2001, Chen *et al.* 2004, both as cited in Confalonieri *et al.* 2007). A recent study found increases in CO_2 concentrations lead to increases in water vapor and temperatures. These lead to higher ozone concentrations in polluted areas, resulting in

[22] FMCSA conducted the Large Truck Crash Causation Study (LTCCS) sample of 963 crashes involved 1,123 large trucks and 959 motor vehicles that were not large trucks between 2001 and 2003. The LTCCS defines the Critical Reason as the immediate reason for the critical event (*i.e.*, the failure leading to the critical event). The critical reason is assigned to the vehicle coded with the critical event in the crash. It can be coded as a driver error, vehicle failure, or environmental condition (roadway or weather). Other causal coding includes a Critical Event and Associated Factors.

[23] Nitrogen oxides are emitted, in part, through the burning of fossil fuels. Volatile organic compounds are emitted from varying sources including burning of fossil fuels, transpiration, evaporation from stored fuels, solvents and other chemicals.

an increase in ozone-related deaths by 40 percent (Jacobson 2008). Climate change is anticipated to increase ozone-related diseases (Sussman *et al.* 2008).

Ozone exposure is associated with respiratory ailments such as pneumonia, chronic obstructive pulmonary disease, asthma, allergic rhinitis, chest pain, shortness of breath, and premature mortality (Mudway and Kelly 2000, Gryparis *et al.* 2004, Bell *et al.* 2005, 2006, Ito *et al.* 2005, Levy *et al.* 2005, all as cited in Confalonieri *et al.* 2007,; American Lung Association, 2008). Asthmatics are considered a sensitive population (Ebi *et al.* 2008). Long-term exposure to elevated amounts of ozone has been shown to affect lung efficiency (Ebi et al 2008; American Lung Association 2008).

Particulate matter comprises solid and liquid particles suspended in the atmosphere varying in both chemical composition and origin. Concentrations of particulate matter are affected by emission rates and local weather conditions such as atmospheric stability, wind, and topography. Some particulates display seasonal variability directly linked to seasonal weather patterns (Alvarez *et al.* 2000, Kassomenos *et al.* 2001, Hazenkamp-von Arx *et al.* 2003, Nagendra and Khare 2003, Eiguren-Fernandez *et al.* 2004, all as cited in Confalonieri *et al.* 2007). In Mexico City and Los Angeles, local weather conditions can create a stagnant air mass, restricting dispersion of pollution. Seasonal weather patterns can further enhance the chemical reactions of emissions, thereby increasing secondary particulate matter (Rappengluck *et al.* 2000, Kossmann and Sturman 2004, both as cited in Confalonieri *et al.* 2007).

Breathing particulate matter can cause respiratory ailments, heart attack, and arrhythmias (Dockery *et al.* 1993, Samet *et al.* 2000, Pope *et al.* 1995, 2002, 2004, Pope and Dockery 2006, Dominici *et al.* 2006, Laden *et al.* 2006, all as cited in Ebi *et al.* 2008). Populations at greatest risk could include children, the elderly, and those with heart and lung disease, diabetes (Ebi *et al.* 2008), and high blood pressure (Künzli *et al.* 2005, as cited in Ebi *et al.* 2008). Chronic exposure to PM could decrease lifespan by 1 to 3 years (Pope 2000, as cited in American Lung Association 2008). Increasing PM concentrations will have a measurable adverse impact on human health (Confalonieri *et al.* 2007).

Forest fires contribute to poor air quality conditions. During the 5th largest United States wildfire in 1999, medical visits at the Hoopa Valley National Indian Reservation increased by 52 percent with symptoms affecting lower respiratory tract and preexisting cardiopulmonary conditions (Mott *et al.* 1999). Human health ailments associated with forest fires include burns, smoke inhalation, mortality, eye illnesses, and respiratory illnesses (Confalonieri *et al.* 2007; Ebi *et al.* 2008). Certain regions are anticipated to experience an increase in frequency and intensity of fire events with projected changes in temperature and precipitation. Pollution from forest fires along with other pollutants, such as carbon monoxide, ozone, desert dust, mould spores and pesticides, can be transported thousands of kilometers on time scales of 4 to 6 days affecting populations far from the sources (Gangoiti *et al.* 2001, Stohl *et al.* 2001, Buchanan *et al.* 2002, Chan *et al.* 2002, Martin *et al.* 2002, Ryall *et al.* 2002, Ansmann *et al.* 2003, He *et al.* 2003, Helmis *et al.* 2003, Moore *et al.* 2003, Shinn *et al.* 2003, Unsworth *et al.* 2003, Kato *et al.* 2004, Liang *et al.* 2004, Tu *et al.* 2004, all as cited in Confalonieri *et al.* 2007).

4.5.8.2.5 Water-borne and Food-borne Diseases

Substantial morbidity and childhood mortality has been linked to water- and food-borne diseases. Climate change is projected to alter temperature and the hydrologic cycle through changes in precipitation, evaporation, transpiration, and water storage. These changes, in turn, potentially affect water-borne and food-borne diseases, such as salmonellosis, campylobacter, leptospirosis, and pathogenic species of vibrio. They also have a direct impact on surface water availability and water quality. It has been estimated that over 1 billion people in 2002 did not have access to adequate clean water (McMichael *et al.* 2003, as cited in Epstein *et al.* 2006). Increased temperatures, greater evaporation, and heavy rain events have been associated with adverse impacts on drinking water through increased waterborne diseases, algal blooms, and toxins (Chorus and Bartram 1999, Levin *et al.* 2002, Johnson and Murphy 2004 (all cited in Epstein *et al.* 2006)). In the United States, 68 percent of all waterborne diseases between 1948 and 1994 happened after heavy rainfall events (Curriero *et al.* 2001a, as cited in Epstein *et al.*, 2006). Climate change could further impact a pathogen by directly affecting its life cycle (Ebi *et al.* 2008). The global increase in the frequency, intensity, and duration of red tides could be linked to local impacts already associated with climate change (Harvell *et al.* 1999, as cited in Epstein *et al.* 2006); toxins associated with red tide directly affect the nervous system (Epstein *et al.* 2006).

Many people do not report or seek medical attention for their ailments of water-borne or food-borne diseases; hence, the number of actual cases with these diseases is greater than clinical records demonstrate (Mead et al 1999, as cited in Ebi *et al.* 2008). Many of the gastrointestinal diseases associated with water-borne and food-borne diseases can be self-limiting; however, vulnerable populations include young children, those with a compromised immune system, and the elderly.

4.5.8.2.6 Vector-borne Diseases

Infections can be spread by the bite of an infected arthropod (termed vector-borne), such as mosquitoes, ticks, sandflies, and blackflies, or through non-human vertebrates such as rodents, canids, and other mammals. Such diseases include typhus, malaria, yellow fever, dengue fever, West Nile virus, Western Equine encephalitis, Eastern Equine encephalitis, Bluetongue virus, and lyme disease. Increased insect density has been correlated with milder seasonal variability (Confalonieri *et al.* 2007) and tick distributions tend to expand with higher minimum temperatures (Ebi *et al.* 2008). In general, climate and weather are important constraints on the range of transmission for vector-borne diseases. For example, temperature and flooding are key constraints on the range of mosquitoes, which serve as a primary vector for malaria and other diseases (Epstein *et al.* 2006). Changes in seasonal duration and increases in weather variability reduce/eliminate these constraints (Epstein *et al.* 2006). In southern Mozambique a the number of malaria cases increased four to five times over long-term averages in the days and weeks following a severe flooding event in 2000 (Epstein *et al.* 2006). Temperature and the availability of water can both play key roles in regulating population size as well. For the deer tick, the disease vector for Lyme disease, off-host survival is strongly affected by these two variables, and thus climate is the primary factor determining size and distribution of deer tick populations (Needham and Teel 1991, Bertrand and Wilson 1996, both as cited in Epstein *et al.* 2006). Changes in land use practice or to the habitat and behavior of wildlife hosts of the insect can also impact latitudinal or altitudinal shifts in the disease carrying species (Confalonieri *et al.* 2007).

4.5.8.3 Projected Health Impacts of Climate Change on the United States

Human health is projected to be adversely affected by rising temperatures, increasing ground-level ozone concentrations, changes in extreme weather events, and increasing food and water-borne pathogens. The impact of the varying health-related event is dependent on location. The United States is anticipated to sustain fewer cases of illness and death associated with climate change compared with the developing world (CCSP 2008f). The current health infrastructure along with the United States government's disaster planning and emergency response systems are key assets to enable the United States to meet changing health effect demands associated with climate change. These health impacts will vary in scope across the United States.

In the United States, there have been 20,000 heat and solar-related deaths from 1936 to 1975, with the heat wave of 1980 accounting for over 1,250 deaths (NOAA 2005). There could be a rise in heat-related morbidity and mortality in the coming decades (CCSP 2008f) due, in part, to an aging population. By 2010, 13 percent of the population of the United States is projected to be over the age of 65, and 20 percent by 2030 (Day 1996, as cited in Ebi *et al.* 2008). Studies have shown a decline in heat-related mortality over the past decades, possibly due to increased air conditioning usage and improved health care (Davis *et al.* 2002, Davis *et al.* 2003a, Davis *et al.* 2003b, Carson *et al.* 2006 (all cited in Ebi *et al.* 2008)). Heat waves are anticipated to increase in severity, frequency and duration, particularly in the Midwest and Northeast sections of the country (CCSP 2008f; Frumkin 2008).

The northern latitudes of the United States are likely to experience the greatest increases in average temperature and concentrations of many of the airborne pollutants (CCSP 2008f). In particular, urban centers in the West, Southwest, Mid-Atlantic and Northeast regions are projected to incur the largest increases in average temperatures (Frumkin 2008). A regional climate simulation projected air quality to worsen in Texas but to improve in the Midwest in 2045 to 2055 compared with 1995 to 2005 (Leung and Gustafson 2005, as cited in Ebi *et al.* 2008). In urban areas, ground-level ozone concentrations are anticipated to increase in response to higher temperatures and increases in water vapor concentration (CCSP 2008f; Jacobson 2008). Climate change could further cause stagnant air masses that increase pollution concentrations of ground-level ozone and PM in populated areas. For example, one study projected an increase in the upper Midwest stagnant air between 2000 and 2052 (Mickley *et al.* 2004, as cited in Ebi *et al.* 2008). Further, Frumkin (2008) found that climate change is likely to alter the air pollution contribution from natural sources and increase the creation of secondary pollutants; however, an alternative study found an increase in evaporative losses from nitrate particles reduces PM levels (Aw and Kleeman 2003, as cited in Ebi *et al.* 2008). A recent study concluded that continuous local outdoor CO_2 emissions can increase the respective CO_2 concentration for that area, thereby increasing ozone levels (Jacobson 2008).

The spring pollen season has been shown to begin earlier than usual in the Northern Hemisphere (D'Amato *et al.* 2002, Weber 2002, Beggs 2004 all cited in Confalonieri *et al.* 2007). There is further evidence suggesting a lengthening of the pollen season for some plant species (Confalonieri *et al.* 2007). A recent study determined that the density of air-borne pollen for some species has increased, however, it is not understood what the allergenic content of this additional pollen is (Huynen and Menne 2003, Beggs and Bambrick 2005, both as cited in Confalonieri *et al.* 2007). Additionally, climate change could alter the pollen concentration of a given plant species as the species reacts to increased concentration of CO_2. Current findings demonstrate that ragweed pollen production and the length of the ragweed pollen season increase with rising CO_2 concentrations and temperatures (Wan *et al.* 2002, Wayne *et al.* 2002, Singer *et al.* 2005, Ziska *et al.* 2005, Rogers *et al.* 2006a all cited in Confalonieri *et al.* 2007). Invasive plant species with high allergenic content such as ragweed and poison ivy have been found to be spreading in particular locations around the world, increasing potential health risks (Rybnicek and Jaeger 2001, Huynen and Menne 2003, Taramarcaz *et al.* 2005, Cecchi *et al.* 2006 all cited in Confalonieri *et al.* 2007).

Extreme weather events are likely to be altered by climate change, though there is uncertainty predicting the frequency and severity of events. Some regions in the United States might experience drought conditions due to the reduction in rainfall, while other sections of the country are likely to experience increased frequency of heavy rainfall events, leading to potential flood risk (Frumkin 2008). On the west coast, water quality could be adversely affected as water supplies reduce with decreases in regional precipitation and depletion of mountain snowpacks (Frumkin 2008). It is considered *very likely* (greater than 90 percent certainty) that over the course of this century there will be an increase in the frequency of extreme precipitation (IPCC 2007a). The Southeast, Intermountain West and West are likely to experience an increase in frequency, severity and duration of forest fires (CCSP 2008f, Brown *et al.* 2004, Fried *et al.* 2004 (all cited in Ebi *et al.* 2008)). Impacts to respective vulnerable populations could change in the future as shifts occur in population, suburban development, and community preparedness. It is very likely that a large portion of the projected growth of the United States population will occur in areas considered to be at risk for future extreme weather events (Ebi *et al.* 2008). Hence, even if the rate of health impacts were to decrease, the growth in population in risk areas will still cause an increase in the total number of people affected.

Pathogen transmission depends on many climate-related factors such as temperature, precipitation, humidity, water salinity, extreme weather events, and ecological shifts, and could display seasonal shifts (Ebi *et al.* 2008). Few studies have projected the health impact of vector-borne diseases. Vector-borne illnesses are likely to shift or expand northward and to higher elevations with the possible introduction of new vector-borne diseases (CCSP 2008f, Frumkin 2008), while decreasing the range of tick-borne encephalitis in low latitudes and elevation (Randolph and Rogers 2000, as cited in Ebi *et al.* 2008). Malaria and dengue fever in the United States are unlikely to be affected by climate change variables given the housing quality, land use patterns, and vector control (Frumkin 2008).

Overall, populations within certain regions of the United States regions could experience climate change-induced health impacts from a number of pathways simultaneously. For instance, populations in coastal communities could experience an extreme weather event, such as a tropical cyclone and flooding, adding to health burdens associated with sea-level rise or coastal erosion.

4.5.8.3.1 Adaptation

The United States has a number of organizations and activities that identify and plan for the prevention of adverse health impacts associated with weather and climate although recent experiences following extreme weather and vector-borne disease outbreaks have demonstrated there is a need for improvement (Confalonieri *et al.* 2007, as cited in Ebi *et al.* 2008). The regions where there is an anticipated increase in the health impacts of climate change are very likely to have a greater proportion of poor, elderly, disabled, and uninsured residents. In addition, the American Academy of Pediatrics has determined children are a vulnerable population, recommending the United States government give children particular attention when developing emergency management and disaster response systems (American Academy of Pediatrics 2007; McMichael and Githek 2001; U.S. Department of Health and Human Services 2007, as cited in American Academy of Pediatrics 2007).

The public health sector has divided the activities associated with preventing diseases into one of three classifications: primary, secondary and tertiary. Primary prevention protects the unaffected population from contracting diseases. Secondary prevention focuses on the response action that starts at the onset of a disease. Tertiary prevention deals with an existing disease and focuses on reducing suffering and long-term health difficulties. Primary prevention tends to be the most effective and least costly compared to secondary or tertiary prevention (Ebi *et al.* 2008).

Adaptation policies and measures to address impacts to human health due to climate change should be continually managed as climate change is dynamic. Such adaptation might include the:

- Support and maintenance of the public health infrastructure (Frumkin 2008)
- Improvement and dissemination of preventive care in the public health infrastructure (Frumkin 2008)
- Continued use of nationwide surveillance as a tool to identify, track and map vector-borne diseases (Frumkin 2008)
- Utilization of preparedness tools to identify and assist vulnerable populations during extreme weather events (Frumkin 2008)
- Strengthening of infrastructure to withstand extreme weather events

4.5.8.4 Projected Global Health Impacts of Climate Change

Globally, climate change is anticipated to contribute to both adverse and beneficial health impacts. Projected adverse health impacts include malnutrition leading to disease susceptibility (*high confidence*); increased heat-wave, flood, storm and fire-induced mortality (*high confidence*); decrease in cold-related deaths (*high confidence*); increased diarrheal disease burden (*medium confidence*); increased levels of ground-level ozone (*high confidence*); and altered geographic distribution of some infectious disease vectors (*high confidence*) (Confalonieri *et al.* 2007). A decrease in cold-related mortality and some pollutant-related mortality, increased crop yields in certain areas, and restriction of certain diseases in certain areas (if temperatures or precipitation rises above the critical threshold for vector or parasite survival) are examples of projected beneficial health impacts (Confalonieri *et al.* 2007). The adverse impacts, however, greatly outweigh the beneficial impacts, particularly after the mid-century mark (Confalonieri *et al.* 2007).

Regionally, the impact on human health will vary. Some Asian countries could experience increasing malnutrition by 2030 with crop yields decreasing later in the century, rendering the population in the region particularly vulnerable to malnutrition-associated diseases and disorders (Confalonieri *et al.* 2007). Certain coastal areas will experience flooding by 2030 impacting human mortality (Confalonieri *et al.* 2007). By 2080, lyme disease is projected to have moved northward into Canada, due to a two- to four-fold increase in tick abundance (Confalonieri *et al.* 2007). By 2085, climate change is projected to increase the population at risk to dengue fever to a total of 3.5 billion people (Confalonieri *et al.* 2007).

Heat waves have been experienced globally: thousands of deaths incurred in India over the eighteen heat-waves recorded between 1980 and 1998 (De and Mukhopadhyay 1998, Mohanty and Panda 2003, De *et al.* 2004 all cited in Confalonieri *et al.* 2007). In August 2003, approximately 35,000 deaths were linked to a heat-wave experienced in Europe, with France alone incurring over 14,800 deaths (Hemon and Jougla 2004, Martinez-Navarro *et al.* 2004, Michelozzi *et al.* 2004, Vandentorren *et al.* 2004, Conti *et al.* 2005, Grize *et al.* 2005, Johnson *et al.* 2005 all cited in Confalonieri *et al.* 2007). Around 60 percent of the heat-wave related deaths in France were people at or over 75 years of age (Hemon and Jougla, 2004, as cited in Confalonieri *et al.* 2007). Overall, studies have linked high temperatures to about 0.5-2 percent of annual mortality in the elderly European population (Pattenden *et al.* 2003, Hajat *et al.* 2006, both as cited in Confalonieri *et al.* 2007).

In 2003, floods in China affected 130 million people (EM-DAT 2006, as cited in Confalonieri *et al.*2007). In 1999, storms with floods and landslides in Venezuela killed 30,000 people (Confalonieri *et al.* 2007).

The World Health Organization (WHO) estimates that a high proportion of those in dry regions (approximately 2 billion) experience malnutrition, infant mortality, and water-related diseases (WHO 2005, as cited in Confalonieri *et al.* 2007). Children in low-income countries are particularly vulnerable to loss of life due to diarrhea. The transmission of the enteric pathogen appears to increase during the rainy season for children in the sub-Saharan Africa (Nchito *et al.* 1998, Kang *et al.* 2001, both as cited in Confalonieri *et al.* 2007). In Peru, higher temperatures have been linked to periods of increased diarrhea incidence experienced by adults and children (Checkley *et al.* 2000, Speelmon *et al.* 2000, Checkley *et al.* 2004, Lama *et al.* 2004, all as cited in Confalonieri *et al.* 2007).

Cholera outbreaks associated with floods can occur in areas of poor sanitation. A study in Sea surface temperatures in the Bay of Bengal demonstrated a bimodal seasonal pattern that translated to increased plankton activity leading to increases in cholera in nearby Bangladesh (Colwell 1996, Bouma and Pascual 2001, both cited in Confalonieri *et al.* 2007).

Dengue is considered the most important vector-borne viral disease (Confalonieri *et al.* 2007). A strong correlation exists between climate-based factors such as temperature, rainfall and cloud cover with the observed disease distribution in Colombia, Haiti, Honduras, Indonesia, Thailand and Vietnam (Hopp and Foley 2003, as cited in Confalonieri *et al.* 2007). Favorable climate conditions for dengue exist to about one-third of the world's population (Hales *et al.* 2002, Rogers *et al.* 2006b, both as cited in Confalonieri *et al.* 2007).

Malaria is a vector-borne disease spread by mosquitoes. Depending on location, malaria outbreaks could be influenced by rainfall amounts and sea-surface temperatures in southern Asia, Botswana, and South America (Kovats *et al.* 2003, Thomson *et al.* 2005, DaSilva *et al.* 2004, all as cited in Confalonieri *et al.* 2007). A recent study of malaria in East Africa found that the measurable warming trend the area has experienced since the 1970s can be correlated with the potential of disease transmission. (Pascual *et al.* 2006, as cited in Confalonieri *et al.* 2007) However, southern Africa was not shown to exhibit the same trend (Craig *et al.* 2004, as cited in Confalonieri *et al.* 2007). External factors are also influencing the number of cases of the disease in Africa, such as drug-resistant malaria, and parasite and HIV infection. Studies did not provide clear evidence that malaria in South America or the continental regions of the Russian Federation have been affected by climate change (Benitez *et al.* 2004, Semenov *et al.* 2002, both as cited in Confalonieri *et al.* 2007). In general, however, higher temperatures and more frequent extreme weather occurrences (such as floods and droughts) are predicted to have a stronger influence on the wider spread of malaria with increasing climate change (McMichael *et al.* 1996, as cited in Epstein *et al.* 2006).

Temperature has been shown to affect food-borne and water-borne diseases. Several studies have found increases in salmonellosis cases (food poisoning) within 1 to 6 weeks of the high-temperature peaks (controlled by season). This could be due, in part, to the processing of food products and the population varying its eating habits during warmer months (Fleury *et al.* 2006, Naumova *et al.* 2006, Kovats *et al.* 2004, D'Souza *et al.* 2004, all as cited in Ebi *et al.* 2008). High temperatures have been shown to increase common types of food poisoning (D'Souza *et al.* 2004, Kovats *et al.* 2004, Fleury *et al.* 2006, all as cited in Confalonieri *et al.* 2007). Increasing global temperatures could contribute to a rise in salmonellosis cases (Ebi *et al.* 2008). There is further concern that projected increasing temperatures from climate change will also increase leptospirosis cases, a disease that is resurging in the United States.

The effects of climate change on air quality are expected to adversely impact people suffering from asthma and other respiratory ailments. Increases in temperature, humidity, the prevalence and frequency of wildfires, and other factors are expected to result in more smog, dust, and particulates that exacerbate asthma. Widespread respiratory distress throughout many regions of the world is a possible result of climate change. Current asthma treatment and management plans might be overwhelmed, leading to major increases in asthma-related morbidity and mortality (Epstein *et al.* 2006).

Warm climates are more apt to support the growth of the pathogenic species of Vibrio, leading to shell-fish related death and morbidity that might affect the United States, Japan and South-East Asia (Janda *et al.* 1988, Lipp *et al.* 2002, both as cited in Ebi *et al.* 2008, 2-10; Wittmann and Flick 1995, Tuyet *et al.* 2002, both as cited in Confalonieri *et al.* 2007). If temperatures increase, the geographic range and concentration of the Vibrio species could expand. For example, as the waters of the northern Atlantic have warmed, the concentration of Vibrio species has also (Thompson *et al.* 2004, as cited in Ebi *et al.* 2008). Future ocean warming might also lead to the proliferation of harmful algal blooms, releasing toxins that contaminate shellfish and lead to food-borne diseases (Confalonieri *et al.* 2007). Algal blooms such as red tide can also increase if fecal bacteria concentrations and nutrient loading increases from storm water runoff during heavy precipitation events (Frumkin 2008).

In 2000, WHO estimated that climate change has caused the loss of more than 150,000 lives (Campbell-Lendrum *et al.* 2003, Ezzati *et al.* 2004, McMichael 2004 (as cited in Confalonieri *et al.* 2007)). The projected risks in 2030 described by the WHO study vary by health outcome and region; most of the increase in disease is due to diarrhea and malnutrition. More cases of malaria are predicted in those countries that are situated at the edge of the current distribution. The projected health impact associated with malaria is mixed, with some regions demonstrating increased burden and others exhibiting decreased burden.

4.5.8.4.1 Adaptation

Climate change is considered to pose a risk to the health of both the United States and global populations (Ebi *et al.* 2008). Developed societies such as the United States are more likely to implement effective adaptation measures reducing the magnitude of severe health impacts. For example, the risk and impact of floods on a population can be reduced with changes in water management practices, improved infrastructure, and land use practices (EEA 2005, as cited in Confalonieri *et al.* 2007). Unblocking drains also helps to reduce the transmission of enteric pathogens (Parkinson and Butler 2005, as cited in Confalonieri *et al.* 2007). However, improvements world-wide in adaptive capacity are needed (*high confidence*; Confalonieri *et al.* 2007). Many governments have increased their efforts to cope with extreme climate events moving from disaster relief to risk management. Efforts in Portugal, Spain, France, UK, Italy and Hungary focus on short-term events such as heat waves (Pascal *et al.* 2006, Simón *et al.* 2005, Nogueira 2005, Michelozzi *et al.* 2005, NHS 2006, Kosatsky and Menne 2005, all as cited in Confalonieri *et al.* 2007) while other efforts have undertaken long-term strategies addressing policies for agriculture, energy, forestry and transport (Confalonieri *et al.* 2007).

4.6 ENVIRONMENTAL JUSTICE

4.6.1 Affected Environment

Executive Order (EO) 12898, *Federal Actions to Address Environmental Justice in Minority Populations and Low Income Populations*, directs federal agencies to "promote nondiscrimination in federal programs substantially affecting human health and the environment, and provide minority and low income communities access to public information on, and an opportunity for public participation in, matters relating to human health or the environment." EO 12898 also directs agencies to identify and consider disproportionately high and adverse human health or environmental effects of their actions on minority and low-income communities, and provide opportunities for community input in the NEPA process, including input on potential effects and mitigation measures. CEQ, the entity responsible for compliance with EO 12898, has provided agencies with general guidance on how to meet the requirements of the EO as it relates to NEPA in *Environmental Justice Guidance Under the National Environmental Policy Act*. This guidance document also defines the terms "minority" and "low-income community" in the context of environmental justice analysis. Members of a minority are defined as: American Indians or Alaskan Natives, Asian or Pacific Islanders, Blacks, and Hispanics. Low-income communities are defined as those below the poverty thresholds from the U.S. Census Bureau.

In compliance with EO 12898, NHTSA provides in this FEIS a qualitative analysis of the cumulative effects of the proposed action with climate change and other identified relevant actions on these populations.

Environmental justice populations tend to be concentrated in areas with a higher risk of climate-related impacts. USCCSP notes that this geographic placement might put these communities at higher risk, "from climate variability and climate-related extreme events such as heat waves, hurricanes, and tropical and riverine flooding" (CCSP 2008f).

4.6.2 Environmental Consequences

4.6.2.1 Non-climate Change Effects

With consideration of the reasonably foreseeable increase in CAFE standards for MY 2016-2020, the minimum threshold for which has already been established by Congress as 35 mpg, a further decrease in oil consumption and production is predicted. These changes would further the trends affecting environmental justice populations described in Section 3.5.

NHTSA predicts that oil refining would decrease as a result of the reductions predicted to result from the MY 2011-2015 CAFE standards, which could cause a decrease in related air pollutant discharges and a local improvement in air quality for residents near oil refineries. This improvement could represent a small positive impact on environmental justice populations near these facilities.

All six criteria air pollutants regulated by EPA under the Clean Air Act and all but one of vehicle emission toxic air pollutants would decrease overall with adoption of any of the action alternatives and the foreseeable MY 2011-2015 standards (see Section 4.3). However, increases in VMT due to the rebound effect are still projected to cause increases in some criteria and toxic air pollutants in some air quality nonattainment areas. The large size of each nonattainment area, the uniform distribution of increases in VMT, and the minor emissions increases in affected nonattainment and other areas make it unlikely that there would be disproportionate effects to environmental justice populations.

4.6.2.2 Effects of Climate Change in the United States

Environmental justice populations in the United States, as defined by EO 12898, would experience the same general impacts as a result of global climate change felt by the U.S. population as a whole and described in Sections 4.5.6, Food, Fiber, and Forest Products; 4.5.7, Industries, Settlements, and Society; and 4.5.8, Human Health. However, the USCCCP notes that the general climate change impacts to the U.S. population might be differentially experienced by environmental justice populations, explaining that "[e]conomic disadvantage, lower human capital, limited access to social and political resources, and residential choices are social and economic reasons that contribute to observed differences in disaster vulnerability by race/ethnicity and economic status" (CCSP 2008f). A general description of the potential impacts of climate change on the population of the United States is provided below. These impacts are similar to those that would be experienced globally, although the severity of impacts experienced by developing countries would likely be disproportionately larger than those experienced in developed nations, such as the United States. The most likely anthropogenic climate change impacts include:

- *Human Health* – increased mortality and morbidity due to excessive heat, increases in respiratory conditions due to poor air quality, increases in water- and food-borne diseases and changes to the seasonal patterns of vector-borne diseases, increases in malnutrition (*see* Section 4.5.7 for details)

- *Services* – disruption of ability to transport goods and services, shifts in the location of certain crops, disaster-related damage to transportation infrastructure (roads, rail, ports), tourism location shifts, insurance premium increases (*see* Section 4.5.6 for details)

- *Utilities and Infrastructure* – more frequent droughts and increases in demand for irrigation or drinking water, flood-related impacts on sewage systems with potential water quality impacts, and disaster-related damage to transportation, power, and communications systems (*see* Section 4.5.6 for details)

- *Human Settlement* – synergistic effects with existing resource scarcities (energy and water), inundation of inhabited coastal areas due to sea-level rise, urban temperature increases (*see* Section 4.5.6 for details)

- *Social Issues* – increased stress on public services and disruptions to traditional cultures (*see* Section 4.5.6 for details)

- *Agriculture* – changes in crop yields, more intense droughts and floods, changes in the length of growing seasons (*see* Section 4.5.6 for details)

- *Forest and Ecosystem Services* – increased risk of forest fires, redistribution and extinction of economically or culturally important wildlife species, expanded ranges for pests and invasive species (*see* Section 4.5.6 for details)

Environmental justice populations would likely be disproportionately affected by some of these potential impacts. The rest of this section discusses, qualitatively, the most substantial areas of potential disproportionate impact for these populations in the United States.

4.6.2.2.1 Human Health

Low-income and minority communities exposed to the direct effects of extremes in climatic conditions might also experience synergistic effects with pre-existing health risk factors, such as limited availability of preventative medical care and inadequate nutrition (CCSP 2008f).

As stated in Section 4.5.7, increases in heat-related morbidity and mortality as a result of higher overall and extreme temperatures is likely to disproportionately affect minority and low-income populations, partially as a result of limited access to air conditioning and high energy costs (CCSP 2008f, O'Neill *et al.* 2005a). Urban areas, which often have relatively large environmental justice populations, would likely experience the most substantial temperature increase due to the urban "heat island" effect and could be particularly vulnerable to this type of health impact (CCSP 2008f, Knowlton *et al.* 2007).

Increasing temperatures could also lead to expanded ranges for a number of diseases (CCSP 2008f). As described in Section 4.5.8, the number and severity of outbreaks for vector-borne illnesses, such as the West Nile Virus, could become more frequent and severe. Because the vectors of these diseases (such as mosquitoes) are more likely to come into contact with environmental justice populations, disproportionate impacts might occur. For example, an outbreak of the mosquito-borne dengue fever in Texas primarily affected low-income Mexican immigrants living in lower quality housing without air conditioning, leading a team researching the outbreak to conclude that the low prevalence of dengue in the United States is primarily due to economic, rather than climatic, factors (Reiter *et al.* 2003).

4.6.2.2.2 Land Use

In the United States, two primary types of geographical environmental justice communities are likely to be affected by global climate change: urban areas, because of their relatively high concentrations of low-income and minority residents, and indigenous communities. Environmental justice communities in urban areas, because of previously mentioned heat exposure and health issues, are likely to experience climate change impacts more acutely. Additionally, environmental justice populations in coastal urban areas (vulnerable to increases in flooding as a result of projected sea-level rise, larger storm surges, and human settlement in floodplains) are less likely to have the means to quickly evacuate in the event of a natural disaster (CCSP 2008f, National Science and Technology Council 2008). USCCSP, as an example, notes that flooding in Louisiana following the 2005 Hurricane Katrina primarily killed poor and elderly residents having no means to flee (National Science and Technology Council 2008). As stated in Section 4.5.7, indigenous communities in the United States, particularly Alaska, could face major impacts on their subsistence economies from climate change. These impacts would result from their partial reliance on arctic animals, such as seals and caribou, for food and the potential destruction of transportation infrastructure due to ground thaw.

In coastal and floodplain areas prone to flooding because of larger storm surges and generally more extreme weather, increases in flood insurance premiums could disproportionately affect environmental justice populations unable to absorb the additional cost. Lack of sufficient insurance coverage might render these populations more financially vulnerable to severe weather events.

Potential food insecurity as a result of global climate change, particularly among low-income populations in the United States and abroad, is an often mentioned concern (Wilbanks *et al.* 2007, CCSP 2008f). Climate change is likely to affect agriculture by changing the growing season, limiting rainfall and water availability, or increasing the prevalence of agricultural pests (*see* Section 4.5.6 for more information). In the United States, the most vulnerable segment of the population to food insecurity is likely to be low-income children (Cook and Frank 2007, as cited in CCSP 2008f).

4.7 NON-CLIMATE CUMULATIVE IMPACTS OF CO_2

4.7.1 Affected Environment

In addition to its role as a GHG in the atmosphere, CO_2 is exchanged from the air to water, plants, and soil. CO_2 dissolves easily in water and more easily in salt water such as oceans. In water, CO_2 combines with water molecules to form carbonic acid. The amount of CO_2 dissolved in oceans is related to its concentrations in the air. This process reduces the amount of CO_2 in the atmosphere as a GHG, but also increases the acidity of the ocean. Increasing levels of CO_2 are having a global effect on the oceans. By 2100, ocean pH could drop 0.5 units from pH levels of the 1900s (Hall-Spencer *et al.* 2008).

Plants remove CO_2 from the air through photosynthesis and use the carbon for plant growth. This uptake by plants can influence annual fluctuations of CO_2 on the order of 3 percent from growing season to non-growing season (Schneider and Londer 1984, as cited in Perry 1994). Increased levels of CO_2 essentially act as a fertilizer influencing normal annual plant growth.

In addition, CO_2 concentrations affect soil microorganisms. Only recently have the relationships between above-ground ecosystems and below-ground components of ecosystems been considered significant; there is increasing awareness of the fact that feedbacks between the above-ground/below-ground components play a fundamental role in controlling ecosystems processes. For example, the organic carbon required for below-ground decomposition is provided by plants. Plants also provide the resources for root-associated microorganisms (Wardle *et al.* 2004). The "decomposer subsystem in turn breaks down dead plant material and indirectly regulates plant growth and community composition by determining the supply of available root nutrients" (Wardle *et al.* 2004).

Specific plant species, depending on the quantity and quality of resources provided to below-ground components, might have greater impacts on soil biota and the processes regulated by those biota than do other plants. Variation in the quality of forest litter produced by co-existing species of trees, for instance, "explains the patchy distribution of soil organisms and process rates that result from 'single tree' effects" (Wardle *et al.* 2004). The composition of plant communities has a consistent and substantial impact on the composition of root-associated microbes; however, the effects of plant community composition on decomposer systems are apparently context-dependent. In one example cited, manipulating the composition of plant communities in five sites in Europe produced distinctive effects on decomposer microbes, while root-related soil microbes experienced no clear effect (Wardle *et al.* 2004).

The amount of carbon stored in soils of temperate and boreal forests is about four times greater than the carbon that is stored by vegetation and is "33 percent higher than total carbon storage in tropical forests" (Heath *et al.* 2005). Terrestrial communities contain as much carbon as the atmosphere. Forest soils are also the longest-lived carbon pools in terrestrial ecosystems (King *et al.* 2004). Several experiments involving increases of atmospheric CO_2 resulted in increasing carbon mass in trees, but a reduction of carbon sequestration in soils. This is associated with increasing soil microorganism respiration (Heath *et al.* 2005, Black 2008); respiration is associated with "root herbivory, predation, consumption of root exudates, and the decomposition of root and leaf litter" (King *et al.* 2004). In future real-world scenarios, however, the reduction of soil carbon via increased soil respiration could be countered by an increase in litter on the forest floor.

4.7.2 Environmental Consequences

4.7.2.1 Ocean Acidification

One of the large-scale non-climatic effects of an increase in CO_2 emissions is the potential for ocean acidification. The ocean exchanges huge quantities of CO_2 with the atmosphere, and when atmospheric concentrations rise (due to anthropogenic emissions), there is a net flux from the atmosphere to the oceans. This lowers the pH of the oceans (the water becomes more acidic), which reduces the ability of shell-forming organisms to produce their shells. Most shells are made of calcium carbonate, which dissolves under acidic conditions (Hall-Spencer *et al.* 2008, Kleypas *et al.* 2006). According to Kleypas *et al.* (2006), under increasing atmospheric CO_2, "A variety of evidence indicates that calcification rates will decrease, and carbonate dissolution rates increase, as $CaCO_3$ (calcium carbonate) saturation state decreases." Studies have also shown that long-term ocean acidification, such as a pH drop of 0.7 units, has negative effects on fish through reduction in metabolic rates, reproductive dysfunction, growth reduction and survivorship reduction (Michaelidis *et al.* 2005, Shirayama and Thronton 2005, Pane and Barry 2007, all as cited in Keller *et al.* 2008).

In conjunction with rapid climate change, ocean acidification could pose severe threats to coral reef ecosystems. Reef building and reef dissolution are always occurring, but dissolution of coral reefs is expected to increase, and surpass reef building, as anthropogenic CO_2 in the atmosphere increases. If the water column above reefs becomes saturated with the CO_2 from the atmosphere, the water could be less able to hold the CO_2 respired by microorganisms in the reef environment. Although the interactions are complex and difficult to project, a possible scenario is that the excess CO_2 in the reef environment could prevent reef-building. Thresholds for calcium carbonate dissolution exceeding calcification varies for different reef systems (Kleypas *et al.* 2006).

A recent study found that one-third of the 704 zooxanthellate reef-building coral species assessed are at risk of extinction (Carpenter *et al.* 2008). This number has increased dramatically in recent decades due to bleaching and diseases driven by elevated sea surface temperatures. Because NHTSA cannot quantify the impacts of this rulemaking action on threatened species or critical habitat, a Section 7 consultation is not possible. NHTSA discussed this issue with the U.S. Fish and Wildlife Service as part of the development of the FEIS.

4.7.2.2 Plant Growth and Soil Microorganisms

In contrast to its potential adverse effect on the productivity of marine ecosystems, higher CO_2 concentrations in the atmosphere could increase the productivity of terrestrial systems. Plants use CO_2 as an input to photosynthesis. The IPCC Fourth Assessment Report (IPCC 2007a) states that "On physiological grounds, almost all models predict stimulation of carbon assimilation and sequestration in response to rising CO_2, referred to as 'CO_2 fertilization'" (Denman *et al.* 2007).

Under bench-scale and field-scale experimental conditions, several investigators have found that higher concentrations have a fertilizing effect on plant growth (*e.g.,* Long *et al.* 2006, Schimel *et al.* 2000). IPCC reviewed and synthesized field and chamber studies, finding that:

> There is a large range of responses, with woody plants consistently showing net primary productivity (NPP) increases of 23 to 25 percent (Norby *et al.* 2005), but much smaller increases for grain crops (Ainsworth and Long 2005). Overall, about two-thirds of the experiments show positive response to increased CO_2 (Ainsworth and Long 2005, Luo *et al.* 2005). Since saturation of CO_2 stimulation due to nutrient or other limitations is

common (Dukes *et al.* 2005, Köerner *et al.* 2005), the magnitude, and effect of the CO_2 fertilization is not yet clear.

The CO_2 fertilization effect could mitigate some of the increase in atmospheric CO_2 concentrations by resulting in more storage of carbon in biota.

The current annual exchange in CO_2 between the atmosphere and terrestrial ecosystems is estimated at nine to ten times greater than annual emissions produced as a result of burning fossil fuels. Even a small shift in the magnitude of this exchange could have a measurable impact on atmospheric CO_2 concentration (Heath *et al.* 2005). The above-ground/below-ground processes and components in terrestrial ecosystems typically sequester carbon. Studies are now confirming that variations in atmospheric CO_2 have impacts not only on the above-ground plant components, but also on the below-ground microbial components of these systems.

In one study, CO_2 levels were artificially elevated in a forest for the purpose of studying the effect of atmospheric CO_2 on soil communities. An *indirect* impact of the increased CO_2 was that distinct changes in the composition of soil microbe communities occurred as a result of increased plant detritus (BNL 2007, Science Daily 2007). In another study, an increase in CO_2 *directly* resulted in increased soil microbial respiration. However, after 4 to 5 years of increased exposure to CO_2, "the degree of stimulation declined" to only a 10- to 20-percent increase in respiration over the base rate (King *et al.* 2004). Additionally, the degree of stimulation was linked to variability in seasonal and interannual weather (King *et al.* 2004).

The increase in microbe respiration could, therefore, diminish the carbon sequestration role of terrestrial ecosystems. Upon reaching a certain level of CO_2 in the atmosphere, carbon sinks in soils could become net carbon emitters (Heath *et al.* 2005, Black 2008). Because of the number of factors involved in determining soil respiration and carbon sequestration, the threshold for substantial changes in these activities varies spatially and temporally (King *et al.* 2004).

As with the climatic effects of CO_2, the changes in non-climatic impacts associated with the alternatives is difficult to assess quantitatively. In the Reference Case, atmospheric CO_2 concentrations increase from current levels of about 380 ppm to as much as 800 ppm in 2100 (Kleypas *et al.* 2006). Whether the distinction in concentrations is substantial across alternatives is not clear because the damage functions and potential existence of thresholds for CO_2 concentration are not known. However, what is clear is that a reduction in the rate of increase in atmospheric CO_2 would reduce the ocean acidification effect and the CO_2 fertilization effect.

Chapter 5 Mitigation

Council on Environmental Quality (CEQ) regulations for implementing the procedural requirements of the National Environmental Policy Act (NEPA) require that the discussion of alternatives in an Environmental Impact Statement (EIS) "[i]nclude appropriate mitigation measures not already included in the proposed action or alternatives" (40 CFR § 1502.14(f)). In particular, an EIS must discuss the "[m]eans to mitigate adverse environmental impacts" (40 CFR § 1502.16(h)). As defined in the CEQ regulations (40 CFR § 1508.20), mitigation includes:

(a) Avoiding the impact altogether by not taking a certain action or parts of an action.

(b) Minimizing impacts by limiting the degree or magnitude of the action and its implementation.

(c) Rectifying the impact by repairing, rehabilitating, or restoring the affected environment.

(d) Reducing or eliminating the impact over time by preservation and maintenance operations during the life of the action.

(e) Compensating for the impact by replacing or providing substitute resources or environments.

The National Highway Traffic Safety Administration's (NHTSA's) proposed action is to implement Corporate Average Fuel Economy (CAFE) standards for model years (MY) 2011-2015, as required by the Energy Independence and Security Act of 2007 (EISA). The cumulative impacts analysis (*see* Chapter 4) considers the implementation of CAFE standards for MY 2011-2015 and for MY 2016-2020.[1] Under Alternative 1, No Action, NHTSA would take no action to implement the MY 2011-2015 CAFE standards. The No Action Alternative assumes that average fuel economy levels in the absence of CAFE standards beyond 2010 would equal the higher of a manufacturer's product plans or the manufacturer's required level of average fuel economy for MY 2010. Compared to the No Action Alternative, each of the six action alternatives (Alternatives 2 through 7) would result in a decrease in carbon dioxide (CO_2) emissions and associated climate-change effects, and a decrease in energy consumption. This is true regardless of the Input Scenario employed (Reference Case and Mid-1, Mid-2 and High Scenarios).

Under the No Action Alternative, CO_2 emissions and energy consumption would continue to increase; by reducing these increases, as would occur under any of the six action alternatives, the CAFE standards will have a beneficial effect that does not require mitigation.

Emissions from criteria air pollutants and mobile source air toxics (MSATs) are generally anticipated to decline as well. According to the analyses described in Sections 3.3 and 4.3, some emissions would increase under some alternatives and for some analysis years, while most demonstrate uniform declines. Health costs and impacts are estimated to be reduced under all alternatives for the Reference Case and the High Scenario as a first approximation.

Oxides of nitrogen (NO_x), particulate matter ($PM_{2.5}$), oxides of sulfur (SO_x), volatile organic compounds (VOCs), benzene, 1,3-butadiene, and diesel particulate matter (DPM) exhibit decreases in emissions for all alternatives and input scenarios and for all analysis years under both the Reference Case and the High Scenario. Therefore, any negative health impacts associated with these emissions are similarly expected to be reduced, and no mitigation would be required.

[1] Although NHTSA will set CAFE standards for MY 2016-2020 in a future rulemaking, this NEPA analysis makes assumptions about the MY 2016-2020 standards based on the MY 2011-2015 standards and EISA requirements.

According to NHTSA's analysis, emissions of carbon monoxide (CO), acetaldehyde, acrolein, and formaldehyde could increase under certain alternatives or input scenarios, which requires further examination regarding the need for mitigation. Note that NEPA does not require that an agency adopt mitigation measures. The potential for harm depends on the selection of the final standards, the magnitude of the increases, and other factors. In all cases, the increases are approximately 1 percent or less over the No Action Alternative.

The analysis for acrolein emissions is incomplete because upstream emissions factors are not available. Upstream emissions demonstrate decreases due to fuel savings and reduced emissions from fuel refining and transportation. If upstream emissions of acrolein were included in the analysis, total acrolein emissions would show smaller increases or might decrease. Thus, the acrolein emissions reported in the FEIS represent an upper bound.

It should be noted that even if CO emissions show some level of increase, the associated harm might not increase concomitantly. There have been no violations of the CO standards for several years after a long downward trend, owing to the success of regulations governing fuel composition and vehicle emissions.

Two further considerations are relevant to these potential emissions increases. First, the choice of technologies to meet new CAFE standards is left to the vehicle manufacturers. Some of their choices have higher or lower impacts for these emissions. Second, EPA regulates these emissions under the Clean Air Act, which could result in future reductions as EPA promulgates new regulations. Nevertheless, there is the potential that some air pollutant emissions will increase in some years for some alternatives.

Beyond these considerations at the national level, there could also be localized increases in criteria and toxic air pollutant emissions in some nonattainment areas as a result of implementation of the CAFE standards under the action alternatives. These localized increases would represent a slight decline in the rate of reductions being achieved by implementation of Clean Air Act standards.

Federal transportation funds administered by the Federal Highway Administration (FHWA) might be available to assist in funding projects to reduce any increases. FHWA provides funding to states and localities specifically to improve air quality under the Congestion Mitigation and Air Quality Improvement (CMAQ) Program. FHWA and FTA also provide funding to states and localities under other programs that have multiple objectives including air quality improvement. As state and local agencies recognize the need to reduce emissions of CO, acetaldehyde, acrolein, or formaldehyde – or other emissions eligible under the CMAQ Program, including the criteria pollutants and MSATs analyzed for this FEIS – they have the ability to apply CMAQ funding to reduce impacts in most areas. Further, the EPA has the authority to continue to improve vehicle emissions standards.

Chapter 6 Unavoidable Adverse Impacts; Short-term Uses and Long-term Productivity; Irreversible and Irretrievable Commitment of Resources

6.1 UNAVOIDABLE ADVERSE IMPACTS

The National Highway Traffic Safety Administration (NHTSA) proposed action is to implement Corporate Average Fuel Economy (CAFE) standards for model years (MY) 2011-2015. The cumulative impacts analysis (*see* Chapter 4) considers implementation of CAFE standards for MY 2011-2015 and implementation of CAFE standards for MY 2016-2020.[1] Under Alternative 1 (No Action), NHTSA would not take action to implement the MY 2011-2015 CAFE standards. The six action alternatives (Alternatives 2 through 7) would result in a decrease in carbon dioxide (CO_2) emissions and associated climate change effects and a decrease in energy consumption as compared to the No Action Alternative.

Based on NHTSA's current understanding of global climate change, certain effects are likely to occur due to total greenhouse gas (GHG) emissions to the atmosphere. Neither the proposed action nor its alternatives would prevent these effects. As described in Sections 4.4 and 4.5, the action alternatives could diminish the effects of climate change and contribute to global GHG reductions.

Oxides of nitrogen (NO_x), particulate matter ($PM_{2.5}$), oxides of sulfur (SO_x), volatile organic compounds (VOCs), benzene, 1,3-butadiene, and diesel particulate matter (DPM) exhibit decreases in emissions for all alternatives and input scenarios and for all analysis years under both the Reference Case and the High Scenario. Any negative health impacts associated with these emissions are expected to be similarly reduced, and there would be no unavoidable negative impacts of these emissions.

According to NHTSA's analysis, emissions of carbon monoxide (CO), acetaldehyde, acrolein, and formaldehyde could increase under certain alternatives or input scenarios. Thus, the potential for unavoidable impacts depends on the selection of the final standards. In all cases, the increases are approximately 1 percent or less over the No Action Alternative. In addition, as noted in Chapter 5, the acrolein emissions reported in the FEIS represent an upper bound, and thus potential unavoidable impacts of acrolein emissions might be less.

Localized increases in criteria and toxic air pollutant emissions could occur in some nonattainment areas as a result of implementation of the CAFE standards under the action alternatives, largely due to increases in vehicle miles traveled. These localized increases represent a slight decline in the rate of reductions being achieved by implementation of Clean Air Act standards.

6.2 THE RELATIONSHIP BETWEEN LOCAL SHORT-TERM USES OF THE ENVIRONMENT AND THE MAINTENANCE AND ENHANCEMENT OF LONG-TERM PRODUCTIVITY

The six action alternatives (Alternatives 2 through 7) would result in a decrease in energy (crude oil) consumption and reductions in CO_2 emissions and associated climate change impacts compared to those of Alternative 1, No Action. Manufacturers would need to apply various technologies to the production of passenger cars and light trucks to meet the MY 2011-2015 CAFE standards under the six

[1] Although NHTSA will set CAFE standards for MY 2016-2020 in a future rulemaking action, NHTSA's National Environmental Policy Act analysis makes assumptions about the MY 2016-2020 standards based on the MY 2011-2015 standards and the EISA requirements.

action alternatives. NHTSA cannot predict which specific technologies manufacturers would apply to meet the CAFE standards under any of the six action alternatives; however, existing technologies and existing vehicle production facilities can be applied to meet the standards under the six action alternatives. Some vehicle manufacturers might need to commit additional resources to existing, redeveloped, or new production facilities to meet the CAFE standards. Such short-term uses of resources by vehicle manufacturers to meet the CAFE standards would enable the long-term reduction of national energy consumption and would enhance long-term national productivity.

6.3 IRREVERSIBLE AND IRRETRIEVABLE COMMITMENTS OF RESOURCES UNDER THE ACTION ALTERNATIVES

Energy consumption in the United States would decrease under all the action alternatives compared to the No Action Alternative. Tables 3.2-2 and 3.2-3 (*see* Section 3.2 of this FEIS) summarize fuel consumption for the Reference Case under each alternative for passenger cars and light trucks, respectively, and Tables 3.2-4 and 3.2-5 summarize fuel consumption for the High Scenario under each alternative for passenger cars and light trucks, respectively. For the Optimized Alternative (Alternative 3) the Reference Case fuel savings[2] over the No Action Alternative in 2060 would be 4.3 billion gallons for passenger cars and another 4.3 billion gallons for light trucks. The Optimized Alternative High Scenario fuel savings over the No Action Alternative in 2060 would be 9.6 billion gallons for passenger cars and 11.0 billion gallons for light trucks.

As discussed in Section 6.2, manufacturers would need to apply various technologies to the production of passenger cars and light trucks to meet the MY 2011-2015 CAFE standards under the six action alternatives. NHTSA cannot predict which specific technologies manufacturers would apply to meet the CAFE standards under any of the six action alternatives. Existing technologies and existing vehicle production facilities can be applied to meet the CAFE standards under the six action alternatives. However, some vehicle manufacturers might need to commit additional resources to existing, redeveloped, or new production facilities to meet the standards. The specific amounts and types of irretrievable resources (such as electricity and other energy consumption) manufacturers would expend in meeting the CAFE standards would depend on the specific methods and technologies manufacturers choose to implement. Commitment of resources for manufacturers to comply with the CAFE standards would tend to be offset by the fuel savings from implementing the standards.

[2] Fuel savings are expressed as the sum of the number of gallons of diesel fuel and gasoline without adjustment for the energy content per gallon of each fuel.

Chapter 7 Preparers

7.1 NATIONAL HIGHWAY TRAFFIC SAFETY ADMINISTRATION

Name	Qualifications/Experience
PREPARERS	
Michael J. Savonis (Project Manager)	
	M.R.P., Cornell University; B.S., Chemistry, State University of New York – Buffalo
	25 years of experience in transportation policy, with extensive expertise in air quality and emerging environmental issues
Carol Hammel-Smith (Project Manager)	
	M.P.A., Environmental Management and Policy, University of Colorado; B.A., Political Science, University of Colorado
	20 years of experience in environmental impact assessment
Sarah Alves	
	J.D., Boston University School of Law; B.A., Astronomy and Physics, Boston University
	1 year of legal experience; 2 years of experience in macroeconomic analysis
Brigid Decoursey	
	B.S., Biochemistry; B.S., Environmental Policy, The University of Tulsa
	3 years of experience in transportation-sector environmental-policy analysis
Kevin Green	
	M. Eng., Applied & Engineering Physics; B.S., Applied & Engineering Physics, Cornell University
	17 years of experience in vehicle emissions analysis and regulation
Michael M. Johnsen	
	M.S., Environmental Science and Policy, Johns Hopkins University; B.S., Natural Resource Management, University of Maryland
	20 years experience in the environmental field; extensive experience in NEPA and climate change
Don H. Pickrell	
	Ph.D., Urban Planning, M.A., Urban Planning, University of California, Los Angeles; B.A. (with high honors), Economics and Mathematics, University of California, San Diego
	30 years of experience in applied transportation economics, including 15 years of experience in analysis of environmental impacts of transportation activity

Name	Qualifications/Experience
PREPARERS (cont'd)	
Kerry E. Rodgers	
	J.D., New York University School of Law; M.E.S., Environmental Studies, Yale University School of Forestry & Environmental Studies; A.B., Biology, Brown University
	12 years of experience in environmental law
Henrietta Spinner	
	D.B.A., California Coast University; M.B.A., Howard University; B.S., Virginia State University
	19 years of fuel-economy and regulatory experience; 10 years of budgeting and quantitative analysis experience
Mark Talty	
	J.D. Candidate, University of Baltimore School of Law; B.S., Political Science, Northeastern University
	1 year of legal experience
Kevin Wang	
	J.D. Candidate, University of Maryland School of Law; B.S. Civil Engineering, University of California, Davis
	2 years of experience in structural, hydraulic, and environmental engineering; less than 1 year of legal experience
Jessica G. Wilson	
	J.D., College of William & Mary; B.A., International Affairs, James Madison University
	4 years of legal experience
REVIEWERS	
Julie Abraham, Director, Office of International Policy, Fuel Economy and Consumer Programs	
	M.S., Bioengineering, University of Michigan; M.S., Electrical Engineering, Wayne State University
	16 years of experience in domestic and international vehicle safety and fuel economy rulemaking
John Donaldson	
	J.D., Boston College Law School; B.A., Economics, Cornell University
	24 years of experience in vehicle safety issues, including environmental impact assessments
Helen L. Serassio	
	J.D., S.J. Quinney College of Law, University of Utah; B.S., Political Science, University of Utah
	8 years of legal experience in NEPA and environmental issues

Name	Qualifications/Experience
REVIEWERS (cont'd)	
Stephen P. Wood	
	J.D., Columbia Law School; B.A., Political Science, Williams College
	39 years of experience in vehicle safety rulemaking and 33 years in fuel economy rulemaking

7.2 CONSULTANT TEAM

ICF International supported the National Highway Traffic Safety Administration (NHTSA) in conducting its environmental analysis and preparing this Environmental Impact Statement.

Name/Role	Qualifications/Experience
PROJECT MANAGEMENT	
Alan Summerville, Officer in Charge	
	M.A., City Planning, University of Pennsylvania; B.A., Economics and Political Science, University of Vermont.
	18 years of experience participating in and managing the preparation of NEPA documents
Michael Smith, Project Manager	
	Ph.D., Sociology, Utah State University; M.A., Geography, University of Wyoming; B.A., Environmental Studies (Honors), University of California
	15 years of experience in environmental impact assessment
Karen Fadely, Deputy Project Manager	
	M.E.M., Conservation Science and Policy, Duke University; B.S., Biology, Bucknell University
	8 years of environmental experience; 3 years participating in and managing the preparation of NEPA documents
TECHNICAL AND OTHER EXPERTISE (alphabetically)	
Linda Amato, AICP, Document Review Lead	
	M.U.R.P., Community Planning & Design, The George Washington University; B.A., Art History, State University of New York – Stony Brook; Certificate, Technical Writing & Communication, Bellevue Community College
	23 years of experience in managing and preparing environmental documentation
Jeffrey Ang-Olson, Senior Technical Air Quality Advisor	
	M.C.P., City Planning, M.S., Transportation Engineering, University of California – Berkeley; B.S., Electrical Engineering, Rice University
	12 years of experience analyzing the air quality impacts of transportation programs, plans, and projects

Name/Role	Qualifications/Experience
TECHNICAL AND OTHER EXPERTISE (alphabetically) (cont'd)	
Nicholas Baker, Comment Analyst	
	M.E.M., Conservation Science and Policy, Duke University; B.S., Wildlife Biology, Colorado State University
	1 year of experience in preparing NEPA documents
Leiran Biton, Air Quality Analyst	
	M.S., Environmental Science, University of North Carolina, Chapel Hill; B.A., Environmental Science & Policy and Theater Arts, Clark University
	2 years of experience in environmental analysis
Brent Bouldin, Editor	
	M.A., Communications, Louisiana State University – Baton Rouge; B.S., Communications, University of Texas – Austin
	30 years of experience in managing document publications, including environmental impact statements and resource management plans
Adam Brundage, Climate Change Modeling Analyst	
	M.E.M., Environmental Management, Duke University; B.S., Atmospheric Science, McGill University
	3 years of experience assessing and analyzing climate change issues
David Burch, Human Health Analyst	
	M.E.M., Environmental Chemistry and Toxicology; B.S., Chemistry, Duke University
	13 years of professional experience in human-health risk and exposure assessment and environmental chemistry and toxicology, including 3 years of related experience assisting with preparation of NEPA documents.
Edward Carr, Air Quality Analyst	
	M.S., Atmospheric Science, University of Washington – Seattle; B.S., Chemistry, Duke University
	14 years of experience in assessing mobile source air toxic emissions
Jenny Chen, Energy Analyst	
	M.A., Urban Planning and Policy, University of Southern California; B.A., Economics (Summa Cum Laude), University of California, Irvine
	2 years of experience in researching fuels and technology for NEPA documents
Laura Cooper, Editor	
	B.A., Psychology, Reed College
	18 years of experience writing and editing technical documents; 3 years of experience managing publications processes and teams

Name/Role	Qualifications/Experience
TECHNICAL AND OTHER EXPERTISE (alphabetically) (cont'd)	
Charlotte Coultrap-Bagg, Climate Change Analyst	
	B.A., Environmental Studies, with honors, Dartmouth College
	4 years of experience in assessing the impacts of climate change
Elizabeth Dederick, Human Health Analyst	
	Ph.D., Environmental Health Policy, M.H.S., Environmental Health Sciences, Johns Hopkins Bloomberg School of Public Health; M.A., Ethics, Union Theological Seminary; B.A. Renaissance Studies, Davidson College
	5 years of experience analyzing human environmental health effects with emphasis on chemical exposure and risk assessment
David Ernst, Team Leader, Air Quality	
	B.C.R.P., Environmental Policy, Harvard University; B.S., Urban Systems Engineering; B.A., Ethics and Politics, Brown University
	28 years of experience preparing air quality analysis for NEPA documents
Cristiano Facanha, Safety Analyst	
	Ph.D., Civil and Environmental Engineering; M.S., Transportation Engineering, University of California, Berkeley; M.S., Management of Transportation, Chalmers University of Technology, Gothenburg, Sweden; B.S., Industrial Engineering, Federal University of Rio de Janeiro, Brazil
	5 years in transportation analysis.
Mark Flugge, Climate Change Analyst	
	Ph.D., Atmospheric Chemistry; M.C., Chemistry, University of Oxford, United Kingdom
	10 years of experience analyzing atmospheric chemistry, greenhouse-gas, and climate-change issues
Randall J. Freed, Senior Technical Climate Change Advisor	
	M.S., Water Resource Management; B.S., Zoology, University of Maryland – College Park
	33 years experience in assessing and managing environmental risk; 14 years of experience assessing climate-change issues
Frank Gallivan, Air Quality Analyst	
	Master of City Planning, University of California, Berkeley; B.A., Economics/Classical Archaeology, Dartmouth College
	2 years of experience preparing economic and environmental analyses for NEPA documents
Ralph Grismala, P.E., Quality Control	
	M.S., Civil Engineering, B.S., Civil Engineering, Massachusetts Institute of Technology
	30 years of experience in geothermal and environmental impact analyses

Name/Role	Qualifications/Experience
TECHNICAL AND OTHER EXPERTISE (alphabetically) (cont'd)	
Philip Groth, Climate Change Analyst	
	Master of Planning, University of Southern California – Los Angeles; B.A., Anthropology, Williams College
	4 years of experience in climate change analysis
Steven Hackett, Land Use Analyst	
	Ph.D., Economics, M.S., Economics, Texas A&M University; B.S., Agricultural Business/Economics, Montana State University
	19 years of experience analyzing economic impacts
John Hansel, Senior NEPA Advisor	
	J.D., Cum Laude, American University; B.A., Economics, University of Wisconsin – Madison
	30 years of experience managing the preparation of NEPA documents
Melinda Harris, Lead, Climate Change Cumulative Impacts Analysis	
	M.A., Economics; B.A., Economics, University of Maryland
	20 years of experience analyzing economics and environmental policy analysis, including 12 years in assessing climate change impacts
William Hartley, Air Quality Analyst	
	M.S., Atmospheric Sciences, University of Washington – Seattle; B.S., Physics North Carolina State University
	10 years of experience in air quality analysis
Joseph Herr, Climate Change Analyst	
	B.S., Natural Resources, B.S., Business Administration, University of Vermont – Burlington
	3 years of experience in air quality analysis
David Johnson, Coastal Analyst	
	B.S., Biology, Minors in Geology and Chemistry, University of Minnesota – Twin Cities
	9 years of experience assessing aquatic resources; resource inventory and classification; impact assessment; permitting assistance; regulatory compliance
Penelope Kellar, Technical Editor	
	M.S., Ecology, University of California – Davis; B.S., Conservation of Natural Resources, University of California – Berkeley
	25 years of experience in environmental science writing and editing, with extensive expertise in communication environmental assessments and 2 years in NEPA document preparation

Name/Role	Qualifications/Experience
TECHNICAL AND OTHER EXPERTISE (alphabetically) (cont'd)	
Whitney Kihlstrom, Research Assistant	
	B.S., Environmental Science, University of North Carolina – Chapel Hill
	1 year of experience assisting with NEPA document production
Robert Lanza, P.E., QA/QC Lead	
	M. Eng., Chemical Engineering, B.S., Chemical Engineering, Cornell University
	20 years of experience in preparing and reviewing NEPA documents
Andrew Leung, Energy Analyst	
	B.S., Economics, Carnegie Mellon University
	2 years of experience in energy analysis
Brian Lutenegger, Safety Analyst	
	Master of Urban Planning, University of Michigan; B.S., Sociology & Political Science, University of Wisconsin – Madison
	1 year of experience in the preparation of NEPA documents
Amalia Marenberg, Climate Change Analyst	
	B.S., Environmental Science, University of Maine – Farmington
	1 year of experience assisting in NEPA document preparation
Suzanne Martos, Research Assistant	
	B.S., Science of Earth Systems: Biogeochemistry, B.S., Biology, Cornell University
	1 year of experience assisting in NEPA document preparation
Stacy McDowell, Document Coordinator	
	B.S., Environmental Studies, Portland State University
	6 years of experience in project coordination, publication development, and production
William Mendez, Jr., QA/QC Analyst	
	Masters, Public Policy Program, John F. Kennedy School of Government, Harvard University, Ph.D., Biochemistry, University of Chicago, B.S., Natural Sciences, Colgate University
	29 years of experience in assessing human-health risks
Rawlings Miller, Human Health Analyst	
	Ph.D., Atmospheric Sciences, University of Arizona; M.S., Aerospace Engineering, Boston University; B.S., Physics, Union College
	5 years of experience modeling the impacts of climate issues

Name/Role	Qualifications/Experience
TECHNICAL AND OTHER EXPERTISE (alphabetically) (cont'd)	
Christopher Moelter, Terrestrial Analyst	
	M.E.M., Environmental Tourism, University of Queensland, B.S., Zoology, University of Wisconsin – Madison
	5 years of consulting on environmental issues; 1 year of experience in preparing NEPA documents
Danielle Monteverde, Research Assistant	
	B.S., Environmental Studies, Bucknell University
	1 year of experience assisting in NEPA document production
Deborah Munkburg, Land-Use Analyst	
	M.Plan., University of Minnesota, Humphrey Institute of Public Affairs; BA, Urban Planning, 1980, University of Washington, College of Architecture and Urban Planning
	20 years of experience in land-use analyses and NEPA documentation
Rick Nevin, Alternatives Analyst	
	M.M., Concentration in Finance, Managerial Economics, and Strategy, J.L. Kellogg Graduate School of Management, Northwestern University; M.A., Economics, Boston University; B.A., Economics and Mathematics, Boston University
	25 years of experience managing and preparing environmental, energy, and economic analyses
Andrew Papson, Air Quality Analyst	
	M. Eng., Transportation Engineering, University of California – Berkeley; B.S., Materials Science, Stanford University
	2 years of experience analyzing vehicle emissions and fuel efficiency
Melissa Pauley, Freshwater Analyst, Comment Analyst	
	M.S., Environmental Science and Management, Duquesne University; B.S., Environmental Studies, Bucknell University
	4 years of consulting on environmental issues; 1 year of experience in preparing NEPA documents
Bill Pepper, Climate Change Team Leader	
	M.A., Mathematics, Temple University; B.S., Mathematics, University of Maryland
	20 years of experience modeling and evaluating climate change issues
Annah Peterson, Comment Analyst	
	M.E.M., Environmental Economics and Policy, Duke University; B.A., Biology, Reed College
	1 year of experience preparing NEPA documents

Name/Role	Qualifications/Experience
TECHNICAL AND OTHER EXPERTISE (alphabetically) (cont'd)	
Marybeth Riley, Terrestrial Analyst	
	M.S., Atmospheric Science, Cornell University; B.S., Geology, University of New Mexico
	3 years of experience in climate change analysis
Kathleen Rooney, Transportation Analyst	
	M.P.P., Environmental Policy, University of Maryland – College Park; B.A., Political Science, Tulane University.
	5 years of analyzing environmental and transportation policies, planning, and programs
Arlene Rosenbaum, Technical Director	
	M.P.H. Environmental Health Planning, University of Michigan; M.S. Engineering-Economic Systems, Stanford University; B.S. Chemistry, University of Michigan
	25 years of experience in environmental health analysis, population exposure assessment for air pollutants
Zeta Rosenberg, Energy Analyst	
	M.A., Economics, George Washington University, Ph.D (less dissertation) History; B.A. and M.A., History, with Honors, University of Toronto, Canada
	3 years of experience in energy analysis
Karen Savage, Transportation Analyst	
	M.A., Public Systems Planning, Transportation, University of California – Los Angeles; B.A., Urban Planning, University of Washington
	30 years of experience analyzing environmental impacts of transportation programs and planning
Liz Schoeneck, Human-Health Analyst	
	B.S., Public Health, Environmental Sciences and Engineering, University of North Carolina – Chapel Hill
	5 years of experience with a focus on exposure assessment and risk assessment
Andy Shapiro, Human-Health Analyst	
	B.S., Public Health, Environmental Health Science, University of North Carolina – Chapel Hill
	1 year of experience analyzing human-health impacts
Judith Shipman, Technical Editor	
	A.A., General Studies, University of South Carolina – Aiken
	30 years of experience in NEPA document preparation, including technical writing and editing, document production support; document production coordination

Name/Role	Qualifications/Experience
TECHNICAL AND OTHER EXPERTISE (alphabetically) (cont'd)	
Jennifer Singer, Terrestrial Analyst	
	M.A., Urban and Environmental Policy and Planning, Tufts University; B.A., Politics, Honors, Brandeis University
	4 years of experience analyzing ecosystem impacts
Allison Stork, Comment Analyst	
	M.S., Geography, University of Tennessee – Knoxville; B.A. Geography; B.A. English, State University of New York – Geneseo
	1 year of experience in preparing NEPA documents
Fran Sussman, Climate Change Cumulative Impacts Analysis Lead	
	Ph.D., Economics; M.A., Economics, University of Maryland; B.A., Economics, State University of New York – Stony Brook
	20 years of experience in climate change analysis
Audrey Turley, Human Health Analyst	
	M.S., Mechanical Engineering, North Carolina State University; B.A. Mathematics, Texas A&M University
	2 years of experience analyzing toxicological effects of inhaled particulate matter and executing models to calculate human exposure and risk based on air quality data
John Venezia, Climate Change and Economics Analyst	
	M.S., Environmental Science and Policy, Johns Hopkins University; B.S., Biology and Environmental Science & Policy, Duke University
	10 years of experience analyzing the technical and economic aspects of global climate change issues
Nate Wagoner, Other Environmental Impacts Analyst, Comment Lead	
	M.S., Human Dimensions of Ecosystem Science and Management, Utah State University; B.S., Natural Resources Integrated Policy and Planning, Ohio State University
	5 years of experience in environmental impact analysis

Chapter 9 Distribution List

National Environmental Policy Act implementing regulations (40 Code of Federal Regulations 1501.19) specify requirements for circulating an Environmental Impact Statement (EIS). In accordance with those requirements, the National Highway Transportation Safety Administration is mailing this Final EIS to the agencies, officials, and other interested persons listed in this chapter.

9.1 FEDERAL AGENCIES

- Advisory Council on Historic Preservation
- Centers for Disease Control and Prevention
- Council on Environmental Quality
- Delaware River Basin Commission
- Denali Commission
- Environmental Protection Agency
- International Boundary and Water Commission, Environmental Management Division
- Marine Mammal Commission
- National Capital Planning Commission, Office of Urban Design and Plan Review
- National Oceanic and Atmospheric Administration
- National Park Service
- National Science Foundation, Office of General Counsel
- Office of Science and Technology Policy, National Science and Technology Council
- Presidio Trust
- Susquehanna River Basin Commission
- Tennessee Valley Authority
- U.S. Agency for International Development, Bureau for Economic Growth, Agriculture and Trade
- U.S. Department of Agriculture, Agricultural Research Service
- U.S. Department of Agriculture, Animal and Plant health Inspection Service
- U.S. Department of Agriculture, Cooperative State Research, Education and Extension Service
- U.S. Department of Agriculture, Farm Service Agency
- U.S. Department of Agriculture, Natural Resources Conservation Service
- U.S. Department of Agriculture, Rural Business-Cooperative Service
- U.S. Department of Agriculture, Rural Housing Service
- U.S. Department of Agriculture, Rural Utilities Service
- U.S. Department of Agriculture, U.S. Forest Service
- U.S. Department of Commerce, National Oceanic and Atmospheric Administration
- U.S. Department of Commerce, Economic Development Administration
- U.S. Department of Commerce, National Marine Fisheries Service
- U.S. Department of Defense
- U.S. Department of Defense, Army Corps of Engineers
- U.S. Department of Energy, Office of NEPA Policy and Compliance
- U.S. Department of Energy, Office of Climate Change Policy
- U.S. Department of Health and Human Services, Office of the Secretary
- U.S. Department of Health and Human Services, Centers for Disease Control and Prevention
- U.S. Department of Health and Human Services, Food and Drug Administration (FDA)
- U.S. Department of Health and Human Services, FDA, Center for Food Safety and Applied Nutrition

- U.S. Department of Health and Human Services, Health Resources and Services Administration
- U.S. Department of Health and Human Services, Indian Health Service
- U.S. Department of Health and Human Services, National Institutes of Health
- U.S. Department of Homeland Security, Office of Safety and Environment
- U.S. Department of Homeland Security, Federal Emergency Management Agency
- U.S. Department of Homeland Security, U.S. Coast Guard
- U.S. Department of Housing and Urban Development
- U.S. Department of Interior, Office of Environmental Policy and Compliance
- U.S. Department of Justice, Environment and Natural Resources Division
- U.S. Department of Labor, Mine Safety and Health Administration
- U.S. Department of Labor, Occupational Safety and Health Administration
- U.S. Department of State, Bureau of Oceans and International Environmental and Scientific Affairs
- U.S. Department of Transportation, Secretary for Policy
- U.S. Department of Transportation, Federal Aviation Administration
- U.S. Department of Transportation, Federal Highway Administration
- U.S. Department of Transportation, Federal Motor Carrier Safety Administration
- U.S. Department of Transportation, Federal Railroad Administration
- U.S. Department of Transportation, Maritime Administration
- U.S. Department of Transportation, Federal Transit Administration
- U.S. Department of Transportation, Pipeline and Hazardous Materials Safety Administration
- U.S. Department of Transportation, Research and Innovative Technology Administration
- U.S. Department of Transportation, Saint Lawrence Seaway Development Corporation
- U.S. Department of Transportation, Surface Transportation Board
- U.S. Environmental Protection Agency, Office of Federal Activities
- U.S. Environmental Protection Agency, NEPA Compliance Division
- U.S. Federal Energy Regulatory Commission, Office of Energy Projects
- U.S. Federal Energy Regulatory Commission, Division of Hydropower, Environment and Engineering
- U.S. Federal Energy Regulatory Commission, Division of Gas – Environmental and Engineering
- U.S. Federal Transit Administration
- U.S. Fish and Wildlife Service
- U.S. Forest Service
- U.S. Institute for Environmental Conflict Resolution
- Valles Caldera Trust

9.2 STATE AGENCIES

- Alabama Department of Environmental Management
- California Office of Attorney General
- Connecticut Office of Attorney General
- Florida Department of Environmental Protection
- Florida Department of Transportation
- Florida Energy Office
- Hawaii Department of Transportation
- Maryland Department of the Environment
- Maryland Historical Trust
- Massachusetts Office of Attorney General
- Minnesota Pollution Control Agency

- Missouri Department of Natural Resources
- Montana Department of Transportation
- New Jersey Department of Environmental Protection
- New Jersey Office of Attorney General
- New Mexico Department of Attorney General
- New York City Corporation Council
- New York State Department of Transportation
- New York State Environmental Law Division
- New York State Office of Attorney General
- Nevada Department of Transportation
- Nevada Division of Environmental Protection
- Oregon Department of Attorney General
- Oregon Department of Environmental Quality
- Pennsylvania Department of Environmental Protection
- Rhode Island Department of Attorney General
- Rhode Island Department of Environmental Management
- South Carolina Department of Transportation
- South Dakota Department of Environmental & Natural Resources
- Tennessee Department of Transportation
- Vermont Agency of Natural Resources
- Vermont Office of Attorney General
- Washington State Department of Ecology
- Washington State Department of Transportation

9.3 ELECTED OFFICIALS

- The Honorable Sarah Palin, Governor of Alaska
- The Honorable Togiola T.A. Tulafono, Governor of American Samoa
- The Honorable Janet Napolitano, Governor of Arizona
- The Honorable Mike Beebe, Governor of Arkansas
- The Honorable Bill Ritter, Governor of Colorado
- The Honorable Ruth Ann Minner, Governor of Delaware
- The Honorable Sonny Perdue, Governor of Georgia
- The Honorable Felix P. Camacho, Governor of Guam
- The Honorable C.L. “Butch” Otter, Governor of Idaho
- The Honorable Rod R. Blagojevich, Governor of Illinois
- The Honorable Mitchell E. Daniels, Governor of Indiana
- The Honorable Chet Culver, Governor of Iowa
- The Honorable Kathleen Sebelius, Governor of Kansas
- The Honorable Steve Beshear, Governor of Kentucky
- The Honorable Bobby Jindal, Governor of Louisiana
- The Honorable John E. Baldacci, Governor of Maine
- The Honorable Martin O’Malley, Governor of Maryland
- The Honorable Jennifer M. Granholm, Governor of Michigan
- The Honorable Tim Pawlenty, Governor of Minnesota
- The Honorable Haley Barbour, Governor of Mississippi
- The Honorable Dave Heineman, Governor of Nebraska
- The Honorable John Lynch, Governor of New Hampshire
- The Honorable Bill Richardson, Governor of New Mexico
- The Honorable Michael F. Easley, Governor of North Carolina
- The Honorable John Hoeven, Governor of North Dakota

- The Honorable Benigno R. Fitial, Governor of the Commonwealth of the Northern Mariana Islands
- The Honorable Ted Strickland, Governor of Ohio
- The Honorable Brad Henry, Governor of Oklahoma
- The Honorable Edward G. Rendell, Governor of Pennsylvania
- The Honorable Aníbal Acevedo-Vilá, Governor of Puerto Rico
- The Honorable Rick Perry, Governor of Texas
- The Honorable Jon Huntsman, Jr., Governor of Utah
- The Honorable John P. deJongh, Jr., Governor of the United States Virgin Islands
- The Honorable Timothy M. Kaine, Governor of Virginia
- The Honorable Joe Manchin III, Governor of West Virginia
- The Honorable Jim Doyle, Governor of Wisconsin
- The Honorable Dave Freudenthal, Governor of Wyoming

9.4 NATIVE AMERICAN TRIBES

- Atmautlauk Traditional Council
- Big Pine Paiute Tribe of the Owens Valley
- Bois Forte Band of Chippewa
- Buckland Fuel Project
- Chalkyitsik Village Council
- Chickasaw Nation
- Enterprise Rancheria
- Flandreau Santee Sioux Tribe
- Fond du Lac Reservation
- Goshute Business Council
- Greenville Rancheria
- Holy Cross Village
- Jena Band of Choctaw Indians
- Kaibab Paiute Tribe
- Kokhanok Village Council
- Leech Lake Band Ojibwe
- Leisnoi Village aka Woody Island Tribal Council
- Lime Village Traditional
- Louden Tribal Council
- Miami Tribe of Oklahoma
- Mille Lacs Band of Ojibwe
- Minto Village Council
- Modoc Tribe
- Native Village of Atka
- Native Village of Buckland
- Native Village of Savoonga
- Native Village of Wales
- Nightmate Traditional Council
- Pinoleville Domo Nation
- Pueblo de San Illdefonso
- Red Cliff Tribe
- Skagway Traditional Council
- Swinomish Indian Tribal Community
- Tatitlek Village IRA Council

- Wiyot Tribe
- Yakutat Tlingit Tribe

9.5 COUNTY/LOCAL GOVERNMENTS

- Knox County, TN Department of Air Quality Management
- City of New York Environmental Law Division

9.6 STAKEHOLDERS

- Akiak EPA IGAP
- AkPIRG
- Alina Fortson
- Alliance of Automobile Manufacturers
- Allison Forbes
- American Association of Blacks in Energy
- American Council for an Energy-Efficient Economy
- American International Automobile Dealers Association
- American Jewish Committee
- Annie Chau
- Arizona Consumers Council
- Arizona PIRG
- BG Automotive Group, Ltd.
- BMW (US) Holding Corp.
- California Air Pollution Control Officers Association
- CALPIRG
- Carl Henne
- Caroline Keicher
- Catherine Easton
- Center for Biological Diversity
- Ceribon
- Charles C. Yoder
- Christina Marie Yagjian
- Chrysler, LLC
- Citizens' Utility Board of Oregon
- Columban Justice, Peace and Integrity of Creation Office (USA)
- Conservation Law Foundation
- Consumer Action
- Consumer Assistance Council of Cape Cod
- Consumer Federation of America
- Consumer Federation of the Southeast
- Consumers for Auto Reliability and Safety
- Consumers Union
- Daimler
- Dale Olson
- Democratic Process Center
- Doug Molof
- Eliza Berry
- Elizabeth R. McGurk
- Emanuel Figueroa
- Emily Spear

- Empire State Consumer Association
- Environment America
- Environmental Council of the States
- Environmental Defense Fund
- Evangelical Lutheran Church in America
- Florida Consumer Action Network
- Florida PIRG
- Ford Motor Co.
- Fred Dobb
- Fred Marshall
- Fred T. Teal, Jr.
- Friends Committee on National Legislation
- Fuji Heavy Industries USA/Subaru
- General Motors Corporation
- Gibson, Dunn & Crutcher LLP
- Greater Washington Interfaith Power and Light
- Heather Moyer
- Illinois PIRG
- Insurance Institute for Highway Safety
- Jaafar Rizvi
- James Adcock
- James Farrelly
- Jazzlin Allen
- Jewish Community Relations Council of Greater Washington
- Jewish Council of Public Affairs
- Jim Derzon
- Jim Pierobon
- Joan Claybrook
- John Schieber
- Joseph Frewer
- Julie Locascio
- Kirkland & Ellis LLP
- Lake Michigan Air Directors Consortium
- Lake Michigan Air Directors Consortium
- Lee Auto Malls
- Marissa Knodel
- Mary Hamilton
- Maryknoll Office of Global Concerns
- Maryland Consumer Rights Coalition
- Maryland PIRG
- Massachusetts Consumers Council
- Matt Dernoga
- Matt Kirby
- Matthew Du Pont
- Michael A. Kirchner
- Mike Koerber
- Nancy Miller
- National Automobile Dealers Association
- National Council of Churches USA
- National Tribal Environmental Council
- Natural Resources Canada

- Natural Resources Defense Council
- New Jersey Citizen Action
- New Mexico PIRG
- Nissan North America, Inc.
- Northeast States for Coordinated Air Use Management
- NYPIRG
- Pamela Woodward
- Peggy Gilges
- Presbyterian Church (USA) Washington Office
- Public Citizen
- Robert Burchard
- Robert Dawes
- Sam Blodgett
- Sarah Karlin
- Sarah Larsen
- Sierra Club
- The Consumer Alliance
- The Episcopal Church
- The United Methodist Church General Board of Church and Society
- Union for Reform Judaism
- Union of Concerned Scientists
- United Church of Christ
- United Church of Christ Justice and Witness Ministries
- University of Colorado School of Law
- US Public Interest Research Group
- Utility Consumers Action Network
- Vice Admiral Dennis McGinn, USN, Retired
- Victims Committee for Recall of Defective Vehicles
- Virginia Citizens Consumer Council
- Volkswagen Group of American
- VPIRG
- Western Regional Air Partnership
- Wisconsin Consumers League
- Yuli & Susan Chew

Chapter 10 Responses to Public Comments

On June 26, 2008, the National Highway Traffic Safety Administration (NHTSA) submitted to the U.S. Environmental Protection Agency (EPA) a draft Environmental Impact Statement (DEIS) to disclose and analyze the potential environmental impacts of the new Corporate Average Fuel Economy (CAFE) standards for MY 2011-2015 and reasonable alternative standards in the context of NHTSA's CAFE Program pursuant to National Environmental Policy Act (NEPA) implementing regulations issued by Council of Environmental Quality (CEQ), U.S. Department of Transportation (DOT) Order 5610.1C, and NHTSA regulations. On July 2, 2008, NHTSA published a *Federal Register* Notice of Availability of its DEIS. NHTSA's Notice of Availability also made public the date and location of a public hearing, and invited the public to participate at the hearing on August 4, 2008, in Washington, DC. On July 3, 2008, the EPA issued its Notice of Availability of the DEIS, triggering the 45-day public comment period. In accordance with CEQ NEPA implementing regulations, the public was invited to submit written comments on the DEIS until August 18, 2008.

NHTSA mailed approximately 200 copies of the DEIS to interested parties, including federal, state, and local officials and agencies; elected officials, environmental and public interest groups; Native American tribes; and other interested individuals, as listed in Chapter 9 of the DEIS. NHTSA held a public hearing on the DEIS at the National Transportation Safety Board Conference Center in Washington, DC, on August 4, 2008.

NHTSA received 66 written comments from interested stakeholders, including the EPA, the Centers for Disease Control (CDC), state and local agencies, elected officials, automobile trade associations, organizations, and individuals. In addition, NHTSA received one petition with 10,540 signatures expressing support for more stringent CAFE standards and the use of higher gas prices in the Volpe model. *See* Document ID No. NHTSA-2008-0060-0599.1. During the public comment hearing in Washington, DC, 44 people provided oral statements. In this chapter of the final Environmental Impact Statement (FEIS), NHTSA has quoted excerpts from and responded to the comments received.

NHTSA considered and evaluated all written and oral comments received during the public comment period in the preparation of this FEIS. NHTSA changed the EIS, in part, to respond to comments on the DEIS. We also changed the EIS as a result of updated information that became available after issuance of the DEIS.

We appreciate the comments provided during development of the EIS. The transcript from the public hearing and written comments submitted to NHTSA are part of the administrative record, and are available on the Federal Docket, which can be found on the Web at http://www.regulations.gov, Reference Docket No. NHTSA-2008-0060. Written comments and the public hearing transcript can also be viewed in their entirety in Appendix D of this FEIS. Sections 10.1 through 10.4 provide comments on the DEIS and NHTSA's responses to those comments. Table 10-1 lists the topics addressed in this chapter. Table 10-2 is an index of the comments from individuals, federal and state agencies, and private industry and the location in this chapter of NHTSA's responses to those comments.

Table 10-1

Outline of Issues Raised in Public Comments on the DEIS

10.1	**PURPOSE AND NEED**
10.1.1	NEPA Process
10.1.2	Timing of NEPA Process/Public Participation
10.1.3	Document Structure/Readability
10.1.4	NHTSA's Decision to Prepare an EIS
10.1.5	Functional Equivalence Doctrine
10.1.6	Transboundary Effects
10.2	**PROPOSED ACTION AND ALTERNATIVES**
10.2.1	General Context Comments
10.2.1.1	Clarifying Comparative Reduction Plans
10.2.1.2	Effects on Other Countries' Standards
10.2.2	Volpe Model
10.2.2.1	Fuel Price Assumptions
10.2.2.2	Rebound Effect
10.2.2.3	Social Cost of Carbon
10.2.2.4	Technologies/Vehicle Attributes Considered
10.2.2.5	Fleet Turnover
10.2.2.6	Consumer Demand/Behavior
10.2.2.7	Fleet Composition Assumption
10.2.2.8	Discount Rate
10.2.2.9	Creation of a Backstop
10.2.2.10	Military/National Security
10.2.3	Alternatives
10.2.3.1	Reasonable Range of Alternatives
10.2.3.2	Different Economic Inputs to Volpe Model
10.2.3.3	Alternative 1 (No Action)
10.2.3.4	Alternative 3 (Optimized Scenario)
10.2.3.5	Alternative 6 (Total Costs Equal Total Benefits)
10.2.3.6	Alternative 7 (Technology Exhaustion)
10.2.3.7	New Alternatives
10.2.3.8	Alternatives Relationship to Maximum Feasible Fuel Economy Standards
10.2.3.9	The Need of the United States to Conserve Energy
10.2.3.10	More Aggressive Alternative
10.3	**AFFECTED ENVIRONMENT AND ENVIRONMENTAL CONSEQUENCES**
10.3.1	Introduction
10.3.1.1	Approach to Scientific Uncertainty and Incomplete Information
10.3.1.2	Modeling After 2020
10.3.2	Air Quality
10.3.2.1	Affected Environment
10.3.2.2	Methodology
10.3.2.3	Consequences
10.3.2.4	Health
10.3.3	Climate
10.3.3.1	Methodology
10.3.3.2	MAGICC Model
10.3.3.3	IPCC Scenarios
10.3.3.4	Non-CO2 GHGs
10.3.3.5	Consequences
10.3.3.6	Sea-Level Rise

10.1 PURPOSE AND NEED

Comments

Comment Number: 0554-10
Organization: Individual
Commenter: James Adcock

Given the uncertainty in future gas prices, as evidenced by the disparity between the EIA [Energy Information Administration] values NHTSA [National Highway Transportation Safety Administration] has used vs. recent gas prices, and recent large decreases in the estimated GHG [greenhouse gas] concentrations necessary to reach tipping point [http://www.columbia.edu/~jehl] NHTSA should reduce the numbers of years its proposed regulations extend forward. The farther one projects into the future, the greater the error in these projections. Given the rapid changes in our understanding of Global Warming and GHG, and the rapid changes in gas prices, it would be rational to extend the regulations forward for fewer years, allowing NHTSA to respond more appropriately once better understanding of these issues have been reached.

Comment Number: 0564-15
Organization: Consumer Federation of America
Commenter: Mark Cooper

Throughout its analysis, NHTSA indicates that certain assumptions were made with incomplete data and without critically important information about the auto market. Nevertheless, for no apparent reason, NHTSA set this low standard for the maximum period allowable under the law. NHTSA excuses the failure to obtain complete and accurate data for its assumptions with a claim that it must promulgate a standard for model year 2011 by mid-2009 in order to give automakers proper advanced notice. While that is correct, there was no need to rush to promulgate standards for later model years, certainly not 2013 through 2015. With numerous important issues still under study, it was incredibly irresponsible for NHTSA to write rules for years that do not require an expedited process, when additional time would afford a much more informed rulemaking. Critical information missing from NHTSA's analysis includes:

- The effectiveness of available technologies for improving fuel economy;
- The cost of technologies for improving fuel economy;
- Market shares of various models in the vehicle fleet; and
- The value of reduced emissions of greenhouse gases.

Unbelievably, NHTSA fully recognized that it did not have reliable and accurate information in these areas and would obtain that information only after the rule was promulgated. Additional and critical information missing from the Administration's analysis resulted in NHTSA making projections that were way ahead of the data available to them. This is, however, data that could be obtained, which would provide a much firmer basis for developing a rule that applies to 2013 vehicles and beyond. Without this critical data, NHTSA's conclusions:

- Relied on old sales data and projections in a time of rapid change in the industry;
- Failed to consider the impact of vehicle mix on safety;
- Did not incorporate technology adoption strategies ("pull ahead") that speed penetration of fuel-saving technology into the vehicle fleet;

- Ignored recent changes in fuel economy and the practices of automakers in adopting fuel economy technologies; and
- Overlooked changes in vehicle usage patterns across time.

Some underlying data used by NHTSA is suspect and would benefit greatly from even a small amount of further research and disclosure by the automakers, including:

- The production plans of automakers;
- Market share and price data;
- The validity of the speed of adoption of technology (phase-in caps) in light of dramatic changes in auto market behavior; and
- Assumptions about the compliance strategies of auto manufacturers.

There is no question that NHTSA needed to get the rulemaking started for 2011, and perhaps 2012, so it could complete the process eighteen months before the model year, as mandated by the new statute, but going beyond that, in light of the incredible importance of this regulation and the woeful lack of knowledge of critical aspects of the analysis, was irresponsible. NHTSA certainly could have moved forward with this rulemaking in light of these uncertainties by providing the minimum notice necessary, thereby keeping its options open for writing fuel economy standards for later years based on better information.

By rushing ahead with imperfect knowledge, faulty assumptions and a bias against fuel savings, NHTSA's approach denies the critical benefits of reduced gasoline and oil consumption to individual consumers and the nation as a whole. Therefore, it was unreasonable for NHTSA to set standards that run so far ahead of its knowledge. Adopting proposed standards for 2013 to 2015 based on such faulty data is arbitrary and capricious and leads to standards that are unreasonable.

The damage of NHTSA's proposed rule goes beyond the immediate impact of lost savings. By relying on a flawed analytic framework and flawed empirical specifications, this rulemaking undermines future rulemakings in two ways.

- First, procedurally, once this framework is set, it will be difficult to change. Inertia and judicial deference make it difficult to reverse agency decisions.
- Second, setting a low standard makes it far more difficult for the industry to meet higher future standards. Requiring large jumps in improvements is always more expensive than gradual improvements toward a goal, so fixing the mistakes later is harder because the industry is farther behind.

Because of the enormous importance of this particular rulemaking, it is critical for NHTSA to get the fundamental framework correct from the start and to set the standard at a reasonable and achievable level.

Comment Number: TRANS-05-4
Organization: Consumer Federation of America
Commenter: Mark Cooper

Our recommendation that you increase the level of the standards for 2011 and 2012, and that you withdraw the 2013 through 2015 proposals so that you can fix the fundamentally analytic flaws in the analytic framework and the erroneous economic assumptions is all the more compelling in light of the mounting evidence that the rule NHTSA has proposed fails to be a reasonable standard that comports with the act.

Comment Number: TRANS-06-9
Organization: Public Citizen
Commenter: Lena Pons

NHTSA has not presented a regulatory alternative that would result in actually reducing greenhouse gas emissions from motor vehicles. This is unacceptable. NHTSA has the responsibility to use its expertise to pose a theory wherein there is a regulatory alternative that could result in producing impacts that actually reduce greenhouse gas emissions from the motor vehicle sector.

And considering again that there is leeway for the agency to consider impacts that are the result of regulations that are outside of the lead agency's jurisdiction, then it could look at things that would address vehicle miles traveled reductions, or other types of policies that might, as a whole, result in reductions that will result in improving the situation in terms of global warming, which again goes to the issue of context.

Comment Number: TRANS-14-3
Organization: U.S. Public Interest Research Group
Commenter: Annie Chau

[NHTSA should rescind] the 2013 to 2015 standards, which are based on incomplete information.

Response

Commenters suggested that NHTSA set model year (MY) 2011-2012 standards in this current rulemaking and postpone the setting of MY 2013-2015 standards until the agency receives additional information. Although we appreciate the commenters' suggestion, we have concluded that the best approach for achieving at least the 35-mile-per-gallon (mpg) level specified in the Energy Policy and Conservation Act of 1975 (EPCA) is to set standards 5 years in advance, a regulatory option Congress has explicitly provided NHTSA in that statute. By doing so, NHTSA also promotes regulatory stability and allows manufacturers appropriate lead time to implement approaches to comply with more ambitious Corporate Average Fuel Economy (CAFE) standards.

NHTSA acknowledges that the amount of information concerning a future model year steadily increases as time passes. If NHTSA waits the maximum amount of time permissible under EPCA (that is, until just 18 months before a model year) to set standards for that model year, NHTSA would have little ability to require the manufacturers to make more than relatively minor improvements to the product plans they would already have established for that year. Changing plans requires lead time. Due to the nature of automobile production, manufacturers generally set production and supply contracts years in advance. While minor changes can be made in 18 months, substantial changes would be economically impracticable in such a short time.

For both the Notice of Proposed Rulemaking (NPRM) and for the alternatives described in this Final Environmental Impact Statement (FEIS), NHTSA used the best available information it could gather, including all the comments it received on its NPRM, and consulted with various experts, inside and outside the Federal Government, to derive the estimates it is using in the Volpe model. Waiting several years to set MY 2013-2015 CAFE standards might enable NHTSA to obtain additional and more up-to-date information regarding, for example, available technologies, product plans and market share, among other Volpe model components and inputs. However, in deciding whether to wait, NHTSA would also have to weigh the fact that the loss of several years of lead time before MY 2013-2015 would mean that, on balance, NHTSA would have to set lower standards than we could set now. The longer NHTSA waited to set the standards, the less ability it would have to require manufacturers to depart from their product plans for those model years, while still satisfying the EPCA factors of technological feasibility and economic practicability. More lead time allows manufacturers to structure their production cycles to meet more aggressive future standards.

Congress has already considered whether it is appropriate to set standards for up to 5 model years. In enacting the Energy Independence and Security Act of 2007 (EISA), Congress granted NHTSA the discretion to set CAFE standards anywhere from 1 model year to 5 model years at a time. See 49 United States Code (U.S.C.) § 32902(b)(3)(B). Further, Congress provided a process in EPCA by which NHTSA may amend previously promulgated CAFE standards if it determines that a different level would be the maximum feasible level for that model year. See 49 U.S.C. § 32902(c). Hence, there is a process to refine the CAFE standards if new information concerning the maximum feasible level becomes available after CAFE standards are initially set. Taking into account these available regulatory strategies in light of the comments raised, NHTSA believes that the best approach is to set CAFE standards for 5 model years. This will provide useful and important lead time information to the manufacturers, while preserving a regulatory tool to make adjustments to CAFE standards if new information should so warrant.

As explained in the NPRM, NHTSA will work with the National Academy of Sciences to update the list of fuel-saving technologies and their associated costs and effectiveness numbers on a 5-year interval, as required by EISA. To ensure that the combined passenger-car and light-truck fleets meet the statutorily mandated floor of 35 mpg in 2020, NHTSA will continue to request product plan updates from manufacturers during the 5 years covered by this rulemaking to assess whether the industry is on track and whether any changes to the standards are needed.

The comment that NHTSA must look at regulatory options that would reduce vehicle miles traveled (VMT) or GHG emissions goes beyond NHTSA's statutory authority. As explained in the NPRM and the Draft Environmental Impact Statement (DEIS), EPCA (as amended by EISA) requires NHTSA to set average fuel economy standards at "the maximum feasible average fuel economy level that [NHTSA] decides the manufacturers can achieve in that model year." VMT is related to fuel economy in that increases in VMT due, for example, to increases in the vehicle population, will increase fuel consumption and carbon dioxide (CO_2) emissions. More stringent standards will generally increase VMT (because they decrease the per-mile cost of fuel). This is known as the "rebound effect" and is considered by the Volpe model. Similarly, increasing fuel prices will generally decrease VMT. Thus, although CAFE standards indirectly affect VMT, NHTSA cannot control the growth of VMT.

10.1.1 NEPA Process

Comments

Comment Number: 0574-1
Organization: Alliance of Automobile Manufacturers
Commenter: Julie Becker

Moreover, as the Alliance [of Automobile Manufacturers] noted in its NEPA [National Environmental Policy Act] scoping comments, to the extent NEPA applies at all to the process of setting fuel economy standards under EPCA and EISA, it is a supplementary tool designed to provide additional information to NHTSA decisionmakers. It cannot be allowed to overtake or misshape the careful balancing of factors mandated by Congress in EPCA and refined in the Reform CAFE approach under EISA. Under bedrock NEPA precedent, the statute is purely procedural in nature and cannot be used to require an agency to act in any particular way. Numerous individuals or organizations testifying at the August 4 public hearing appeared to suggest otherwise. As it proceeds, NHTSA should be careful to maintain a clear distinction between its substantive obligations under EISA and its procedural obligations under NEPA.

Comment Number: 0576-36
Organization: Public Citizen
Commenter: Joan Claybrook

NHTSA has not completed this draft EIS [Environmental Impact Statement] in accordance with the requirements under the National Environmental Policy Act (NEPA) [42 U.S.C. § 4321 et seq., Pub. L. 91-190 (Jan. 1, 1970)]. This document does not put the potential impacts of fuel economy standards in a context that allows for a meaningful comparison of alternatives, which unfairly biases judgment in favor of NHTSA's preferred action. The purpose of the EIS process is to provide an analysis of the environmental impacts that allows decisionmakers to consider whether the preferred action is also the action that produces the greatest environmental benefits.

Comment Number: 0574-16
Organization: Alliance of Automobile Manufacturers
Commenter: Julie Becker

Sierra is flexible about the process NHTSA could employ to answer these questions [regarding clarification of the benefit estimates that NHTSA is assuming for specific technologies]. They could be resolved by way of a written response, or, more profitably, they could be answered by way of a telephonic conference call in which any relevant staff from NHTSA or the Volpe Center [Volpe National Transportation Systems Center] are made available so that Sierra's consultants could have an interactive conversation with them. The Alliance's [Alliance of Automobile Manufacturers's] only interest is that the questions be answered, and that they be answered as expeditiously as possible. Sierra may have additional questions as it continues its analysis, and so I would also suggest that NHTSA establish a means for resolving those questions that will not require further letter-writing.

In sum, consistent with its obligations under the law and with the diligence and thoroughness for which the agency is known, NHTSA should quickly initiate a process with Sierra to resolve Sierra's serious questions, and bring such a process to a conclusion as soon as is practicable. Please let me know expeditiously if for some reason NHTSA disagrees with the need to resolve Sierra's questions.

Response

NHTSA understands the balancing process required under EPCA, as amended by EISA, and the essentially procedural nature of NEPA. However, NEPA independently requires decisionmakers to integrate its requirements into agency decisions to inform them of the potential environmental impacts of these decisions and to present alternatives for consideration. Accordingly, NHTSA has analyzed the environmental impacts of a wide range of alternatives, some of which might weigh one or more of the four EPCA statutory factors (technological feasibility, economic practicability, the effect of other motor vehicle standards of the government on fuel economy, and the need of the Nation to conserve energy) in a manner that NHTSA might not ultimately accept, as it applies its discretion to determining the "maximum feasible" level for CAFE standards. See 49 U.S.C. 32902(f).

NHTSA believes that we have fully met our responsibilities under NEPA and its implementing regulations. NHTSA has completed a comprehensive analysis of the environmental impacts of seven alternatives ranging from the No Action Alternative to the Technology Exhaustion Alternative. In response to comments, NHTSA has expanded the analysis to account for a variety of different input assumptions. NHTSA's results, first set forth in its DEIS and now in this FEIS, are being used to inform the agency of the range of reasonably foreseeable environmental impacts of setting the final CAFE standards for MY 2011-2015.

Regarding the Sierra Research, Inc. letter to which the Alliance of Automobile Manufacturers (AAM) refers, see responses in Section 10.2.2 (Volpe model) of this chapter.

10.1.2 Timing of NEPA Process/Public Participation

Comments

Comment Number: TRANS-05-1
Organization: Consumer Federation of America
Commenter: Mark Cooper

We urge the administration to hold hearings all across the country, not just here in Washington in the dead of August, so the public can weigh in on the issue of fuel economy, which is vital not only to consumer pocketbooks, but also to national security and the environment.

Consumer attitudes and behavior toward fuel economy play a vital role in NHTSA's market model and analysis, and as we show in our comments, NHTSA has completely misjudged the consumer. There would be no better way for NHTSA to correct this flaw than to hear directly, in person, from the people who it has failed to comprehend in its analysis.

Comment Number: 0559-1
Organization: The Northeast States for Coordinated Air Use Management (NESCAUM)
Commenter: Arthur Marin

In our previous comments, we noted that the Proposed Rule was published on May 2, 2008 with a deadline for comments of July 1, 2008, but NHTSA did not release the DEIS until June 24, 2008. Consequently, there was little opportunity to consider the DEIS while reviewing and developing comments on the Proposed Rule. The applicable federal regulations state, "NEPA procedures must insure that environmental information is available to public officials and citizens before decisions are made and before actions are taken." [Footnote: 40 CFR [Code of Federal Regulations] 1500.1 & 1500.2.] Further, these regulations require federal agencies to "[i]ntegrate the requirements of NEPA with other planning and environmental review procedures…so that all such procedures run concurrently rather than consecutively." In so doing, the effect is to "[e]ncourage and facilitate public involvement in decisions which affect the quality of the human environment." Unfortunately, by separating the review periods for these two actions, the public involvement processes, both for the Proposed Rule and for the DEIS, were not well served.

Comment Number: 0559-10
Organization: The Northeast States for Coordinated Air Use Management (NESCAUM)
Commenter: Arthur Marin

In the context of these stated purposes of NEPA, we take note of the fact that the notice of proposed rulemaking [NPRM] was published on May 2, 2008 with a deadline for comments of July 1, 2008. However, NHTSA did not release the Draft Environmental Impact Statement until June 24, 2008, and NESCAUM did not receive a copy of the DEIS from NHTSA until June 30, 2008, which is only one day before the rulemaking comment deadline. Consequently, NESCAUM and other public commentators have essentially no opportunity to consider the environmental impacts, as stated by NHTSA, while reviewing and developing comments on the proposed rule. To be consistent with legislative intent and regulations implementing NEPA, NHTSA should provide an additional comment period on the proposed rule after the DEIS becomes final.

NHTSA's selection of the $7 per ton value for the social cost of carbon emissions is one example of how the absence of concurrent processes hinders efforts to provide fully informed comments and make better informed decisions. It would have been beneficial to have had the DEIS in hand while assessing the appropriateness of this figure. Considering the late release of the DEIS relative to the comment period for the proposed rule, there simply is not enough time to adequately formulate a comment in this regard.

Comment Number: 0572-2
Organization: Center for Biological Diversity
Commenter: Brian Nowicki, Mickey Moritz, Kassie Siegel

The NHTSA has also violated NEPA because the NEPA analysis has not informed the EPCA balancing and the Volpe model – rather, the NHTSA has done a post-hoc EIS on the "black box" number from the Volpe model. The federal NEPA regulations are clear on the order in which decision-making must proceed:

The statement shall be prepared early enough so that it can serve practically as an important contribution to the decision-making process and will not be used to rationalize or justify decisions already made (§§ 1500.2(c), 1501.2, and 1502.2). For instance: … (d) For informal rulemaking the draft environmental impact statement shall normally accompany the proposed rule. 40 C.F.R. § 1502.5. See also, *Pit River Tribe v. U.S. Forest Service*, 469 F.3d 768, 785 (9th Cir. 2006) (reviewing relevant statutes and holding that a post-hoc EIS does not cure failure to complete an EIS before lease extensions were granted; "The purpose of an EIS is to apprise decisionmakers of the disruptive environmental effects that may flow from their decisions at a time when they retain a maximum range of options").

Comment Number: 0596-8
Organization: Environmental Defense Fund
Commenter: Martha Roberts

Although the EIS assesses a range of CAFE alternatives, NHTSA selected a preferred alternative (the "optimized" alternative) a priori to the environmental analysis. Nowhere does NHTSA provide a reasoned argument for why the findings of the EIS should not alter the choice of the preferred alternative.

This blatantly contravenes the purpose that "[e]nvironmental impact statements shall serve as the means of assessing the environmental impact of proposed agency actions, rather than justifying decisions already made." [Footnote: CEQ [Council on Environmental Quality] 40 CFR Sec. 1502.2 (g).]

Response

NHTSA recognizes the importance of public input in the NEPA process and has provided ample opportunity for interested parties to be heard. In March and in April 2008, NHTSA informed the public through notices in the Federal Register regarding its plans to prepare an EIS. First, on March 28, 2008, NHTSA published a notice announcing its intent to prepare an EIS and requesting scoping comments. See 73 Federal Register (FR) 16615. One month later, on April 28, 2008, NHTSA published a supplemental notice of public scoping providing additional information about the standards, the alternatives NHTSA expected to consider, and inviting further comments. See 73 FR 22913. On May 2, 2008, NHTSA published a notice of proposed rulemaking proposing standards for MY 2011-2015 passenger cars and light trucks, informing the public that an EIS process was underway, and seeking comments on the proposed rule. See 73 FR 24352. On July 3, 2008, EPA published a Notice of Availability of the DEIS, which reflected our careful review and consideration of public scoping comments and the studies suggested by the commenters. See 73 FR 38204. After issuing the DEIS, NHTSA provided a 45-day public-comment period, which closed on August 18, 2008. On August 4, 2008, well before the close of the comment period, NHTSA held a public hearing on the DEIS in Washington, DC, during which interested parties were invited to testify. Forty-four persons and entities testified at that hearing. Sixty-six persons and entities submitted written comments to the DEIS public docket. NHTSA is confident that it has received full and extensive public input and that it has satisfied the public participation requirements of NEPA and the CEQ NEPA implementing regulations.

An agency may formulate a proposal or even identify a preferred course of action prior to completing work on an EIS. See Association of Public Agency Customer, Inc. v. Bonneville Power Administration, 126 F.3d 1158, 1184 (9th Cir. 1997) (citing Natural Resources Defense Council v. Hodel, 624 F. Supp. 1045 (D. Nev. 1985)). NHTSA has carefully considered, individually and collectively, all comments on the DEIS, and our final action will be fully informed by the environmental review process and analysis of alternatives encompassed in this FEIS.

10.1.3 Document Structure/Readability

Comments

Comment Number: 0575-25
Organization: Union of Concerned Scientists
Commenter: Eli Hopson

One of the overarching challenges with commenting on NHTSA's analysis is the opaqueness of its economic practicability analysis. Because of the complexity of the Volpe model, its use of confidential product plans, limited agency explanations of computer model behavior, and general opaqueness of the agency's measurement process in determining economic practicability, a shadow is cast on the credibility of NHTSA's analysis. While UCS [Union of Concerned Scientists] appreciates the great deal of effort put into providing the information in the NPRM and PRIA [Preliminary Regulatory Impact Analysis], more explicit information is necessary to effectively and fully comment on the proposed rule.

The mere *appearance* of wrongdoing by either automakers or the agency can undermine the value of this work. As future fuel economy regulations are set, mechanisms must be instituted to improve transparency of the process. Such options could include, for example, improved documentation and on-site, third-party access to NHTSA-supplied confidential product plan information. (Signed non-disclosure agreements would be required.)

Comment Number: 0576-28
Organization: Public Citizen
Commenter: Joan Claybrook

Another serious problem with the Volpe Model is that it is not transparent, which significantly undermines the ability of public commenters to provide an opinion as to whether NHTSA has set standards at the maximum feasible level that maximizes public good. Automakers provide the inputs for the Volpe Model through product plans, which are closed from public view as confidential business information. This significantly biases the standards in favor of industry by shutting the public out of the process. NHTSA does not establish what is technological feasible and economically practicable based on an independent assessment of the current vehicle fleet and the available technology to improve the fleet, but rather accepts industry inputs, which are run through the black box of the Volpe Model, and a variety of "optimization" factors, which are tied to maximizing industry-wide benefits (73 *FR* 24416). In the past, rulemaking NHTSA has done its own research and evaluation of these factors which was more transparent.

Thus, the public is foreclosed from real participation in this system. There is intense public interest in new fuel economy standards. These upgrades are the first for passenger cars in over twenty years, and they will dictate the level of fuel economy new vehicles will get until 2015, which affects the new car market and will skew purchase decisions. High gas prices and concern about global warming contribute to increased consumer interest in fuel economy; however, the agency's scheme for setting fuel economy standards leaves them largely in the dark. Consumers must essentially trust that NHTSA has set standards in their interest using information provided by industry.

Comment Number: 0585-2
Organization: Attorneys General of the States of California, Massachusetts, New Jersey, New Mexico, New York, and Oregon, Secretary Of The Commonwealth of Pennsylvania Department of Environmental Protection, and New York City Corporation Counsel
Commenter: Edmund Brown Jr., Joseph Powers, Martha Coakley, Michael Cardozo, Anne Milgram, Gary King, Andrew Cuomo, Hardy Myers

In order to fulfill NEPA's goal of informing the public of the environmental impacts of the agency's decision, the EIS must "be written in plain language and may use appropriate graphics so that decisionmakers and the public can readily understand them" (40 C.F.R. 1502.8). Further, the EIS "must be organized and written so as to be readily understandable by governmental decisionmakers and by interested non-professional laypersons likely to be affected by actions taken under the [FEIS]." *Earth Island Institute v. U.S. Forest Service*, 442 F.3d 1147, 1160 (9th Cir. 2006) (quoting *Oregon Environmental Council v. Kunzman*, 817 F.2d 484, 494 (9th Cir. 1987). The DEIS fails to meet this standard.

Comment Number: TRANS-16-5
Organization: Individual
Commenter: Matthew Du Pont

You have a duty to make that EIS report transparent to the public … it's currently failing to do so.

And this leads to the conclusion that simply by throwing on a very accessible, readable, lower level two to three page summary in addition to what you already have in this report, you can make this much more accessible to the public who demand this information.

So first of all, I think it's not too controversial that people find this issue important, after all this directly impacts global warming which according to a March 2006 *Time* [Magazine] poll, 88 percent of Americans find relevant for future generations.

But more importantly for our purposes here, 49 percent of Americans think that this is one of the issues that is very important to them, one of the issues that they are going out of their way to actually find out information about, instead of just reading it in the papers. So we know it's important, we know it's important to Americans.

And secondly, it's very non-controversial that the EIS is supposed to inform the public, not just policy makers. People look to the CEQ regulations governing the EIS creation, which cite a purpose of the EIS as "to encourage and facilitate public involvement in decisions which affect the quality of the human environment." And there are also several clarity and brevity requirements meant to make them more accessible to the public.

So we've got this demand for information. We've got this EIS with a burden to show the public how that information is being used. It sounds pretty good. But in reality right now, this particular environmental impact statement is failing to make itself accessible to the public.

I mean, first of all there is the length. Now, the CEQ guidelines say that reports should be less than 150 pages in most cases, in very special cases under 300. So if I, as an average citizen who is not getting paid to deal with these issues, am confronted with this 414 page monstrosity, it's highly likely I'm not going to read more than the summary, if I read anything at all.

But this brings us to the second problem. Even if I got to that summary, the very first sentence in the forward, I am confronted with no less than nine acronyms, probably six of which I don't know. It's just not very encouraging for me as an average person trying to vote correctly, to advocate policy, to be able to read this report, although maybe it's applicable to policy makers. But I, you know, as just a regular citizen, it's hard for me to get through.

So, and it doesn't get much better from there on in because the summary assumes knowledge of a lot of things. It assumes that I know why rising sea levels are bad, which admittedly is explained in the report, but I'm probably not going to go to page 270 or wherever that's explained, if I'm not grabbed in the beginning. And so we have this inaccessibility, and I think it's a huge problem. The citizens who are interested but don't have a career as a nonprofit policy wonk or an auto industry lobbyist are simply not going to read a 414 page report, or even a 25 page summary.

And this brings me to the point of my speech, something you could do very easily. It's not a solution, but it's certainly a step in the right direction. By simply providing a short jargon free summary, say just two to three pages long, in addition to what's already in the report, specifically labeled, for average citizens who don't know as much about the issue, you can allow people to make meaningful conclusions from this EIS, to be able to read it and perhaps talk to their neighbor about it, or talk to their Congress person.

Response

A number of commenters asserted that the DEIS failed to inform the public because it lacked transparency, particularly regarding the use of confidential manufacturer product plans and the Volpe *model. NHTSA believes that the least-speculative approach to assessing the costs and benefits of setting CAFE standards entails the use of the product plans of vehicle manufacturers for the periods at issue. These plans enable NHTSA to create standards that are tied to realistic production goals. The Volpe model is a tool we use to apply technologies and assess costs and benefits given a range of input assumptions, including product plan information, technology costs and effectiveness, and economic externalities. NHTSA selects the input assumptions based on the best available information and data at the time of the rulemaking. NHTSA recognizes that some of the assumptions could change over time, and updates these assumptions as new and more-up-to-date information becomes available.*

With the exception of manufactures' confidential product plans, which are a crucial part of the process and subject to confidentiality under federal regulation, NHTSA provides interested parties and the public with all relevant data and information used in the Volpe model and the rationale for selecting those inputs. See 5 U.S.C. § 552(b)(4); 18 U.S.C. § 1905; 49 U.S.C. § 30167(a); 49 CFR Part 512; Critical Mass Energy Project v. Nuclear Regulatory Comm'n, 975 F.2d 871 (D.C. Cir. 1992); FEIS Section 3.1.4 (detailing Volpe model inputs); NPRM, 73 FR 24352, 24391 (May 2, 2008); CAFE Compliance and Effects Modeling System Documentation, Docket No. NHTSA-2008-0089-0047; How to Obtain Volpe Model Installation Files, Docket No. NHTSA-2008-0089-0048; PRIA, Docket No. NHTSA-2008-0089-0003.1, pp. V1-V141. In an effort to provide further clarification, Chapter 2 and Section 10.2.2 provide more information about how the Volpe model works.

NHTSA has made every effort to make this FEIS as accessible and reader-friendly as possible. However, the extreme complexity and uncertainty surrounding climate-change science and the difficulty associated with measuring emissions and impacts warrant detailed and technical discussion. Readers should turn to the FEIS Summary, which provides a short, plain-language discussion of the analysis and findings described in the FEIS chapters and appendices.

10.1.4 NHTSA's Decision to Prepare an EIS

Comment

Comment Number: 0574-14
Organization: Alliance of Automobile Manufacturers
Commenter: Julie Becker

For the foregoing reasons [functional equivalence doctrine, NHTSA's pending en banc petition, the Ninth Circuit's en banc *McNair* decision, unlawful consideration of transboundary effects], NHTSA should either determine not to proceed with a NEPA EIS or, alternatively, announce its desire to do so only on a voluntary basis, producing in the alternative an EA/FONSI [Environmental Assessment/Finding of No Significant Impact]. In addition, NHTSA must address the other comments on the DEIS advanced by the Alliance herein and in its scoping comments filed June 2, 2008.

Comment Number: 0574-3
Organization: Alliance of Automobile Manufacturers
Commenter: Julie Becker

"[P]rojected differences among the CAFE alternatives are small — i.e., CO_2 concentrations as of 2100 are within 1.7 to 3.2 parts per million across alternatives . . . — regardless of reference scenario and climate sensitivity." 73 Fed. Reg. at 37,926. NHTSA's analysis of the effects on rainfall and sea level rise are similar. See DEIS 2-17 to 2-18. See also 73 Fed. Reg. at 37,926 (predicting sea level rise by the year 2100 by 0.1 centimeters). All of these impacts are sufficiently small that they fully vindicate NHTSA's decision in prior CAFE rulemakings to perform environmental assessments ("EAs") in lieu of performing full-blown EIS-level analyses.

Comment Number: 0574-9
Organization: Alliance of Automobile Manufacturers
Commenter: Julie Becker

On February 6, 2008, with the permission of the Solicitor General, NHTSA petitioned for en banc [in full court] review of the Ninth Circuit's decision concerning NHTSA's MY 2008-2011 light truck CAFE rules in *Center for Biological Diversity* [*Center for Biological Diversity v. NHTSA*, 508 F.3d 508 (9th Cir. 2007)]. NHTSA argued that it could not be ordered to complete an EIS, but instead, consistent with limitations on remedies under the Administrative Procedure Act (which provides the only basis for enforcing NEPA in court), NHTSA had to be allowed the choice to exercise its discretion on remand as to whether to prepare an EIS or an EA. That en banc petition remains pending.

It is wholly inconsistent for NHTSA to voluntarily perform an EIS in this CAFE rulemaking while its en banc petition is pending in the Ninth Circuit, absent some explanation of independent reasons for doing so. NHTSA's present course of action risks mooting the en banc petition. (The Alliance points out this issue for NHTSA's consideration without conceding that the voluntary preparation by NHTSA of an EIS in this rulemaking would moot the pending en banc petition. Clearly, the agency would have good arguments that even the voluntary preparation of an EIS on remand would not moot the case.) In order to maintain consistency with the position taken in the Ninth Circuit, NHTSA should issue, in the alternative, an EA/FONSI form of NEPA compliance document. The evidence NHTSA has developed in the DEIS amply supports a conclusion that environmental impacts are minimal. Doing so would ensure that the pending en banc petition in *Center for Biological Diversity* remains unaffected.

In its en banc decision in *Lands Council, Inc. v. McNair*, --- F.3d ---, 2008 WL264001 (9th Cir. July 2, 2008), the Ninth Circuit took a major step to bring its NEPA jurisprudence into greater harmony with the NEPA case law of other Circuits. In *McNair*, the Ninth Circuit overruled a number of its prior panel opinions in the NEPA area. The decision should be carefully considered by NHTSA in connection with finalizing its NEPA analysis for this rulemaking. (In directing NHTSA's attention to the McNair decision, which as mentioned brings the Ninth Circuit more in line with other Circuits, we also note that even if a future final rule emerging from these proceedings were to be challenged, it is not a foregone conclusion that such a challenge would occur in the Ninth Circuit.) One aspect of the decision that NHTSA should particularly note, which is consistent with its approach in the DEIS (but inconsistent with the approach of many in the August 4 public hearing) is the following: "[T]o require the Forest Service to affirmatively present every uncertainty in its EIS would be an onerous requirement, given that experts in every scientific field routinely disagree; such a requirement might inadvertently prevent the Forest Service from acting due to the burden it would impose." (*Lands Council, Inc. v. McNair*, --- F.3d ---, 2008 WL264001 (9th Cir. July 2, 2008) at *17)

Comment Number: TRANS-01-2
Organization: Alliance of Automobile Manufacturers
Commenter: Julie Becker

The next issue relates to NHTSA's ability to defend its position in ongoing or future litigation. Let me explain. NHTSA petitioned the Ninth Circuit to review en banc the *Center for Biological Diversity* decision. One question before the en banc panel would be whether the reviewing Courts lack the power to order the preparation of an EIS as opposed to ordering the agency to reconsider whether an EIS is appropriate.

The en banc petition has not yet been acted upon. Since the position NHTSA took there was sanctioned by the solicitor general, it would seem that NHTSA needs to reserve its right not to perform an EIS at all.

In order to preserve that right, NHTSA should also produce an environmental assessment, a finding of no significant impact for the current rulemaking. If NHTSA decides to proceed in any other manner, it risks wounding its own en banc petition. So it is critical for NHTSA to take this approach.

Comment Number: TRANS-04-2
Organization: National Automobile Dealers Association
Commenter: David Westcott

In the past, NHTSA has consistently and adequately assessed and accounted for the potential environmental impacts of its proposed CAFE standards. NADA [National Automobile Dealers Association] therefore disagrees with the 2007 Ninth Circuit Court of Appeals decision in *Center for Biological Diversity v. NHTSA* which reviewed NHTSA's '06 reform light truck standards, and suggests that it is incumbent upon NHTSA to conduct a formal EIS in conjunction with its model year 2011-2015 proposal, CAFE proposal.

Response

NHTSA agrees that NEPA does not require an agency to evaluate every possible uncertainty. NHTSA disagrees that the proper course is for NHTSA to publish both an EA and an EIS, regardless of circumstances. Such an approach would confuse the analysis. In any case, on August 18, 2008, the Ninth Circuit vacated and withdrew its decision in Center for Biological Diversity v. NHTSA, 508 F.3d 508 (9th Cir. 2007). See Center for Biological Diversity v. NHTSA, 2008 WL 3822966 (9th Cir. 2008). Specifically, the Ninth Circuit vacated its opinion requiring NHTSA to prepare an EIS in connection with its CAFE rulemaking, and remanded to NHTSA to prepare either a revised EA or an EIS, as appropriate. In so doing, the Ninth Circuit denied as moot NHTSA's petition for rehearing with suggestion for rehearing en banc. NHTSA has decided that it is appropriate to prepare an EIS.

10.1.5 Functional Equivalence Doctrine

Comments

Comment Number: 0574-17
Organization: Alliance of Automobile Manufacturers
Commenter: Julie Becker

NHTSA includes several paragraphs in its DEIS arguing that the functional equivalence doctrine does not apply to CAFE standard-setting under EPCA or EISA. See DEIS at 1-16 to 1-17. This attempted rebuttal does not adequately address the Alliance's NEPA scoping comments for several reasons. First, NHTSA does not consider the cases cited by the Alliance and the point made there that the functional equivalence doctrine has been applied by courts to statutes other than the Clean Air Act and Clean Water Act and in favor of agencies other than the EPA [U.S. Environmental Protection Agency]. NHTSA's rebuttal effectively continues to assert that the functional equivalence doctrine applies only in such highly limited situations, without addressing the other authorities brought to its attention.

Second, NHTSA's rebuttal does not attempt to compare the procedures mandated in statutory contexts where the courts have found the functional equivalence doctrine to apply with the statutory procedures created in EPCA and EISA. Without such a comparison, it is empty for NHTSA to simply declare that the functional equivalence doctrine is only narrowly drawn. Moreover, NHTSA's attempted rebuttal avoids addressing cases like *Portland Cement Ass'n v. Ruckelshaus*, 486 F.3d 375, 384 (D.C. Cir. 1973), *cert. denied*, 417 U.S. 921 (1974) which interprets a vague provision of the Clean Air Act (requiring EPA only to impose "the best system of emission reduction") as requiring the functional equivalent of NEPA analysis.

Third, NHTSA's argument is illogical, because it would render the functional equivalence doctrine useless. Under NHTSA's reasoning, a statute would have to specify a set of procedures that is essentially identical to NEPA (plus the great detail in NEPA's regulations) before it would serve to require the functional equivalent of NEPA analysis. But if that were the case, then the doctrine would serve no purpose at all and would fail to relieve agencies of any kind of compliance burden. Instead, as *Portland Cement* explains, functional equivalence exists whenever a "workable balance is struck between some of the advantages and disadvantages of full application of NEPA." *Portland Cement.* Compare *Center for Biological Diversity v. NHTSA*, 508 F.3d 508, 527-28 (9th Cir. 2007). (EPCA creates a "reasonable" balancing of multiple variables for courts to review deferentially.)

Fourth, NHTSA provides no response at all to subsection III.A.2 of the Alliance's NEPA scoping comments. That subsection makes the point that the passage of EISA and the various directives it gives to NHTSA to consider environmental matters, as well as EISA's legislative history, indicates that environmental issues were in the foreground of Congress's mind in adopting that statute, and on that basis the functional equivalence doctrine can be applied.

Finally, even if NHTSA decides not to rely solely on the functional equivalence doctrine, it should recognize that its invocation in the alternative would help to protect its rulemaking against challenges asserting that the NEPA analysis being performed is defective or insufficient. NHTSA's analysis can be read to suggest that the agency agrees the defense is colorable, but is merely choosing not to invoke it as a discretionary matter. NHTSA should reconsider at least adopting the defense in the alternative, which would permit a court to pass on the issue. There is no downside to the agency acting in that fashion.

Comment Number: 0574-4
Organization: Alliance of Automobile Manufacturers
Commenter: Julie Becker

First, NHTSA argues that the functional equivalence doctrine does not apply to allow NHTSA not to perform an EIS under EPCA and EISA. But NHTSA's analysis in this respect is conclusory and fails to adequately respond to the Alliance's analysis supplied to the agency in its June 2, 2008 comments.

Second, even if the functional equivalence doctrine does not apply, NHTSA has not taken due account of the en banc petition it filed, with the permission of the Solicitor General, in the Ninth Circuit in *Center for Biological Diversity v. NHTSA*, No. 06-71891 (and consolidated cases). Should NHTSA vindicate the position it has taken in that en banc petition, then the agency could viably choose not to perform an EIS on remand. Yet, NHTSA is currently proposing to perform an EIS. NHTSA should not take this position before the pending en banc petition is resolved. Instead, NHTSA should at least decide in the alternative that performing an EA and issuing a finding of no significant impact ("FONSI") would be sufficient NEPA compliance to support the NPRM here.

Third, NHTSA should consider the Ninth Circuit's recent en banc decision in *Lands Council, Inc. v. McNair*, --- F.3d ---, 2008 WL 264001 (9th Cir. July 2, 2008). In that case, the Ninth Circuit overturned several aspects of its aggressive approach to the NEPA statute, bringing its jurisprudence more in line with of that of other circuits.

Comment Number: TRANS-01-3
Organization: Alliance of Automobile Manufacturers
Commenter: Julie Becker

In its comments, the Alliance noted that NHTSA already considers environmental impact and energy conservation when it sets CAFE standards. Therefore, CAFE rulemaking is the functional equivalent of performing an EIS. Under the functional equivalence doctrine, an agency need not prepare an EIS if it has already undertaken the functional equivalent of an EIS as part of its rulemaking process. However, in its draft EIS for the CAFE rulemaking, NHTSA takes the position that it cannot rely on the functional equivalence doctrine. In our view there is a solid argument for the functional equivalence doctrine here, and NHTSA should reconsider its position on this issue. At a minimum, NHTSA should assert the functional equivalence doctrine as an alternative basis that supports its final course of action.

Response

NHTSA has carefully studied the functional equivalence doctrine, the associated case law, and the Alliance of Automobile Manufacturers' (AAM's) arguments that NHTSA should assert the doctrine's applicability under EPCA. NHTSA declines to adopt the AAM's suggestion. NHTSA believes that its response to the AAM's scoping comment on the issue adequately explains the agency's rationale for this conclusion. See DEIS pp. 1-16 and 1-17.

After receiving the AAM's DEIS comments on this same subject, we again reviewed established case law applying the functional equivalence doctrine, including cases cited by AAM. NHTSA reasserts the conclusions reached in the DEIS. Our review of the cases indicates that the functional equivalence doctrine is not a "broad exemption from NEPA for all environmental agencies or even for all environmentally protective regulatory actions of such agencies." See Environmental Defense Fund v. EPA, 489 F.2d 1247, 1257 (D.C. Cir. 1973). Rather, the doctrine is a "narrow exemption from the literal requirements for those actions which are undertaken pursuant to sufficient safeguards so that the purpose and policies behind NEPA will necessarily be fulfilled." Id. This narrowly drawn exemption has been applied outside of EPA actions on environmental statutes in very few circumstances. These rare cases involved situations "where an agency is engaged primarily in an examination of environmental questions, where the substantive and procedural standards ensure full and adequate consideration of environmental issues." See Cellular Phone Taskforce v. Federal Communications Comm'n, 205 F.3d 82, 94 (D.C. Cir. 2000) (quoting Environmental Defense Fund, 489 F.2d at 1257). NHTSA does not believe that its actions in this rulemaking under EPCA are analogous.

The AAM urged NHTSA to compare the procedures mandated in statutory contexts where the courts have found the functional equivalence doctrine to apply with the statutory procedures created in EPCA and EISA. Nothing in EPCA or EISA explicitly directs NHTSA to consider environmental impacts of the CAFE standards, except what can be read into the statutory factor concerning the need of the United States to conserve energy, one of four factors to be considered in setting the standards. When courts apply the functional equivalence doctrine to excuse agencies from NEPA procedures, they first determine that the agency is in some other way explicitly required to analyze the environmental impacts of the proposed action so that the purposes and goals of NEPA are served, a circumstance that is not present here.

10.1.6 Transboundary Effects

Comments

Comment Number: 0574-12
Organization: Alliance of Automobile Manufacturers
Commenter: Julie Becker

In the DEIS, NHTSA disagrees with the Alliance's reading of NHTSA's pronouncement that "the appropriate value to be placed on changes [in] climate damages caused by carbon emissions should be ones that reflect the change in damages to the United States alone." (73 Fed. Reg. at 24,414) For NEPA purposes, NHTSA insists that "[p]otential environmental impacts are global in this instance and the analysis must look beyond the borders of the United States. . . . NHTSA has an obligation under NEPA to 'recognize the worldwide and long-range character of environmental problems.'" DEIS at 1-11 (quoting 42 U.S.C. § 4332(F)).

However, Section 4332(F), like much in the NEPA statute, is precatory. It does not create an obligation that attaches to the EIS requirement in Section 4332(C), which is judicially enforceable. Moreover, NHTSA selectively quotes Section 4332(f). In its entirety, Section 4332(F) reads as follows:

> The Congress authorizes and directs that, to the fullest extent possible: (1) the policies, regulations and public laws of the United States shall be interpreted and administered in accordance with the policies set forth in this chapter and (2) all agencies of the Federal Government shall . . . .
>
> > (F) recognize the worldwide and long-range character of environmental problems and, where consistent with the foreign policy of the United States, lend appropriate support to initiatives, resolutions, and programs designed to maximize international cooperation in anticipating and preventing a decline in the quality of mankind's world environment . . . .
> > 42 U.S.C. § 4332(F).

To simply read this provision is to see why it cannot be read to be judicially enforceable, and to our knowledge has not been read by any court to be directly enforceable. Courts cannot police whether agencies have sufficiently "recognize[d] the worldwide and long-range character of environmental problems." Similarly, courts lack the power to decide whether agencies have lent enough support to programs maximizing international cooperation and protecting the world environment. Compare *Norton v. Southern Utah Wilderness Alliance*, 542 U.S. 55, 66-67 (2004) (unanimous) (to be enforceable, statutory mandates must be "discrete," and on that basis refusing to enforce an overly broad "non-impairment mandate" for wilderness study areas in a statute because "[i]f courts were empowered to enter general orders compelling compliance with broad statutory mandates, they would necessarily be empowered, as well, to determine whether compliance was achieved — which would mean that it would ultimately become the task of the supervising court, rather than the agency, to work out compliance with the broad statutory mandate, injecting the judge into day-to-day agency management.").

Finally, the proviso limiting Section 4332(F) to situations not inconsistent with the foreign policy of the United States is very significant. The United States in the past has argued in numerous different forums that the extraterritorial application of NEPA would interfere with the President's foreign policy prerogatives. "It has been the long-standing position of the Justice Department that NEPA was not intended nor can it be invoked to interfere with the President's authority as Commander-in-Chief, or with his exclusive responsibility for the conduct of foreign affairs, regardless of whether the government action in question affects the United States environment, the global commons, or the environment of foreign nations, because these responsibilities are confided to the President by the Constitution." Letter from Bruce C. Navarro, Deputy Assistant Attorney General, Department of Justice, to Minority Leader Robert Dole, 3 (Oct. 9, 1990), *quoted in* Joan M. Bondareff, *The Congress Acts to Protect Antarctica,* 1 Terr. Sea J. 223 n.64 (1991).

To support its contrary conclusion that NEPA can and does have extraterritorial application, NHTSA also cites a 1997 guidance document issued by the Council on Environmental Quality ("CEQ"). See id. at 1-11 n.29 (referencing CEQ, *Council on Environmental Quality Guidance on NEPA Analyses for Transboundary Impacts* (July 1, 1997), at 3, available at http://ceq.hss.doe.gov/nepa/regs/transguide.html. The Mexican Trucks decision by the Supreme Court recognizes that CEQ regulations are entitled to deference, see *Public Citizen*, 541 U.S. at 770, but a guidance document of this nature is void because it represents a clear shift in policy that occurred in 1997 without compliance with the Administrative Procedure Act's requirement to subject any substantive change in agency policy to notice-and-comment review by the public. See, e.g., *CropLife Am. v. EPA,* 329 F.3d 876 (D.C. Cir. 2003); *General Elec. Co. v. EPA*, 290 F.3d 377 (D.C. Cir. 2002); *Barrick Goldstrike Mines, Inc. v. Browner*, 215 F.3d 45 (D.C. Cir. 2000); *Appalachian Power Co. v. EPA*, 208 F.3d 1015 (D.C. Cir. 2000). Hence, NHTSA cannot rely on this lone guidance document. It has no legal effect.

Moreover, the guidance document reflects a divergence from Justice Department-approved interpretations of NEPA both prior to 1997 and after 1997. The Navarro letter to Senator Dole referred to above accurately summarizes policy predating the 1997 CEQ guidance document. And the current Administration had repeatedly made clear its position that NEPA is not sufficiently unambiguous to overcome the presumption against extraterritoriality, which remains vital. See *Microsoft v. AT&T Corp*., 127 S. Ct.1746, 1758 (2007). (*Microsoft v. AT&T* also notes that the canon of presuming against extraterritoriality is entirely consistent with a presumption that "'legislators take account of the legitimate sovereign interests of other nations when they write American laws.'" *Microsoft*, 127 S. Ct. at 1758 (quoting *F. Hoffmann-La Roche Ltd. v. Empagran S. A.*, 542 U.S. 155, 164 (2004)). This helps to explain why Section 4332(F) of NEPA, with its emphasis on agencies giving some consideration to the world environment is fully consistent with concluding that the NEPA statute's enforceable duties nonetheless apply only to require the consideration of domestic effects.) To name just two examples, the Bush Administration took that position in *NRDC v. Department of the Navy*, No. CV-01-07781 CAS(RSZ)(C.D. Cal.) and *Manitoba v. Norton*, No. 02-cv-02057 (RMC) (D.D.C.). NHTSA nowhere even acknowledges these briefs, which represent the true position of the United States spanning across multiple agencies. See 28 U.S.C. § 516 (Attorney General represents the United States and agencies thereof in litigation). These positions therefore clearly trump the unlawfully issued and procedurally defective CEQ guidance document. At the very least, NHTSA must consider the positions taken in these briefs and others similar cases (by, *inter alia*, consulting with the Department of Justice) before deciding that NEPA applies extraterritorially in a final EIS or other final document issued for purposes of complying with the NEPA statute.

Comment Number: 0574-7
Organization: Alliance of Automobile Manufacturers
Commenter: Julie Becker

NHTSA concludes that NEPA requires it to analyze transboundary effects associated with the NPRM's proposed CAFE standards — especially climate-change effects outside the United States. This runs contrary to longstanding litigation positions approved by the Department of Justice. NHTSA does not even attempt to grapple with those prior positions in the DEIS. Since NHTSA's analysis concludes that the worldwide effects of higher CAFE standards would be very small, then they logically would be reduced even further once those effects are scaled back to effects within the United States alone. The

Alliance has also submitted a study by National Environmental Research Associates ("NERA") bearing on this issue. That study attempts to calculate the magnitude of properly limiting an analysis of the social costs of carbon emissions to impacts within the United States alone. The analysis in that study, if adopted by NHTSA, would buttress the conclusion that the CAFE rulemaking here can be supported by an EA/FONSI in preference to an EIS. Instead, the DEIS makes no mention of this analysis.

Comment Number: TRANS-01-4
Organization: Alliance of Automobile Manufacturers
Commenter: Julie Becker

The draft EIS appears to be setting a significant precedent regarding analysis of the trans-boundary effects.

On page 1-11 of the draft EIS NHTSA argues it should analyze trans-boundary effects of the CAFE standards quoting a 1997 CEQ guidance document stating that agencies must analyze such effects underneath them. The statement seems directly at odds with judicial precedent and agency precedent, and we would like for NHTSA to reconsider this.

Response

The AAM misunderstands NHTSA's analysis in the DEIS. According to the AAM, NHTSA has concluded that "NEPA requires it to analyze transboundary effects associated with the NPRM's proposed CAFE standards – especially climate-change effects outside the United States." In fact, the DEIS and this FEIS consider environmental impacts relevant to the United States that stem from emissions generated in the United States that subsequently would affect both the U.S. and the global environment. As explained in the DEIS, an appropriate discussion of global climate change does not make sense if it is limited to analysis of emissions within the United States, because this environmental problem is inherently global in nature. Climate science focuses on the effects of carbon emissions in the global atmosphere because the atmospheric concentration of greenhouse gases is essentially uniform across the globe. That is, carbon emissions from one nation disperse into the global atmosphere and have impacts in other nations, and conversely, benefits from emissions reductions in one nation are felt in all nations for the same reason. Nevertheless, NHTSA considers the AAM's comment as a suggestion to focus its environmental impacts analysis within the United States. NHTSA agrees that this type of national rulemaking warrants specific discussion of regional U.S. impacts and how global climate change specifically impacts the United States. NHTSA devoted substantial parts of the DEIS and this FEIS to such a discussion.[1]

[1] *See DEIS Sections 3.2, 4.2 (Energy); 3.3, 4.3 (Air Quality); 3.4.2.2.1 (United States Climate Change Effects); 3.5.4 (Safety and Other Human Health Impacts); 3.5.5 (Hazardous Materials and Regulated Wastes); 3.5.7 (Historic and Cultural Resources); 3.5.8 (Noise); 3.5.9 (Environmental Justice); 4.5.3.3.2 (Observed and Projected Impacts of Climate Change on Freshwater Resources in the United States – Freshwater Resources); 4.5.3.3.3 (Precipitation); 4.5.3.3.4 (Surface Water); 4.5.3.3.6 (Water Quality); 4.5.3.3.7 (Extreme Events – Floods and Drought); 4.5.4.1.2 (Terrestrial Ecosystems in the United States); 4.5.4.2.2 (Projected Impacts of Climate Change in the United States – Terrestrial Ecosystems); 4.5.5.2.1 (Projected Impacts of Climate Change for the United States – Coastal Systems and Low-lying Areas); 4.5.6.2.1 (Projected Impacts of Climate Change for the United States – Food, Fiber, and Forest Products); 4.5.7.2.1 (Projected Impacts of Climate Change for the United States – Industries, Settlements, and Society); 4.5.8.3 (Projected Health Impacts of Climate Change on the United States); 4.6.2.2 (Effects of Climate Change in the United States – Environmental Justice). See FEIS Sections 3.2, 4.2 (Energy); 3.3, 4.3 (Air Quality); 3.4.2.2.1 (United States Climate Change Effects); 3.5.4 (Safety and Other Human Health Impacts); 3.5.5 (Hazardous Materials and Regulated Wastes); 3.5.7 (Historic and Cultural Resources); 3.5.8 (Noise); 3.5.9 (Environmental Justice); 4.5.3.3.2 (Observed and Projected Impacts of Climate Change on Freshwater Resources in the United States – Freshwater Resources); 4.5.3.3.3 (Precipitation); 4.5.3.3.4 (Surface Water); 4.5.3.3.6 (Water*

NHTSA does not presume to invoke NEPA in such a way as to interfere with the President's exclusive responsibility for the conduct of foreign affairs. As explained above, the inherently global nature of climate change makes a global-level discussion necessary. Transportation-sector carbon emissions in the United States contribute to global climate change, which in turn affects various resources and regions within the United States. This relationship of U.S. emissions to a global environmental phenomenon and the associated impacts that affect the quality of the human environment in the United States warrant discussion in this FEIS.

The AAM asserts that NHTSA's analysis of the global effects of CO_2 *emissions is unlawful because 42 U.S.C. § 4332(F) is not an enforceable statutory mandate, and the CEQ guidance document NHTSA cited in the DEIS was improperly promulgated. NHTSA expresses no opinion as to the enforceability of 42 U.S.C. § 4332(F), but disagrees with the AAM's dismissal of these sources as expressing the purpose and intent of NEPA. The AAM overlooks the more important point that NEPA commands an agency to analyze reasonably foreseeable impacts on the human environment. Such an analysis necessarily includes potential impacts related to global climate change.*[2] *To conduct a proper analysis of the impacts on the United States, it is necessary to look at global temperature, precipitation, and sea-level change because current climate models are not sensitive enough to enable NHTSA to model unique temperature, precipitation, and sea-level changes for the United States or for particular regions within the United States.*

Quality); 4.5.3.3.7 (Extreme Events – Floods and Drought); 4.5.4.1.2 (Terrestrial Ecosystems in the United States); 4.5.4.2.2 (Projected Impacts of Climate Change in the United States – Terrestrial Ecosystems); 4.5.5.2.1 (Projected Impacts of Climate Change for the United States – Coastal Systems and Low-lying Areas); 4.5.6.2.1 (Projected Impacts of Climate Change for the United States – Food, Fiber, and Forest Products); 4.5.7.2.1 (Projected Impacts of Climate Change for the United States – Industries, Settlements, and Society); 4.5.8.3 (Projected Health Impacts of Climate Change on the United States); 4.6.1.2 (Effects of Climate Change in the United States – Environmental Justice).

10.2 PROPOSED ACTION AND ALTERNATIVES

10.2.1 General Context Comments

Comments

Comment Number: 0557-16
Organization: The Natural Resources Defense Council
Commenter: Luke Tonachel, Brian Siu

The NHTSA CAFE DEIS should distinguish how more aggressive alternatives to the proposed standard put the U.S. on a more certain path for solving global warming.

Comment Number: 0598-7
Organization: Sierra Club
Commenter: Caroline Keicher

Fuel economy is only one policy in the tool bag – one which can be effectively utilized to decrease the 20% of U.S. CO_2 emissions that spew from our cars and light trucks. If we are to achieve the goal of the averting dangerous global warming – which requires an 80% reduction in CO_2 below 2000 levels – then we need to assess the CAFE options in this context. In other words, NHTSA should evaluate which of the "right" scenarios will best help the U.S. reduce its emissions to the levels required to avoid dangerous climate change, not whether any of the scenarios will make a difference if we've already gone too far. We must also take measures now to reduce the rate at which emissions are growing. In this context, faster fuel economy increases will result in faster turnover of the fleet, help drive new fuel saving technologies into vehicles, and put the U.S. on the right path to reducing global warming emissions.

I feel the most disappointing thing about the Draft Environmental Impact Statement is that it fails to analyze the benefits of greenhouse gas emission reductions in the proper context. When NHTSA tries to determine the difference in global ocean temperature rise in the year 2100 resulting from a 31.6 mpg standard vs. a 35 mpg standard, statistically, there is none; however, this does not mean that raising fuel economy standards faster will not have a significant impact in our struggle to reduce global warming pollution.

Comment Number: 0550-7
Organization: Individual
Commenter: Sarah Larsen

In the United States, emissions from the transportation sector account for roughly 20% of our country's greenhouse gas pollution; therefore, any projected decreases in greenhouse gas emissions arising from increased fuel economy standards can never be greater than 20%. For that reason, reductions should be considered as a proportion of the 20% – not as a proportion of the entire planet's combined carbon emissions.

Comment Number: 0554-7
Organization: Individual
Commenter: James Adcock

"Divide and Conquer" NHTSA's analysis of GHG emission from cars and trucks which only looks at U.S. cars and trucks, only looks at the regulatory delta of those cars and trucks, and only looks at the U.S. part of the SCC [social cost of carbon] value of those cars and trucks is a case of "Divide and Conquer" where each regulatory agency of the government claims its actions are small enough to be considered "negligible" in the global context, whereas the reality is that GHG pollution from cars and trucks worldwide represents a large fraction of the entire GHG problem. On the contrary, NHTSA should be considering vehicle GHG emissions as being part of an overall scheme necessary to reduce total GHG emissions in the U.S. and around the world. For example, if GHG is reduced by 10% by NHTSA's regulations, consider if this was part of scheme to reduce total GHG emissions by 10% in the U.S., and around the world.

Commenter: Luke Tonachel, Brian Siu

The inability to differentiate the impacts among alternatives is the result of NHTSA's failure to consider light-duty fuel economy increases in the context of other measures designed to reduce global warming pollution. Fuel economy standards must be evaluated in the context of a comprehensive package of emission reduction measures needed to meet GHG emission reduction targets necessary to solve global warming. To draw an analogy, when a state must clean up its air to meet national ambient air quality standards, a State Implementation Plan, or SIP, must be submitted to EPA describing how pollution reductions will be achieved from a package of regulations on vehicles, fuels and consumer products. To solve global warming, GHG emission reductions are needed beyond the transportation from other energy-intensive sectors of the economy including power generation, industrial, commercial and residential sectors. When considered alongside measures in other sectors, it is clear that fuel economy standards play a critical, substantial role in avoiding dangerous climate change and more stringent standards are critical for achieving the necessary global warming pollution reductions in the transportation sector.

The weak passenger vehicle standard proposed by NHTSA for MY 2011-MY2015 does not ensure that vehicle fuel economy levels will be on a continuous, smooth trajectory to meet the longer term fuel economy necessary to achieve 2050 GHG emission reduction targets. This introduces serious risk because the necessary trajectory gets steeper and steeper the longer we wait.

Reducing global warming pollution 80 percent by mid-century will require the United States to substantially transform its energy economy. NRDC examined multiple strategies to reduce global warming pollution on both the demand (energy consuming) side and the supply (energy producing) side of the equation and pinpointed six major groups of energy sector opportunities that will put America on the path to significantly reducing the pace and magnitude of global warming. [Footnote: These measures achieve three-quarters of the reductions needed by 2050. The remainder would come from non-CO_2 gases, forestry measures, and innovations to address thousands of smaller sources.] In this context, fuel economy standards are a very significant strategy for reducing U.S. emissions. As shown in Figure 1 [See original comment document for Figure 1], when combined with smart growth measures, improved vehicle efficiency can contribute 13% of total reductions needed. [See original comment document for Figure 1.]

In terms of the transportation sector alone, fuel economy improvements comprise an even larger share of the GHG reductions. NRDC estimates that improved efficiency can contribute nearly 60 percent of the cumulative GHG reductions needed from the passenger vehicle sector. As shown in Figure 2, achieving 80% reductions from current emissions in the light-duty vehicle fleet requires a combination of improved fuel economy, smart growth, increased transit investments and a transition to low carbon alternative fuels such as electricity and biofuels. [See original comment document for Figure 2.] Without significant and early GHG reductions from greater vehicle efficiency, achieving the 80 percent reduction target becomes extremely challenging, if not impossible.

Commenter: Arthur Marin

The DEIS disregards these factors and NHTSA concludes that the standards will have a negligible impact on climate change. Quoting from the DEIS:

"…because EISA requires average fuel economy of the passenger car and light truck fleet to reach a combined 35 mpg by 2020, the MY 2016-2020 CAFE standards are a reasonably foreseeable future action. Accordingly, the cumulative impacts analysis assumes the minimum MY 2016-2020 CAFE standards necessary to get to 35 mpg by 2020…Overall, the emission reductions for the MY 2011-2015 CAFE alternatives have a small impact on climate change. The emission reductions and resulting climate impacts for the MY 2011-2020 standards are larger, though they are still relatively small in absolute terms."

NHTSA's approach with the DEIS is unfortunately consistent with EPA's discredited argument in *Massachusetts v. EPA* 127 S. Ct. 1438 (2007) as to why that federal agency should not regulate GHGs emissions from new motor vehicles. EPA's rationale was that such regulations would have an insignificant effect on mitigating climate change. The Supreme Court rejected EPA's argument, pointing out that, "Agencies, like legislatures, do not generally resolve massive problems in one fell regulatory swoop. ('[A] reform may take one step at a time, addressing itself to the phase of the problem which seems most acute to the legislative mind' [internal citation omitted].)… And reducing domestic automobile emissions is hardly a tentative step… [T]he United States transportation sector emits an enormous quantity of carbon dioxide into the atmosphere."

Commenter: Mark Cooper

Because improvements in fuel economy alone do not solve the climate change problem, they are shown to have zero effect on the damage that global warming will do. Yet, every reasonable analysis of the big picture and the global impacts of greenhouse gas emissions recognizes that reductions of emissions in the transportation sector must play a large role in the overall solution to the problem. [Footnote: See original comment document.]

- Indeed, because of the nature of the sector, it is vital to get the maximum possible contribution to reductions from this sector to achieve a solution.
- Because no individual policy can solve the problem, this approach will reject every policy measure individually, even though taken together they can actually solve the problem.

Unfortunately, in NHTSA's approach, the whole is not even equal to the sum of its parts. NHTSA's approach embodies a myopic bias against action. NHTSA should start from an estimate of what the value of a solution to the national energy problem would be worth, and then give increases in fuel economy credit for their role in that solution.

The NHTSA has failed to present, as it must, information and analysis in a way that provides meaningful insight into the relevant environmental problems and available solutions. The information in the DEIS on climate impacts is presented in a misleading manner and without appropriate context. Under NEPA an EIS must be written in "plain language" so that decisionmakers and the public can readily understand it. 40 CFR § 1502.8. The ultimate purpose of an EIS is to inform decisions. To do so, the information must not only be comprehensible to non-experts, but also present the context for the information in a manner that elucidates and explains the importance of each aspect of the decision.

The DEIS fails in this regard because it presents the information on the impacts of climate change in a way that minimizes the apparent potential for substantial harm. Even more problematic is the minimization of the apparent influence of each alternative on climate change. Throughout the DEIS the impact of each alternative as well as the difference between alternatives is presented as insignificant and meaningless. Although the DEIS mentions many of the potential consequences of increased atmospheric CO_2, the data is presented in a disjointed manner and qualified as "uncertain." Yet it has been decades since there has been any real scientific uncertainty regarding whether climate change is occurring as a result of increasing concentrations of anthropogenic (Oreskes 2004).

The reality is that, as discussed in previous sections, there is a substantial risk of climate disaster if U.S. greenhouse gas emissions continue unchecked. This collision course towards climate disaster can be avoided through efforts to reduce quickly reduce emissions. The transportation sector is one of the largest sources of emissions, and therefore also an essential part of the solution. Stringent CAFE standards can be part of one of the most significant components of a national greenhouse gas emissions reduction program. This substantial opportunity, however, is never explained to the reader, but rather, the reader is left with the impression that NHTSA's actions will make very little difference one way or another. This is profoundly misleading and violates NEPA's disclosure requirements.

Global warming is the quintessential cumulative impact – the environmental problem caused by all contributing sources of greenhouse gas emissions together is far greater than that caused by any individual source. The purpose of the cumulative impacts section is to discuss the impact of the

NHTSA's rulemaking on the problem overall when considered along with other actions. The NHTSA must place its action in the proper context in order to provide the reader with meaningful information about the impact of its action. For example, the DEIS should answer the question, "to what degree does the NHTSA rulemaking contribute to or hinder the achievement of the greenhouse gas emissions reductions necessary to avoid catastrophic climate change?" The DEIS fails utterly to do so.

The DEIS considered only a single factor in the cumulative impacts section beyond the rulemaking itself – the impact of fuel economy standards for model years 2016-2020. As discussed above, the impact of future fuel economy standards should have been incorporated into the analysis of direct and indirect impacts, as the level chosen by the NHTSA for one year will impact the level achievable in future years. Regardless, however, limiting the cumulative impacts analysis to only considering fuel economy standards for model years 2016-2020 is clearly inadequate on its face to comply with NEPA's requirements.

The DEIS must include a reasonable analysis of the combined impact of the NHTSA's rulemaking on U.S. transportation sector emissions overall, and U.S. emissions overall. For example, is the impact of the current rulemaking sufficient to ensure that the necessary emissions reductions from the U.S. transportation sector overall will be achievable? If the transportation sector does not achieve its "fair share" of necessary emissions reductions, after all, those reductions will have to come from a different sector. While the NHTSA will likely argue that it is difficult to conduct a cumulative impacts analysis for a problem such as greenhouse gas emissions, it is eminently feasible to do so. While the NHTSA has some discretion in choosing the precise methodology of such an analysis, the agency was clearly not free to omit any such analysis altogether.

Figure 1-1 on page 24358 of the NPRM is titled "CO_2 tailpipe emissions avoided due to increases in fuel economy 1975-2005." This graphical presentation of estimated reductions from hypothetical emissions levels seriously misrepresents the situation. Global climate change is a result of increasing atmospheric concentrations of greenhouse gases, and greenhouse gas emissions from automobiles has significantly increased over the past thirty years. It would be much more instructive to the public and to NHTSA to consider both annual and cumulative CO_2 tailpipe emissions over that same period of time.

Commenter: Eli Hopson

If we are the avoid the worst impact of climate change, our nation and the world must adopt a target that will keep global temperature from rising more than 2 ^{o}C above pre-industrial levels. That means stabilizing the concentrations of global warming pollutants in our atmosphere at no more than 450 parts per million carbon dioxide equivalent. Analysis by UCS [Union of Concerned Scientists] shows that one part of achieving this goal means the United States must cut global warming pollution by at least 80% compared to emission levels in 2000. [Footnote: http://www.ucsusa.org/assets/documents/ global_warming/emissions-target-report.pdf.] In addition, UCS analysis indicates that in order to effectively achieve such a long-term goal, U.S. global warming pollution must be cut by more than 20% below 2000 levels by 2020, and at least 50% below by 2030. The need for comprehensive climate policy, both in the near and long term is not properly addressed in the draft EIS, nor is the cost of inaction.

Comment Number: 0575-28
Organization: Union of Concerned Scientists
Commenter: Eli Hopson

Major concern with the draft EIS: The analysis done by NHTSA only presents the reductions in the context of their direct impact relative to all man-made global emissions rather than just the emissions from the sector policy targets. Just because higher U.S. fuel economy standards alone won't solve global warming does not discount the fact that they are a vital, necessary part of the solution. By stating them in terms of the percent reduction from covered vehicles (approximately 30 percent) rather than in percent of worldwide reductions (0.8-1.1 percent reduction according to the DEIS) the value of fuel economy in reducing global warming pollution would be clearer, and less misleading to the public. NHTSA's approach in the EIS is like arguing that we shouldn't worry about smoking in 16 year olds because they only represent a small portion of all smokers. This argument could be applied to any sector of the economy to argue for inaction. Instead we must begin to reduce global warming pollution from every sector as soon as possible.

Comment Number: 0576-6
Organization: Public Citizen
Commenter: Joan Claybrook

For this draft EIS to be useful as a decision-making tool, it must compare the impacts of various alternatives in the proper context. Light duty vehicles built for sale in the United States are part of the whole set of greenhouse gas-emitting sources, regulation of which, as NHTSA has stated, cannot alone stop global warming from happening. [Footnote: See original comment document.] However, the agency has not established a meaningful context, instead choosing to extrapolate the benefits of each alternative over the entire globe 90 years into the future. NHTSA must discuss the benefit of any action in terms of its impact on climate change and it must be placed into a context that includes other strategies to reduce greenhouse gas emissions. This perspective allows for decisionmakers and the public to judge whether the agency's proposed action results in emissions reductions that are consistent with the contribution to emissions from light duty transportation in light of the technological feasibility of making those emissions reductions.

The draft EIS states that none of the proposed alternatives actually result in absolute reductions in greenhouse gas emissions, but instead result in a reduced rate of greenhouse gas emissions from light duty passenger vehicles. [Footnote: See original comment document.] NHTSA must therefore consider fuel economy standards as part of a comprehensive strategy to reduce greenhouse gas emissions from light duty transportation that may include policies that are not within its jurisdiction. NEPA requires "considerations of both context and intensity. . . . [Context] means that the significance of an action must be analyzed in several contexts such as society as a whole (human, national), the affected region, the affected interests, and the locality. Significance varies with the setting of the proposed action. For instance, in the case of a site-specific action, significance would usually depend upon the effects in the locale rather than in the world as a whole. Both short- and long- term effects are relevant. (40 CFR 1508.27) In this case, significance requires that NHTSA consider impacts in the context of multiple strategies for reducing greenhouse gas emissions from light duty transportation as part of a comprehensive strategy to achieve atmospheric concentrations of greenhouse gases that will prevent the most harmful effects of global warming.

For the context to be meaningful, NHTSA needs to establish a target for greenhouse gas reductions. It can then show how the various proposed alternatives fit into the reductions that are necessary from the U.S. light duty transportation sector to meet that target. Public Citizen supports reduction of atmospheric concentrations of CO_2 to 350 parts per million (ppm) to prevent the most catastrophic effects of climate change. [Footnote: See original comment document.] The policy debate surrounding global warming has considered other targets for atmospheric concentrations, such as 450 ppm or 550 ppm. Public Citizen does not seek to resolve the question of a target for atmospheric concentrations of greenhouse gases at this time, nor does it expect that NHTSA resolve this question in the draft EIS. However, NHTSA must present the regulatory alternatives for fuel economy standards required under EISA such a way as to present a clear choice to decisionmakers and the public. The agency must therefore select a target or range of atmospheric concentrations of greenhouse gases to provide a framework within which it can discuss the relative benefit of different regulatory options.

Comment Number: 0585-7

Commenter: Edmund Brown Jr., Joseph Powers, Martha Coakley, Michael Cardozo, Anne Milgram, Gary King, Andrew Cuomo, Hardy Myers

Further, in its cumulative impacts analysis, NHTSA takes into account only the impact of its own rulemaking and ignores actions that can be anticipated in the transportation sector overall, and in other energy sectors in the United States and globally. See, e.g., WCI Statement of Regional Goal; Overview of RGGI CO_2 Budget Trading Program, supra. The DEIS then compares the limited changes in the CAFE sector with worldwide emissions to determine the effect of these changes on CO_2 concentrations and temperature. See, e.g., DEIS at 4-24, 4-31. The analysis demonstrates, not surprisingly, that the change in CO_2 concentrations and temperature caused solely by the CAFE rules will be relatively modest, ranging from 3.5 to 4.9 parts per million (“ppm”) CO_2 concentration, and 0.012 to 0.018 degrees Celsius temperature. Table 4.4-3 at DEIS 4-31.

This comparison is invalid because it considers only the very limited change from the CAFE rules, while ignoring the cumulative impact of all other reasonably anticipated actions that will reduce GHG emissions both in the United States and globally. A proper cumulative impacts analysis requires the agency to consider reasonably anticipated actions by other agencies along with the impact of the CAFE rules, to determine the impact on GHG emissions and global warming.

We recognize that a cumulative impacts analysis is complex in the context of climate change because the problem is global and is being addressed at many levels worldwide. While it is difficult to determine the expected emissions reductions on a global scale, this uncertainty should not result in NHTSA understating the significance of its role in helping to resolve the climate problem. NHTSA thus must make an effort to determine whether better decision-making on its part, and a more stringent CAFE standard, will help to put this country on a path to climate stabilization, even if the Agency, standing alone, cannot resolve the problem.

Comment Number: 0596-5
Organization: Environmental Defense Fund
Commenter: Martha Roberts

We strongly recommend that NHTSA revise this EIS and incorporate a wedge- type analysis of the cumulative emissions resulting from the proposed CAFE alternatives. The EPA transportation sector analysis can serve as a reference, although we find their stabilization target of 560 ppm CO_2 not sufficient to avoid the 2.6 °C increase in global temperature, IPCC’s best current estimate of the threshold that avoids serious climate change effects. We believe the EIS must adopt the 440 ppm CO_2 atmospheric stabilization target identified by the IPCC unless the agency can point to other analyses of equal or greater credibility that justify the use of a higher CO_2 target to reach the same temperature goal.

As a demonstration, we have followed the framework of the EPA's wedge analysis and utilized the predicted future GHG emissions provided in the EIS. We demonstrate in a simplistic manner the contributions of the various CAFE alternatives to a U.S transportation sector target of flattening emissions at 2006 levels. Under the "no action" alternative, cumulative GHG emissions beyond the 2006 baseline total 28,000 MMT [million metric tons] CO_2e [CO_2 equivalent] by the year 2050. The "optimized" alternative results in 21,000 MMT CO_2e and the "technology exhaustion" option releases 18,000 MMT CO_2e. These two options contribute 1.6 wedges ("optimized") and 2 wedges ("technology exhaustion") of 5,000 MMT CO_2e towards flatlining transportation GHG emissions at 2006 levels (figure 2). We note that the EPA's analysis finds 2.4 to 3.0 wedges result from technology exhaustion, while NHTSA claims that this leads to only 2 wedges. We urge NHTSA to account for this difference in their revised EIS, with special attention given to assumptions regarding hybrid vehicle technology.

Increasing fuel efficiency on its own cannot mitigate U.S. transportation-related GHG emissions to an extent that avoids dangerous climate change. However, the transportation sector can stabilize its GHG emissions with a package of approaches. Rapidly increasing fuel efficiency is a key component to reducing cumulative GHG emissions over the next decades, as the EPA recognizes that "[n]ear-term vehicle technologies can have as much of an impact in terms of GHG reductions as future, longer-term technologies." [Footnote: See original comment document.]

Comment Number: 0598-10
Organization: Sierra Club
Commenter: Caroline Keicher

NHTSA should consider the Supreme Court decision in *Massachusetts v. EPA* and that the Court stated, on pages 2 1-23 concerning vehicle emissions, that "reducing domestic automobile emissions is hardly a tentative step." The Court also noted that cars and trucks account "for more than 6% of worldwide carbon dioxide emissions. To put this in perspective: Considering just emissions from the transportation sector, which represent less than one-third of this country's total carbon dioxide emissions, the United States would still rank as the third-largest emitter of carbon dioxide in the world, outpaced only by the European Union and China. Judged by any standard, U.S. motor-vehicle emissions make a meaningful contribution to greenhouse gas concentrations and hence, according to petitioners, to global warming."

This DEIS turns these words on their head – diminishing the differences between the options (which are too low to begin with) and failing to meaningfully express the role fuel economy can have on U.S. emissions. In addition, by allowing that Massachusetts had legal standing in the findings of *Mass. v. EPA*, the Court also recognized the importance of the remedy – that even a small step provides relief from global warming. We would agree that increasing fuel economy, while an important part of this remedy, cannot be the only solution.

Comment Number: 0598-6
Organization: Sierra Club
Commenter: Caroline Keicher

We also have serious concerns that the DEIS fails to meet its primary function to "inform the public that [the agency] has indeed considered environmental concerns in its decision-making process." In this case the agency does not give a fair or reasonable evaluation of the environmental impacts of the proposed standards nor does NHTSA provide a context that reasonably informs the public.

The DEIS takes the real differences between the flawed options considered and runs them so far out – to 2100 – that they cannot meaningfully be differentiated or evaluated. Faster fuel economy increases will help the U.S. cut the 20% of CO_2 emissions that come from vehicles. The difference between 35 in 2015 and 35 in 2020 is real and significant. It creates room for reaching 42 mpg in 2020 – and increases beyond (surpassing 50 mpg by 2030). It would also mean saving an additional 880,000 barrels of oil per day in 2020 and further reductions in emissions.

It is worth noting that the DEIS reveals that this one policy is significant enough that it could affect the climate in 2100 assuming no other action is taken. The problem with NHTSA's analysis is that if we hit 700 plus ppm referenced in the DEIS, then we have not acted to prevent dangerous climate change as provided in Article 2 of Framework Convention on Climate Change.

There is no requirement that NHTSA run its analysis though 2100. NHTSA notes that the VOLPE model estimates emission reductions through 2060. The agency provides that "as a simplifying assumption, annual emissions reductions from 2061-2100 were held constant." NHTSA should assess how the correct scenarios will impact emissions from cars and light trucks in a time frame that is meaningful to the public, within the context of science, and not "simplify" its "assumptions."

Comment Number: 0598-8
Organization: Sierra Club
Commenter: Caroline Keicher

The DEIS fails to analyze the benefits of greenhouse gas emission reductions from various fuel economy standards in the proper context. Not surprisingly, when NHTSA tries to determine the global warming impacts in 2100 resulting from a 31.6 mpg in 2015 standard vs. a 35 mpg in 2015 standard, statistically, the difference is very little. But this does not mean that raising fuel economy standards faster will not have a significant impact in our struggle to reduce global warming pollution.

In order to prevent the worst effects of climate change, the U.S. must decrease its carbon emissions by around 80% by 2050 – with meaningful short-term and interim targets. In order to be on-target for reductions such as these, by 2020 the U.S. needs to reduce its carbon emissions back to at least 1990 levels. The Environmental Protection Agency's (EPA) Greenhouse Gas (GHG) emission inventory reports that 1990 levels were 6,147 Million Metric Tons of CO_2 ($MMTCO_2e$). If our emissions continue to grow, along a "business as usual" trajectory, EPA estimates that by 2020, carbon emissions will have grown to 8,264 $MMTCO_2e$. Therefore, in order to return to 1990 emission levels by 2020, we must cut (=8,264-6,147) 2,116 $MMTCO_2e$ worth of greenhouse gas pollution from various sources by 2020, or equivalent to a 25% decrease in emissions.

Now, considering that the transportation sector is responsible for nearly a third of all GHG emissions in the U.S., with cars and light trucks accounting for 20%, it would make sense that we must proportionally reduce emissions from cars and light trucks to help meet this overall 2,116 $MMTCO_2e$ reduction. Since 20% of emissions come from cars and light trucks, 20% of the 2,116 $MMTCO_2e$ target reduction, or 423 $MMTCO_2e$, should come from cars and light trucks.

The analysis of environmental impact suffers from the same affliction, because improvements in fuel economy alone do not solve the climate change problem. They are shown to have zero effect on the damage that global warming will do. Yet every reasonable analysis of the big picture and the global impact of greenhouse gas emissions recognize that the reduction of emissions in the transportation sector must play a large role in the overall solution. Indeed, because of the nature of the sector, it is vital to get the maximum contribution from transportation sources. NHTSA's approach embodies a myopic bias against action. Because no individual policy can solve the problem, this approach will reject every policy measure individually, even though taken together they can actually do the job. In NHTSA‘s view the whole is not even equal to the sum of the parts.

Comment Number: TRANS-06-8
Organization: Public Citizen
Commenter: Lena Pons

Considering that this is a new type of environmental impact statement, because it considers global impacts, it's very important that the agency put the impacts in a proper context. The agency has not put the environmental impacts into a proper context, considering the issues of global warming. Regardless of the target, NHTSA needs to provide some means of comparing the various alternatives. The way the draft environmental impact statement is currently contextualized, NHTSA states that fuel economy standards alone cannot stop global warming. But the issue is not whether fuel economy standards alone can stop global warming. The issue is to evaluate various environmental impacts of the various regulatory alternatives.

Comment Number: TRANS-07-3
Organization: Individual
Commenter: Eliza Berry

The draft environmental impact statement does not use the appropriate scale with which to measure the benefits of an increase in fuel economy standards. This scale has only allowed NHTSA to prove that a 3.4 mile per gallon increase in vehicle efficiency in the U.S. is not going to be the one thing to save the entire planet from global warming. I don‘t think that very many people would be surprised by this conclusion.

By measuring the importance of a shift in fuel economy standards like this, NHTSA has fundamentally missed something. Few people would claim that there is one silver bullet to solving global warming. Rather, we need to do everything in our power to cut greenhouse gas emissions in all sectors, the transportation sector included.

Together these seemingly small changes will make a major difference. And if the U.S. leads the way in cutting emissions, other countries will follow, thus making an even greater difference on a global scale.

I would like to ask NHTSA to acknowledge the power of collective action and take responsibility for greenhouse gas emissions from the transportation sector. As I have explained, the intergovernmental panel on climate change has emphasized the importance of requiring that greenhouse gas emissions reach their peak in no more than 10 years.

Comment Number: TRANS-08-13
Organization: Sierra Club
Commenter: Ann Mesnikoff

In this case the agency does not give a fair or reasonable evaluation of the environmental impacts of the proposed standards, nor does NHTSA provide a context that reasonably informs the public.

The draft environmental impact statement takes the real differences between the options considered and runs them out so far to 2100 that they cannot meaningfully be differentiated or evaluated. Faster fuel economy increases will help the U.S. cut the 20 percent of CO_2 emissions that come from vehicles.

The difference between 35 in 2015 and 35 in 2020 is real. It is worth noting that the draft environmental impact statement reveals that this one policy could affect climate in 2100. The problem with NHTSA‘s analysis is that if we hit 700 parts per million plus, referenced in the DEIS, we have not averted dangerous climate change.

There is no requirement that NHTSA run its analysis through 2100. NHTSA notes that its Volpe model estimates emissions reductions through 2060. The agency provides, as a simplifying assumption, annual emission reductions from 2061 to 2100 were held constant. NHTSA should assess how the correct scenarios will impact emissions from cars and trucks in a time frame that is meaningful to the public, and within the context of science, not simplifying assumptions.

Fuel economy is only one policy in the tool bag. It will diminish the 20 percent of CO_2 that comes from cars and trucks, but we must achieve and 80 percent reduction below 2000 levels by 2050 if we are to avert dangerous climate change.

Comment Number: TRANS-09-4
Organization: Individual
Commenter: Doug Molof

NHTSA‘s draft EIS fails to analyze, also, the benefits of greenhouse gas emissions reductions through various fuel economy standards in the proper context. Not surprisingly, when NHTSA tries to determine the difference in global ocean temperature rise in 2100, resulting from a 31.6 mile per gallon standard in 2015, versus a 35 mile per gallon standard in 2015, statistically there is no difference.

But emissions from the transportation sector in the United States account for roughly 20 percent of our country‘s greenhouse gas pollution. And as any projection, decreases in greenhouse gas emissions arising from increased fuel economy standards can never be greater than this. These reductions should be considered as a proportion of the 20 percent, not as a proportion of the entire planet‘s combined carbon admissions.

This can simply overwhelm any measurable progress. Success and progress should be measured by how close these fuel economy improvements get us to reducing the transportation sector‘s carbon emissions by 80 percent in 2050. To do otherwise fails to realistically evaluate vehicle emission reductions as a key part of the overarching strategy to curb global climate change.

Comment Number: TRANS-13-3
Organization: Individual
Commenter: Joseph Frewer

As you‘ve heard multiple times, the scientific conclusion is that to mitigate the worst effects we really need to cut our carbon pollution by 80 percent by 2050.

And many of us are agreed that the best way to do this is by utilizing every tool we can. We‘ve got to look at every aspect of our economy, not only the transportation sector, which is addressed here, but many other parts, industrial – I don‘t need to go into them.

But this 20 percent is part of a bigger picture, and we must take that into account when looking at a global solution. Just because it‘s 20 percent doesn’t mean that it’s any less important and that it can be ignored, just because when you look at in the context of 100 percent global emissions picture, it doesn’t seem that important as it is.

NHTSA's draft environmental impact statement fails to analyze the benefits and reduction for fuel economy standards in the proper context because it is going by the bare minimum. As we have said, I'll try not to go into the same statistics that we've heard, but 31.6 miles per gallon, the bare minimum, just won't cut it. There are already cars being released that promise to offer more than 31.6 miles per gallon of gasoline.

Comment Number: TRANS-19-1
Organization: Union of Concerned Scientists
Commenter: Eli Hopson

The fuel economy standards are being measured for their global impact, even though they only affect a portion of all manmade sources of global warming pollution.

Comment Number: TRANS-19-3
Organization: Union of Concerned Scientists
Commenter: Eli Hopson

Analysis by UCS [Union of Concerned Scientists] shows that one part of achieving that goal means the United States must cut its global warming pollution at least 80 percent compared to emissions levels in 2000. In addition, our analysis indicates that in order to effectively achieve such a long term goal, we have to start now. We have to reduce our pollution 20 percent below 2000 levels by 2020 and at least 50 percent below by 2030. The need for these long term targets and immediate action is not effectively covered in the EIS, and the cost of inaction of the size of this challenge also should be better reflected.

Comment Number: TRANS-19-4
Organization: Union of Concerned Scientists
Commenter: Eli Hopson

Unfortunately, the analysis done by NHTSA only presents the reductions from the fuel economy rule in the context of their direct impact relative to all manmade global emissions, rather than just the emissions from our cars and trucks. Because higher fuel economy standards alone won't solve global warming does not discount the fact that they are a vital, necessary part of the solution. By stating them in terms of their percent reduction from the sector, approximately 30 percent, rather than a percent of world reductions which is .8 to 1.1 percent, according to the draft EIS, the value of the fuel economy in reducing global warming pollution and helping us meet those near term targets will be clear and less misleading to the public.

Comment Number: TRANS-20-2
Organization: Sierra Club
Commenter: Caroline Keicher

In the short term this is going to mean that we need to reduce our emissions between 25 and 40 percent by 2020, so a much sooner time line. This is a much bigger number, and this is what's most relevant with these new CAFE increases.

If we're going to evaluate how an increase in corporate average fuel economy affects global warming, this is the target that we should be focused on, not some obscure number in 2100.

Comment Number: TRANS-20-5
Organization: Sierra Club
Commenter: Caroline Keicher

The scientists made it clear that to avoid the worst effects of global climate change, we must achieve 80 percent reduction in our emissions by 2050. This gives us approximately 40 years to get our act together, and we have no time to lose.

Unfortunately, there is no single thing that we can do, or single sector in our economy that we can cut to get us all the way there. We must instead start making manageable emission reductions from each single carbon emitting sector of our economy. And when considering the benefits of doing so, we must consider each reduction as part of the larger long term goal, both for the United States and globally. Each reduction that we fail to make in one area will have to come from somewhere else.

The most disappointing thing for me about NHTSA's draft environmental impact statement is that it fails to analyze the benefits of greenhouse gas emission reductions from various fuel economy standards in the proper context. Not surprisingly, when NHTSA tries to determine the global warming impacts resulting in 2100 from various standards, 31.6 miles per gallon in 2015 versus 35 miles per gallon, there isn't statistically much of a difference.

And this isn't surprising. It also doesn't mean that raising fuel economy standards faster will not have a significant impact in our struggle to reduce global warming pollution.

Emissions from the transportation sector in the United States account for roughly one-third of our greenhouse gas emissions, with cars and light trucks coming in at about 20 percent. That's a fairly large chunk of our contribution to this global problem.

So what is the proper context? How do we consider these various CAFE increases? Globally the science has called for long term reductions of emissions of about 50 percent for the entire world by 2050. Here in the U.S. as an industrialized nation that accounts for nearly a fourth of world carbon dioxide emissions, this translates for us into about 85, 80 to 95 percent needed reductions below 2000 levels by 2050.

Comment Number: TRANS-21-1
Organization: Individual
Commenter: Christina Marie Yagjian

NHTSA's draft environmental impact statement fails to analyze the benefits of greenhouse gas emissions, emission reductions from fuel economy standards in the proper context. As I mentioned, we know that emissions from the transportation sector account for roughly 20 percent of the country's global warming pollution.

The EIS projected decreases in emissions rising from increased fuel economy standards are analyzed as a proportion of combined global carbon emissions. This figure is more clearly evaluated when presented as a proportion of the current 20 percent of domestic emissions.

Comment Number: TRANS-21-4
Organization: Individual
Commenter: Christina Marie Yagjian

The science has made it clear that to avoid the worst effects of global warming, we must achieve 80 percent reductions in global warming emissions by 2050. As cars and light trucks account for 20 percent of the country's global warming emissions, the single biggest step that we can take in this country to reduce global warming emissions, save consumers money at the gas pump, and reduce America's dependence on foreign oil is to make our cars and light trucks go further on a gallon of gas.

Comment Number: TRANS-24-7
Organization: Individual
Commenter: Heather Moyer

Although there is no silver bullet to get us to an 80 percent reduction in carbon emissions by 2050, the single biggest step we can take in this country to reduce our global warming emissions, save consumers money at the pump, and reduce our dependence on foreign oil, is to make our cars and trucks go farther on a gallon of gasoline.

Comment Number: TRANS-27-2
Organization: Individual
Commenter: Sarah Karlin

The science has made it clear that in order to avoid the worst effects of global warming, we must achieve an 80 percent reduction in greenhouse gases by 2050. At first glance, this may seem like a daunting task, but if we start now, and if like the Little Engine That Could, we believe we can, the U.S. can achieve the necessary emission cuts to prevent the most tragic impacts of climate change.

Yet NHTSA's draft environmental impact statement fails to analyze the benefits of greenhouse gas emission reductions from various fuel economy standards in the proper context.

Not surprisingly, when NHTSA tried to determine the difference in global ocean temperature rise in 2100, resulting from a 31.6 miles per gallon in 2015 standards, versus a 35 mile per gallon in 2015 standards, statistically there is none.

But this does not mean that raising fuel economy standards faster will not have a significant impact in our struggle to reduce global warming pollution. Emissions from the transportation sector in the United States account for roughly 20 percent of our country's greenhouse gas pollution, and as any projected decreases in greenhouse gas emission arising from increased fuel economy standards can never be greater than this, those reductions should be considered as a proportion of the 20 percent, not as a proportion of the entire planet's combined carbon emission. The latter simply overwhelms any measurable progress.

Adequate fuel economy standards can help the U.S. make a significant dent in our overall carbon emissions by 2050. Sure, other measures will need to be taken to meet the 80 percent reduction by 2050. But the transportation sector must play its part.

Comment Number: TRANS-32-4
Organization: Environmental Defense Fund
Commenter: James Keck

By presenting only the isolated impact of this one set of U.S. regulations upon the entirety of global climate change, and then asserting that health and other impacts are too uncertain to distinguish among the range of alternatives, NHTSA is certainly closing its eyes to the context of this regulation as well as the full set of cumulative impacts relevant to this EIS.

The EIS draws heavily upon the most recent IPCC report in describing the causes of climate change and its impacts on the environment and human welfare. However, the EIS ignores the IPCC's description of targets for avoiding the most drastic of these impacts. For example, the IPCC states that avoiding a temperature increase of more than 2.6 degrees centigrade from pre-industrial times reduces the risk of key environmental and health vulnerabilities, and to do this greenhouse gas emissions must peak within 10 years, and atmospheric carbon dioxide levels stabilize at less than 440 parts per million.

The absence of this critical context within the EIS leaves the public and policy makers unclear whether the preferred CAFE alternative will support a cumulative strategy to avoid the most serious climate change impacts. Although the IPCC report provides a clear context and benchmark by which NHTSA can assess the alternatives, the EIS has failed to do so.

Comment Number: TRANS-35-4
Organization: Individual
Commenter: Alina Fortson

In order to address climate change, scientists are stressing the importance of achieving an 80 percent reduction in greenhouse gas emissions by the year 2050. This means making small reductions in all of our emission areas, including transportation.

The United States transportation sector amounts to approximately 20 percent of our total greenhouse gas emissions. Therefore, measuring our progress requires considering reductions as a portion of that 20 percent, not as part of the global emissions. In this light, every small improvement does make a difference.

Comment Number: TRANS-36-1
Organization: Individual
Commenter: Matt Kirby

So now the science says we need 80 percent reductions by 2050, as several people have said. And one of the most significant being the cars and light trucks, the 20 percent, the 20 percent of emissions in this country, which emits 25 percent of global emissions. 20 percent of 25 global emissions. That’s the power you have. And that’s what you can change and significantly alter the course of global warming.

As far as the environmental impact statement goes, we know we need to look at this proportionally to our domestic emissions, to our 20 percent of our domestic emissions, and not as part of the global outreach to get a better idea of how to evaluate it.

Also, NHTSA has picked 2100 as a time line for measuring success, which seems a little ridiculous, considering we have until 2050 to avert catastrophic climate change. So I would urge you to actually set a much closer goal, 2020-25 when you actually are going to begin measuring the success.

Comment Number: TRANS-37-4
Organization: Individual
Commenter: Jaafar Rizvi

While the DEIS report shows very detailed calculations and extensive research, the claims of NHTSA just don’t coincide with the claims of other incredibly credible scientific institutions. Like so many people have said, there’s a call for 80 percent reductions by 2050, and this report doesn’t seem to acknowledge that.

And that’s fine, of course, but since, you know, research was done, but there’s no description of where the divergence is coming from.

Comment Number: TRANS-41-3
Organization: Individual
Commenter: Catherine Easton

Global warming is happening right now, and reducing greenhouse gas emissions by 80 percent by 2050 will save us from the worst effects of global warming. But unfortunately, as I think we've all noticed, 80 percent is a lot and increasing CAFE standards will not achieve this.

In fact, no individual sector could reach such a dramatic decrease. And this is why we must strive for smaller achievable decreases in all sectors. These small decreases combined could make a substantial difference.

Comment Number: TRANS-44-1
Organization: Individual
Commenter: Emily Spear

Increasing fuel economy standards would be one step in curbing global warming. Scientific reports have concluded that in order to avoid catastrophic effects of global warming, we must reduce our greenhouse gas emissions by 80 percent by 2050, 2050.

This issue is staring us in the face, but I believe that NHTSA can do its part by requiring vehicles to be more fuel efficient. We know that carbon emissions from transportation mechanisms are great at 20 percent, which contribute directly to global warming. However, it concerns me when NHTSA's draft environmental impact statement analyzed the resulting benefits of greenhouse gas emissions from higher fuel economy standards in an improper context, which makes the greenhouse savings appear insignificant, though increasing fuel economy standards to 35 miles per gallon by 2015 would save 280 million metric tons of carbon dioxide.

Response

The comments above share the themes that the DEIS diminished the effect of the CAFE standards by evaluating them in a global context (thus, their effect on climate conditions would be small, and their contribution to total emissions reductions required to meet any of several long-term stabilization goals would be small); that a timeline stretching to 2100 is too long; and that the environmental impacts can only be characterized adequately if this rulemaking is considered in light of all other possible actions to mitigate climate change.

NEPA requires NHTSA to analyze the reasonably foreseeable environmental impacts of a range of alternatives in setting new CAFE standards for MY 2011-2015. According to NEPA, the alternatives are the "heart of the environmental impact statement." 40 CFR § 1502.14. Under EPCA, as amended by EISA, NHTSA is required to set standards at the "maximum feasible" level, considering technological feasibility, economic practicability, the effect of other government motor vehicle standards on fuel economy, and the need of the United States to conserve energy." 49 U.S.C. § 32902(f). NHTSA has a long-standing practice of analyzing regulatory options based on the best available information regarding: (1) the future vehicle market, (2) the technologies expected to be available during the relevant model years, and (3) the key economic factors, such as future fuel prices, and other statutory factors. The Volpe model is a tool NHTSA uses to help balance these factors. NHTSA has rigorously explored and objectively evaluated the range of possible alternatives, including reasonable alternatives not within the agency's jurisdiction, to provide decisionmakers and the public with information on a broad range of *impacts. NHTSA took the requisite "hard look" at environmental impacts, quantified to the degree possible, from these alternatives.*

Climate change is a global phenomenon. GHGs persist in the atmosphere, and the effects of a given level of emissions in one location occur no matter the location of the emissions. Thus, the appropriate scale is to evaluate the effects of this rulemaking in relation to global emissions and global climate conditions. This is the standard approach for climate modeling. While Sections 3.4 and 4.4 of this FEIS show that the differences in climate effects (CO_2 concentration, temperature, sea–level rise, precipitation) might seem small when expressed in terms of climate endpoints, NHTSA agrees with commenters that this is likely to be true for any given GHG mitigation strategy when taken alone. NHTSA's hard look at the rule's effect on global climate conditions is not intended to diminish the effectiveness or importance of the regulatory options in reducing CO_2 emissions and global warming impacts, but to quantify these potential reductions using the best available science.

Several commenters stated that NHTSA is claiming a reduction in emissions even though total vehicle emissions are rising over time. Specifically, CBD stated that Figure 1-1 on page 24358 of the NPRM titled "CO_2 tailpipe emissions avoided due to increases in fuel economy 1975-2005" was misleading because total vehicle emissions increase over time. NHTSA does not have the authority to control factors that affect total vehicle emissions, such as the number of vehicle miles traveled. NHTSA's CAFE standards set minimum requirements for the fuel efficiency of the vehicles used in travel. In the absence of these minimum requirements, the actual emissions release (if all other factors stayed the same) would be higher. Consequently, NHTSA states that the CAFE rulemaking results in reduced emissions levels compared to not having implemented the regulations. To help the reader understand that the rulemaking reduces the rate of increase of emissions, NHTSA has included a new analysis and a diagram in Section 3.4.4.1 of this FEIS showing the reduction in emissions rates.

To complement the analysis of climate effects, Section 3.4.4.1 of this FEIS includes a section on emissions reductions, putting them in context by comparing them to other large-scale regional programs in the United States. This indicates that the emissions reductions (in relation to Alternative 1, the No Action Alternative) are indeed quite large compared to the other programs. Even though the initiatives might vary in their approach, goals, and reduction comparisons, this discussion places the contribution of this rulemaking in the context of current CO_2 reduction plans.

A theory on climate change mitigation promulgated by Pacala and Socolow (2004), called the Wedge Theory, shows that by taking numerous actions that reduce CO_2 from various sectors, overall there can be CO_2 reductions great enough to reduce further global warming. As several commenters point out, the alternatives identified in this FEIS serve as another contribution to reduce CO_2 emissions that requires a global effort to be successful. NHTSA has expanded the discussion on this issue. <u>See</u> FEIS Section 3.4.4.1.

On the point that environmental impacts can only be characterized adequately if this rulemaking is considered in light of all other possible mitigation actions, IPCC notes that the momentum in the climate system is enormous, and that it would take large-scale action across many sectors and nations to deflect the current course of climate change. These large-scale actions remain to be determined (specific courses of action are not reasonably foreseeable) and they are outside NHTSA's regulatory purview. As discussed in detail in Section 4.4.4.1, U.S. cars and light trucks account for 19.2 percent of CO_2 emissions in the U.S. and about 2.5 percent of global CO_2 emissions. NHTSA's influence from this rulemaking can only affect this set of emissions, and only a portion of that, because NHTSA does not directly control VMT. Establishing national policy or GHG targets (such as an 80 percent reduction by 2050) exceeds NHTSA's authority. Addressing climate change in a meaningful way would likely require new Congressional legislation in conjunction with that from other nations.

Nevertheless, NHTSA fully appreciates the fact that, despite the complex global nature of the problem, NHTSA still has an obligation to take the requisite "hard look" regarding, the effects of this rulemaking on global warming within the context of other actions that affect global warming. Thus, NHTSA believes that the range of alternatives considered in the DEIS and this FEIS will fully inform the decisionmaker and the public about the environmental impacts, including climate change issues, of any CAFE standard that is reasonable to promulgate.

Contrary to several comments, the emissions analysis provides important information concerning the differences between the alternatives. Table 3.4-2, in particular, provides the emissions impact of each alternative for each decade through 2060.

Many comments appear to draw the conclusion that NHTSA does not think the CO_2 reductions from the rulemaking are important and that NHTSA does not show differences between the alternatives. NHTSA recognizes that merely because the reductions are small in a global context does not mean they are unimportant. In addition, NHTSA's analysis shows clear emissions reductions between the alternatives, even if not every climate effect shows measurable differences. NHTSA's environmental analysis differentiates the various alternatives presented in the DEIS and this FEIS.

On the issue of the timeline used in this analysis, the DEIS and this FEIS present climate effects not only for 2100 (a benchmark commonly used in climate change analysis), but also for 2050 and 2075. See DEIS Section 3.3.2.1.2; FEIS Section 3.3.2.2. Thus, the results at earlier points in time are also available to support decisionmaking. At least one commenter suggested that analysis to the year 2100 is not meaningful. Analysis to the year 2100 is necessary to consider NHTSA's action in light of the IPCC's projections and to the extent possible, to identify climate effects. Recognizing the difficulty of forecasting so far into the future, NHTSA tries to limit the number of moving variables to demonstrate the reduction in impacts associated with the various alternatives, while using IPCC emissions projections.

The effects of CO_2 emissions have been modeled and observed but are still difficult to accurately predict. The likely range of the climate sensitivity, which represents the increase in global warming due to increases in CO_2 emissions, ranges from 2.5 to 4.5 ºC. In this FEIS, NHTSA performs an analysis of variations under climate sensitivities of 2.5 and 4.5 ºC. See Section 4.4.4.2.1. The rate and ultimate levels of sea-level rise due to increases in CO_2 concentrations are also uncertain and estimated within very large ranges in the IPCC's Fourth Assessment Report. Recent literature suggests that the IPCC Fourth Assessment Report might have been low in its estimates of sea-level rise resulting from GHG concentration levels from the Special Report on Emission Scenarios (SRES) scenarios.[3] The different SRES scenarios illustrate the uncertainty in future emissions of greenhouse gases, which affect the impact of the CAFE standard alternatives on global mean surface temperature, sea-level rise, and CO_2 concentrations.

Several of the comments involved the issue of sudden and abrupt climate changes (or tipping points). In Section 3.4.3.2.4 of this FEIS, NHTSA has expanded its consideration of the issue of tipping points to include new research, as suggested by commenters, and has expanded the discussion from the IPCC and CCSP literature. NHTSA also includes paleoclimatic research, as suggested by commenters, which supports the theory that abrupt and severe climate change has occurred in the past, and that these changes could occur in multiple climate systems or other climate-related systems on the planet that affect global climate patterns. Readers are encouraged to review FEIS Section 3.4.3.2.4 and NHTSA's detailed response on the issue of tipping points. See Section 10.3.3.

[3] *The SRES scenarios are long-term emissions scenarios representing different assumptions about key drivers of GHG emissions. They are described in more detail in Section 3.4 of this FEIS.*

Finally, several commenters asked NHTSA to state the projected emissions reductions in terms of the overall U.S. transportation emissions sector. NHTSA has expanded the discussion of emissions in FEIS Section 3.4.4.1 to show the emissions reductions in the context of total emissions from cars and light trucks in the United States and to provide a more detailed description by sector.

10.2.1.1 Clarifying Comparative Reduction Plans

Comments

Comment Number: 0585-3
Organization: Attorneys General of the States of California, Massachusetts, New Jersey, New Mexico, New York, and Oregon, Secretary Of The Commonwealth of Pennsylvania Department of Environmental Protection, and New York City Corporation Counsel
Commenter: Edmund Brown Jr., Joseph Powers, Martha Coakley, Michael Cardozo, Anne Milgram, Gary King, Andrew Cuomo, Hardy Myers

The DEIS must clarify that GHG emissions from passenger cars and light trucks will continue to increase from past levels.

One of the most significant pieces of information that must be clarified in the DEIS is that, under the new CAFE rule, GHG emissions from passenger cars and light trucks will continue to rise over past levels, because the increase in miles per gallon ("mpg") mandated by the rule will not completely offset the increase in vehicle miles traveled ("VMT").

Rather than making this increase clear, the DEIS buries the information in the text of the document (*e.g.*, DEIS at 3-57) and repeatedly refers to the *reductions* in emissions, CO_2 concentration, and temperature. [Footnote: See original comment document.] In fact, the only reduction is in the amount of growth in each of these measures over what would otherwise occur without the new rule. The absolute levels are rising and will continue to rise. This distinction must be made clear both in the labeling of the graphs and figures, and in the text of the DEIS.

Response

NHTSA acknowledges that the absolute level of GHG emissions will continue to rise over current levels. This was expressed throughout the DEIS and remains in this FEIS, explicitly in Figure 3.4-4 and Table 3.4-1. The increase in emissions from factors such as an increase in vehicle miles traveled (VMT) is beyond NHTSA's jurisdiction to control. As explained in the NPRM and the DEIS, EPCA (as amended by EISA) requires NHTSA to set average fuel economy standards at least 18 months before the start of each model year and to set them at "the maximum feasible average fuel economy level that [NHTSA] decides the manufacturers can achieve in that model year." 49 U.S.C. §32902(a). In view of this statutory directive, it is not reasonable for NHTSA to explore strategies related to the quantity of vehicle miles traveled by the public. However, NHTSA notes that VMT is related to fuel economy in that higher stringency standards will generally increase VMT (because the per-mile cost of fuel decreases). This is known as the "rebound effect," and is considered by the Volpe model. Similarly, increasing fuel prices will generally decrease VMT. Thus, although CAFE standards indirectly affect VMT, the agency is not authorized to control the growth of VMT.

NHTSA has framed its analysis in terms of reductions because the levels of fuel savings and emissions are projected to be below what they would be without the new CAFE standards, i.e., compared to the emissions reductions that would occur if CAFE levels remained at their MY 2010 levels (the higher of a manufacturer's plans and the manufacturer's required level of average fuel economy for MY 2010).

CEQ's NEPA implementing regulations require that the alternatives be compared against a "no action" alternative – an alternative that projects what emissions levels would be if the proposed action was not implemented. NHTSA's No Action Alternative assumes that the agency would not issue a rule regarding CAFE standards. The MY 2010 fuel economy level (27.5 mpg for passenger cars and 23.5 mpg for light trucks) represents the standard NHTSA believes manufacturers would continue to achieve, assuming that the agency did not issue a rule.

Comparison to a "no action" alternative is done to draw a clearer, more refined distinction in the analysis of the standards and alternatives. NHTSA has endeavored to address this comment from the Attorneys General through additional discussion in Section 2.3.1 of this FEIS. In addition, NHTSA has performed additional analysis to calculate emissions reductions based on different IPCC emissions scenarios, including more aggressive emissions increase scenarios. See Section 4.4.3.5.

10.2.1.2 Effects on Other Countries' Standards

Comment

Comment Number: 0554-8
Organization: Individual
Commenter: James Adcock

NHTSA's analysis of GHG emissions assumes implicitly these regulatory changes only affect the behavior of vehicles in the United States. However most manufacturers are world-wide and can be expected to apply developed technology world-wide. Further, if the U.S. reduces GHG emissions from vehicles that should be expected to engender at least some amount of goodwill "diplomatic synergy" with other nations, particularly with Europe. If the U.S. reduces vehicle GHG Europe can also be expected to reduce vehicle GHG. If a 10% reduction in U.S. vehicle GHG resulted in a 10% reduction in European vehicle GHG one would have 100% diplomatic synergy between the regions. NHTSA is currently assuming implicitly 0% diplomatic synergy, *i.e.*, "Cowboy Diplomacy" where the U.S. acts alone without any other nation following suit. Since both major candidates for the presidency during the years of these regulations have pledged better cooperation with other nations NHTSA should be assuming something more than 0% diplomatic synergy. Further, U.S. GHG reductions from vehicles can be a starting point for cooperation in reducing GHG in other areas, increasing even more the "diplomatic synergy." NHTSA implicitly is assuming a value of 0% for all these synergies when NHTSA rationally should be expecting a higher value.

Response

One commenter suggested that there is a certain level of "diplomatic synergy" that would occur from NHTSA's rulemaking. The commenter states that NHTSA errs by not including the benefits that would occur if other countries increase their fuel economy because of this rulemaking. The international impacts of this rulemaking remain difficult to assess and are not quantifiable, and the commenter did not suggest how the agency could reasonably do so. NHTSA cannot accurately predict the actions of other countries and would point out that fuel economy standards differ from country to country.

10.2.2 VOLPE MODEL

Comments

Comment Number: 0576-27
Organization: Public Citizen
Commenter: Joan Claybrook

In the fuel economy standards for 1981-1984, set in 1977, NHTSA said "[a] cost benefit analysis would be useful in considering [economic practicability] but sole reliance on such an analysis would be contrary to the mandate of th[e Energy Policy and Conservation] Act." (42 *FR* 33537). But such reliance is precisely what the agency has done — it uses a cost benefit analysis to set the standards based on economic practicability as its first criterion.

NHTSA justifies this approach by citing *Public Citizen v. NHTSA* in its 2005 NPRM on light truck fuel economy standards ". . .in determining the maximum feasible level of CAFE, the agency assesses what is technologically feasible for manufacturers to achieve without leading to adverse economic consequences, such as a significant loss of jobs or the unreasonable elimination of consumer choice." [Footnote: See original comment document.] Public Citizen acknowledges that Congress in EPCA named economic practicability as one of the four factors, and that the court in *Public Citizen v. NHTSA* said that consumer choice was part of economic practicability; however, in *Center for Biological Diversity v. NHTSA*, the court states:

> Whatever method it uses, NHTSA cannot set fuel economy standards that are contrary to Congress's purpose in enacting the EPCA—energy conservation. We must still review whether NHTSA' s balancing of the statutory factors is arbitrary and capricious. . . .The need of the nation to conserve energy is even more pressing today than it was at the time of EPCA's enactment. . . . What was a reasonable balancing of competing statutory priorities twenty years ago may not be a reasonable balancing of those priorities today. (*Center for Biological Diversity v. NHTSA*, 508 F. 3d 508 at 14869-71.)

This shift of priorities is exactly relevant to the current situation. Fuel economy has become a significant public concern as gas prices have risen sharply. [Footnote: See original comment document.] Only NHTSA hasn't appropriately responded to these trends, and the Volpe Model, with its now outdated economic assumptions, would set fuel economy standards at a level that is less than consumers need based on a balancing of the statutory factors that does not reflect the current priorities.

Comment Number: 0576-37
Organization: Public Citizen
Commenter: Joan Claybrook

Public Citizen opposes the use of marginal cost-benefit analysis in estimating the maximum feasible level of fuel economy, as this type of economic analysis structurally fails to set the maximum feasible level.

Comment Number: 0572-37
Organization: Center for Biological Diversity
Commenter: Brian Nowicki, Mickey Moritz, Kassie Siegel

Furthermore, the DEIS fails to consider the economic costs of the collapse of the ocean food web. This cost must be included in any cost-benefit assessment conducted by NHTSA to accurately reflect the proper balance between the costs and benefits of reducing CO_2 emissions.

Comment Number: 0572-40
Organization: Center for Biological Diversity
Commenter: Brian Nowicki, Mickey Moritz, Kassie Siegel

The cost-benefit analysis is incomplete because it does not include a monetization of the impacts of black carbon.

Response

Regarding the potential costs associated with ocean acidification and black carbon expressed by the Center for Biological Diversity (CBD), NHTSA considers the societal costs of carbon dioxide emissions by including a monetary value for the "social cost of carbon emissions" in the Volpe model. That value per ton of carbon is the agency's effort to account for the economic value of reductions in CO_2 *emissions. Toward this end, NHTSA took a hard look at numerous published estimates of the social cost of carbon emissions, which assess and monetize future economic damages from climate change. The agency believes that the values in these peer-reviewed studies include damage to the ocean due to carbon emissions, and thus, NHTSA does not explicitly consider ocean acidification's impact on the food web in the Volpe model. However, due to the agency's analysis of peer-reviewed published estimates of social cost of carbon, NHTSA is confident that the social cost of carbon used in the Volpe model addresses CBD's concern.*

NHTSA explained in the DEIS that ocean acidification due to increases in CO_2 *emissions, the cause suggested by CBD for the collapse of the ocean food web, is difficult to assess quantitatively because the interactions are so complex and difficult to project. See DEIS Section 4.7. Where information presented in the EIA analysis was incomplete or unavailable, NHTSA relied on CEQ regulations regarding incomplete or unavailable information. See 40 CFR § 1502.22(b). The DEIS and this FEIS acknowledge that information on ocean acidification is incomplete, and that the state of the science does not allow for a characterization of how the alternatives considered influence these risks, other than to say that the greater the emissions reductions, the lower the risk of ocean acidification.*

Comments

Comment Number: 0572-54
Organization: Center for Biological Diversity
Commenter: Brian Nowicki, Mickey Moritz, Kassie Siegel

The CAFE Compliance and Effects Model, generally referred to as the Volpe model, is designed and used primarily to determine the economic costs and benefits to consumers and automakers with regard to application of technologies. Although an estimate of the social cost of global climate change (estimated by NHTSA at $7 per ton of CO_2) was entered as an input, the Volpe model focuses on the marginal costs and benefits provided to consumers and automakers by each potential technology, under the assumptions of costs and efficiency gains as purported by the automakers. It is much less adept at evaluating costs and benefits to society as a whole.

Comment Number: 0572-58
Organization: Center for Biological Diversity
Commenter: Brian Nowicki, Mickey Moritz, Kassie Siegel

The conclusions of the cost-benefit analyses are highly dependent on the values input into the model, and are particularly sensitive to the estimate of the economic cost of climate change and the projected price of gasoline. NHTSA has consistently chosen unreasonable input values to minimize the fuel economy level that emerges from the "black box" of the Volpe model. The absurdly low gas prices chosen by NHTSA are perhaps the best example. Increasing the gas price by $0.88 in 2016 leads to a nearly 7 mpg increase in the "socially optimal" fuel economy level. 73 FR 24476. Yet nowhere does NHTSA disclose the model results from simply entering today's average gas price of $4.09 per gallon [Footnote: See original comment document.] or the environmental impacts of running the model with "reality-based" inputs. NHTSA has a legal obligation to do so.

NHTSA, on page 24414 of the NPRM, states that, "[for] most of the analysis it performed to develop this proposal, NHTSA required a single estimate for the value of reducing CO_2 emissions." While it may be true that the Volpe model and the calculations used for the cost-benefit analysis required a single estimate—rather than a range of potential values—for each value for any single calculation, such methodological limitations do not restrict NHTSA from running successive calculations with a range of discrete values. This method should be applied to both the Volpe model and the cost-benefit analyses. In general, the projections for the price of gasoline must, at the very least, incorporate the current price of gasoline, and a range of possible scenarios for future prices. The economic cost of climate change must include the range of values reported in Stern (2007). We note that analysis of a range of values is legally required by the National Environmental Policy Act, which requires the analysis of a reasonable range of alternatives to the proposed action. NHTSA's sensitivity analysis is particularly indefensible as the agency has used $14 per metric ton as an upper bound of economic cost of carbon dioxide. The selection of such a low number as the upper bound is utterly unsupportable. Similarly, NHTSA has failed to analyze a gas price that even approaches today's prices, even in the sensitivity analysis. Today's gas price must form the starting point for the analysis, and calculations must be performed that consider the overwhelmingly likely scenario that gas prices will be significantly higher than the projections used in the NPRM.

Comment Number: 0574-13
Organization: Alliance of Automobile Manufacturers
Commenter: Julie Becker

On May 18, 2008, the Alliance sent a letter to NHTSA posing a series of questions about the Volpe model that Sierra Research had formulated because Sierra found it necessary "to resolve [those questions] in order to be able to understand and fully unpack the technical analysis behind NHTSA's notice of proposed rulemaking, as published at 73 *Fed. Reg.* 24,352 (May 2, 2008), and the accompanying preliminary regulatory impact analysis." Appendix B at 1. NHTSA has still not responded to the questions posed.

As NHTSA knows, courts have interpreted the Administrative Procedures Act and other, analogous sources of law to require agencies to provide opportunities not just to comment, but to comment meaningfully upon the agency's analysis. See, e.g., *Honeywell Int'l, Inc. v. EPA*, 372 F.3d 441, 449 (D.C. Cir. 2004). Moreover, an agency cannot rely on data or analysis known only to itself. See *National Classification Committee v. United States*, 779 F.2d 687, 695 (D.C. Cir. 1985). In addition, agency reliance on its experience cannot overcome evidence that shows a particular methodology to be flawed. See *American Pub. Gas. Ass'n v. FERC*, 567 F.2d 1016, 1043 (D.C. Cir. 1977), *cert. denied*, 435 U.S. 907(1978). Finally, in exploring the validity of the various assumptions that NHTSA made, Sierra needs to be able to test NHTSA's conclusions and its reliance on matters requiring judgment. Therefore, under OMB's [Office of Management and Budget's] aegis, NHTSA has been obligated to ensure that its scientific and technical conclusions are "substantially reproducible." (Guidelines for Ensuring and Maximizing the Quality, Objectivity, Utility, and Integrity of Information Disseminated by Federal Agencies, 67 *Fed. Reg.* 8,452 (Feb. 22, 2002). Sierra Research was not able to replicate NHTSA's analysis in some significant ways because the questions it posed were not answered.

Numerous environmental organizations commented at the August 4 public hearing that the Volpe model was central to NHTSA's NEPA analysis. Hence, for NHTSA's protection both against potential legal challenges by those groups and to provide a rational response to the questions raised by the Alliance, NHTSA must provide answers to the issues posed in the May 18 Alliance letter. NHTSA's use of confidential product plans by manufacturers cannot form the answer to the concerns posed in that letter. See *Riverkeeper*, *Inc. v. EPA*, 475 F.3d83, 112 (2d Cir. 2007) (approving agency use of confidential information only so long as it did not prevent the public "from commenting on the methodology and general cost data underlying EPA's approach").

Comment Number: 0574-8
Organization: Alliance of Automobile Manufacturers
Commenter: Julie Becker

As several environmental groups and individual commenters noted at the August 4, 2008 public meeting, NHTSA's NEPA analysis relies heavily on its Volpe model analysis. This makes it critical that the public be able to understand how the Volpe model functions. The letter the Alliance sent to NHTSA on May 18, 2008 presenting questions posed by Sierra Research, Inc. concerning the Volpe model has still not been answered. See Appendix B. This violates basic principles of administrative law. As a general matter, NHTSA's use of confidential product plan information also cannot be used to obscure the functioning of the Volpe model.

Response

The AAM referred to a letter it sent NHTSA in which Sierra Research, Inc. raised very specific issues concerning the application of fuel economy-improving technologies in the Volpe model. After receiving that letter, NHTSA contacted the AAM and informed it that if it believed that the agency did not use correct numbers or make the correct assumptions or calculations, AAM should make what it believed were the necessary corrections for the purposes of its analysis of the agency proposal and submit the results to NHTSA as part of its comments, including an explanation of what errors it believed the agency had made and why the AAM's values and approaches were better than the agency's. Further, in developing the FEIS, NHTSA has taken all of AAM's questions in its letter and suggestions in its comments to the docket regarding technology costs and standards analysis into consideration while revising and updating the technology inputs to the Volpe model. NHTSA does not believe that the agency's handling of the AAM's original letter in the amendments to the technology assumptions in the final rule restricted the ability of the AAM to comment meaningfully on the alternatives presented in the DEIS and their environmental impacts. Indeed, the AAM submitted extensive, detailed comments to the dockets for the NPRM and DEIS.

Moreover, CEQ regulations state that the purpose of an EIS is to "provide full and fair discussion of significant environmental impacts and … inform decision makers and the public of the reasonable alternatives which would avoid or minimize adverse impacts or enhance the quality of the human environment." 40 CFR § 1502.1. The agency purposefully analyzed a range of alternatives that would capture a full spectrum of potential impacts from vehicles continuing to maintain their MY 2010 fuel economy to standards based on the maximum technology expected to be available over the period. The various alternatives analyzed create mpg standards that essentially represent several points on a continuum of alternatives. NHTSA has further refined the fuel saving technology cost and benefit assumptions that go into the Volpe model based on numerous comments received on the NPRM and DEIS.

Comments

Comment Number: 0575-26
Organization: Union of Concerned Scientists
Commenter: Eli Hopson

The following examples illustrate the lack of transparency in NHTSA' s work:

Example A. NHTSA's sensitivity analysis shows that the use of higher externality values (gasoline price, CO_2 valuation, etc.) has a much more significant impact on passenger car fuel economy than it does on light truck fuel economy. NHTSA hypothesizes on some possible reasons for this, but provides no evidence for their hypothesis. If NHTSA cannot explain why this happens, their work appears flawed as it is not even transparent to them. Alternatively, if they can explain, they must provide the data and evidence. NHTSA's current approach is not sufficient for providing the public the ability to fully understand the mechanisms behind NHTSA's methodology.

Example B. One of NHTSA's frequent arguments is that their model is based on specific manufacturer product plans, and that because of this, NHTSA can employ the most realistic scenarios of product availably in their modeling efforts. However, certain assumptions NHTSA makes about product plan availability stand in stark contrast to public statements made by manufacturers. For example, despite the fact that General Motors has repeatedly touted the 2010 target release of its Chevy Volt plug-in hybrid (and a target volume in the tens of thousands) [Footnote: See original comment document.], NHTSA has opted to not include this technology in its model.

It appears that either (a) NHTSA is receiving incomplete or, worse, intentionally distorted product plans—thereby leading the agency to erroneous conclusions about technology availability and applicability, or that (b) NHTSA is disregarding manufacturer claims and selectively applying product plan information. Neither option is acceptable.

Example C. NHTSA appears to restrict final mpg levels using an opaque economic practicability assessment. A 5-year "consumer valuation" criterion is employed that appears to restrict deployment of technology that takes more than five years to recoup, and to value only the first five years of fuel savings. However, how or why this criterion was used in NHTSA's model is far from clear. It should be here noted that use of consumer valuation as a way to restrict application of fuel saving technologies, if indeed that is what is occurring, is incorrect and inappropriate.

Example D. NHTSA's sensitivity analysis includes evaluation at low and high fuel prices. While some of the results seem logical (i.e. an increase in fuel economy with the use of higher gasoline prices) others are completely counterintuitive. For example, the passenger car sensitivity analysis indicates that, relative to proposed fuel economy levels, an *increase* of 0.2 mpg can be achieved in 2015 by employing a *lower fuel price*. This type of information contradicts even the most fundamental logic of the Volpe model, and undermines the value of NHTSA's work.

Inconsistent Data

In reviewing the NPRM and PRIA, issues of inconsistent data came up. UCS understands that typos and errors will occur in volumes of its size, but these errors could also contribute to a perception of a hastily-performed analysis.

Example A. NHTSA claims to apply weight reduction technology to light trucks over 5,000 lbs. curb weight only. However, multiple tables in both the NPRM and PRIA, a 6,000 lb. curb weight threshold is also identified.

Example B. Pages 14 and 15 of the NPRM specify proposed passenger car and light truck standards, along with interim year fleet average estimates. Similarly, this information is shown in Table lb and Appendix Table A-l of the PRIA. Oddly, however, some of this information is inconsistent. While passenger car and light truck standards are consistent with the standards proposed in the NPRM, the PRIA indicates a 0.1 mpg higher fleet average fuel economy for both model years 2012 and 2013, as shown in Table 3. [See original comment document for Table 3 and footnotes.]

We assume this was merely a computational oversight; however we do wish to have NHTSA double-check this information to ensure that fleet average requirements are properly set.

Comment Number: 0576-24
Organization: Public Citizen
Commenter: Joan Claybrook

The model used to set fuel economy standards is heavily influenced by the economic assumptions. NHTSA's failure to make the correct assumptions about potential benefits will put downward pressure on the level and rate of the standards, which robs consumers of considerable value from increased standards, through fuel savings, reduced greenhouse gas emissions, and improved energy security and independence.

Comment Number: 0576-25
Organization: Public Citizen
Commenter: Joan Claybrook

The logic behind the restructured CAFE standards is to add the minimum amount of fuel saving technology to bring a manufacturer into compliance with the standard for a given year, with significant latitude given to individual manufacturers for compliance based on the specific fleet mix of a given manufacturer. This approach necessarily undercuts the maximum feasible level of fuel economy. In its November 2007 decision in *Center for Biological Diversity v. NHTSA* the Court of Appeals for the Ninth Circuit said: "the agency's cost-benefit analysis does not set the CAFE standard at the 'maximum feasible' level and fails to give due consideration to the need of the nation to conserve energy." (*Center for Biological Diversity et al., v. NHTSA.* 508 F. 3d 508. (November 15, 2007)).

NHTSA states in this notice on fuel economy standards: "In striking [a] balance [between costs and benefits], the agency was mindful of the growing need of the nation to conserve energy for reasons that include increasing energy independence and security and protecting the environment." (73 *FR* 24457] However, analysis of the Volpe Model suggests that the assumptions NHTSA uses to set the standards are not sufficiently mindful of the need to conserve energy or environmental protection.

Public Citizen recognizes that since the Ninth Circuit decision there have been changes to the Volpe Model since the 2006 light truck rule: "the set of technologies represented was updated, the logical sequence for progressing through these technologies was changed, methods to account for 'synergies' (*i.e.*, interactions) between technologies and technology cost reductions associated with a manufacturer's 'learning' were added, the effective cost calculation used in the technology application algorithm was modified, and the procedure for calibrating a reformed standard was changed, as was the procedure for estimating the optimal stringency of a reformed standard." (73 *FR* 24396] But these changes have not corrected the problems with the model that prevent it from setting standards at the maximum feasible level. Although Congress authorized NHTSA to restructure the CAFE scheme for passenger cars, but it did not mandate the NHTSA use Volpe Model. There are other ways the agency could model fuel economy that would set targets at the maximum feasible level and would improve public participation in the process.

Comment Number: 0576-26
Organization: Public Citizen
Commenter: Joan Claybrook

Public Citizen raises the following concerns about the Volpe Model:

- fails to correct the light truck loophole, which is the failure to have one continuous standard for passenger cars and light trucks, and ignores the impact of crossover vehicles
- the claim that the Volpe Model protects safety is based on a misapprehension of the relationship between fuel economy and safety
- potentially erodes the fuel savings when the price of oil drops lower than expected
- allows manufacturers to effectively set their own standards by manipulating product plans
- bases fuel economy increases on industry-biased cost assumptions and underestimates of benefits

Response

EPCA, as amended by EISA requires NHTSA to set separate standards for passenger cars and light trucks. Therefore, the option of "one continuous standard for passenger cars and light trucks" is not available. Before EISA, NHTSA had the discretion to prescribe separate standards for different classes of automobiles between 6,000 and 10,000 pounds, which is how the term "light truck" evolved. Under EISA's new definitions, all vehicles under10,000 pounds are classified as passenger automobiles, non-passenger automobiles, or work trucks, and all are subject to a CAFE standard (including crossover vehicles).[4]

Regarding the rest of this comment, see the general response at the end of Section 10.2.2.

Comments

Comment Number: 0576-28
Organization: Public Citizen
Commenter: Joan Claybrook

Another serious problem with the Volpe Model is that it is not transparent, which significantly undermines the ability of public commenters to provide an opinion as to whether NHTSA has set standards at the maximum feasible level that maximizes public good. Automakers provide the inputs for the Volpe Model through product plans, which are closed from public view as confidential business

[4] *A work truck is a vehicle between 8,500 and 10,000 pounds gross vehicle weight and is not a medium duty passenger vehicle as defined in 40 CFR § 86.1803-01. See 49 U.S.C. § 32901(a)(19). EISA requires NHTSA to set CAFE standards for work trucks after a NAS study on the fuel economy of this class of vehicles. See 49 U.S.C. §§ 32902(b)(1), 32902(k).*

information. This significantly biases the standards in favor of industry by shutting the public out of the process. NHTSA does not establish what is technological feasible and economically practicable based on an independent assessment of the current vehicle fleet and the available technology to improve the fleet, but rather accepts industry inputs, which are run through the black box of the Volpe Model, and a variety of "optimization" factors, which are tied to maximizing industry-wide benefits. (73 *FR* 24416). In the past, rulemaking NHTSA has done its own research and evaluation of these factors which was more transparent.

Thus, the public is foreclosed from real participation in this system. There is intense public interest in new fuel economy standards. These upgrades are the first for passenger cars in over twenty years, and they will dictate the level of fuel economy new vehicles will get until 2015, which affects the new car market and will skew purchase decisions. High gas prices and concern about global warming contribute to increased consumer interest in fuel economy; however, the agency's scheme for setting fuel economy standards leaves them largely in the dark. Consumers must essentially trust that NHTSA has set standards in their interest using information provided by industry.

Comment Number: 0576-29
Organization: Public Citizen
Commenter: Joan Claybrook

The Volpe Model uses incremental cost and incremental benefit estimates to determine the increase in fuel economy model-by-model. However, incremental costs are difficult to estimate accurately; many companies are unable even to produce a complete list of regulations that apply to them. [Footnote: See original comment document.] The GAO concluded that industry often overestimates costs or provided cost estimates that were not incremental. [Footnote: See original comment document.] Inaccurate estimates also plague the benefits side. As described above, many of the economic assumptions NHTSA made in estimating benefits were too low and too conservative. Since the Volpe Model only adds technology until marginal cost balances marginal benefit, the standards will not be set at the maximum feasible level, and consumers will not get the best available technology. (73 *FR* 24416)

Comment Number: 0576-31
Organization: Public Citizen
Commenter: Joan Claybrook

The Volpe Model estimates are also skewed by out-of-date and incomplete product plans. If NHTSA is to rely on product plans as their primary source of information for setting fuel economy standards, then those plans should be as up-to-date and complete as possible. However, not all manufacturers provided NHTSA with complete product plans, and in light of recent shifts in the auto industry in response to high gas prices and consumer demand shifts, the product plans that NHTSA used to run the model for this proposal are now out-of-date. [Footnote: See original comment document.] These insufficiencies in the information stream potentially undercut the potential for NHTSA to set technology-forcing standards which appropriately serve the need of the U.S. to conserve energy.

Comment Number: 0576-13
Organization: Public Citizen
Commenter: Joan Claybrook

The Volpe model also uses incomplete and inaccurate inputs from the auto industry to make projections about the future fleet mix and market preference. NHTSA solicited the automakers to provide product plans with which it could complete the modeling to set the fuel economy standards. However, many of the automakers solicited provided incomplete data, or no data at all. In these cases, NHTSA assumed that automakers would make no change from model year to model year, which skews the model to prefer no change in vehicle characteristics or fleet mix. In recent months, several major automakers have announced plans to substantially change their product plans. [Footnote: See original comment document.]

Comment Number: 0576-38
Organization: Public Citizen
Commenter: Joan Claybrook

The structure of the Volpe model is such that the standards it prescribes are heavily influenced by the economic assumptions and product plans provided by the auto industry.

Comment Number: 0576-39
Organization: Public Citizen
Commenter: Joan Claybrook

The minimizing effect of the economic assumptions used Volpe model serves to obscure the relative benefits of its proposed alternatives.

Comment Number: 0576-40
Organization: Public Citizen
Commenter: Joan Claybrook

NHTSA has a responsibility to respond to these problems in the most expedient possible manner. The agency estimates that if fuel economy standards are set at the level where total costs balance total benefits (the truly "maximum feasible" level) then passenger cars should reach an average of 43.3 mpg and light trucks should reach an average of 33.1 mpg by model year 2015. [Footnote: See original comment document.] This gets us to a fleetwide average of 37.3 in model year 2015, assuming NHTSA's assumptions that the fleet mix between passenger cars and light trucks stays around 50 percent — a dubious assumption given the flight from these vehicles in the face of high gas prices. This exceeds the goal set by EISA in level and speed; however, Congress mandated a *minimum* level of fuel economy. Gas prices have been rising steadily since 2004. However, the price increases in the last six to 12 months have been especially dramatic, rising by over a third in the past six months, and by nearly 170 percent in five years.

The agency appears to have considered 35 mpg by 2020 to be a ceiling, and has not attempted to strive for the maximum feasible level of fuel economy. "While the agency carefully considered alternative stringencies . . . it tentatively concludes that in stopping at the point that maximizes net benefits, it has achieved the best balancing of all of the statutory requirements, including the 35 mpg requirement." (73 *FR* 24457) NHTSA's conservative estimates for future fuel costs, undervaluation of carbon dioxide, zero valuation of military and strategic costs of oil, and high discount rate all push the outcome of the Volpe Model towards inaction.

If NHTSA increased fuel economy by 4.5 percent per year through the entire period over which standards are set, then the fleetwide fuel economy would reach 33.1 mpg by 2015. In addition, NHTSA's total cost balances total benefit scenario would increase fuel economy by nearly 10 percent per year to reach a fleetwide average above 37 mpg by 2015. This suggests that the technologically feasible pace of increasing fuel economy is much higher than what NHTSA is requiring in this proposal. The agency has given the industry considerable lead time to adjust for higher standards in the later years, yet inexplicably requires a slower pace of increases for these years.

Response

NHTSA recognizes that EISA identifies 35 mpg as a floor and not a ceiling for the combined fleet average statutory fuel economy required by 2020. Accordingly, NHTSA has considered and evaluated the environmental impacts of CAFE standards that reach to at least this level in 2015, such as the Total Costs Equal Total Benefits Alternative and the Technology Exhaustion Alternative. NHTSA also notes that EISA requires the agency to set fuel economy standards "based on 1 or more vehicle attributes related to fuel economy and express each standard in the form of a mathematical function." 49 U.S.C. § 32902(b)(3)(A).

Several reviewers expressed concern – and some have evidenced confusion – regarding NHTSA's approach to establishing the stringency of CAFE standards, the "Volpe model." Some commenters claimed that the Volpe model, by generating standards at levels that maximize net benefits to society, does not comport with EPCA's requirements. The Center for Biological Diversity (CBD) and Public Citizen referred to the Volpe model and its inputs as a "black box." NHTSA does not agree with this characterization.

As required by EPCA, NHTSA sets standards at the maximum feasible level, considering technological feasibility, economic practicability, the effect of other standards of the Government on fuel economy, the need of the nation to conserve energy, as well as other relevant considerations such as safety.

NHTSA has a long-standing practice of analyzing regulatory options based on the best available information regarding (1) the future vehicle market, (2) the technologies expected to be available during the relevant model years, and (3) the key economic factors, such as future fuel prices and the other statutory factors.

Among these categories, all information except NHTSA's forecast of the future vehicle market is made available to the public. The forecast of the future vehicle market is based significantly on confidential product planning information manufacturers submit to the agency. Individual manufacturers are better able than any other entity to anticipate what mix of products they are likely to sell in the future. The submitted product plans contain confidential business information, which the agency is prohibited by federal law from disclosing; making this information publicly available would cause competitive harm to manufacturers. <u>See</u> 5 U.S.C. § 552(b)(4); 18 U.S.C. § 1905; 49 U.S.C. § 30167(a); 49 CFR Part 512; <u>Critical Mass Energy Project v. Nuclear Regulatory Comm'n</u>, 975 F.2d 871 (D.C. Cir. 1992). Notwithstanding this restriction, in its publicly available rulemaking documents, the agency provides aggregated information (compiled from individual manufacturer submissions) regarding its forecasts of the future vehicle market.

All of the other information NHTSA uses to conduct its analysis – such as estimates of economic factors and estimates of the availability, cost, and effectiveness of fuel-saving technologies – is presented in the agency's rulemaking documents and is available to the public. <u>See</u> NPRM, 73 <u>FR</u> 24352, 24391 (May 2, 2008); CAFE Compliance and Effects Modeling System Documentation, Docket No. NHTSA-2008-0089-0047; How to Obtain Volpe Model Installation Files, Docket No. <u>NHTSA-2008-0089-0048</u>; PRIA, Docket No. NHTSA-2008-0089-0003.1, pp. V1-V141. The agency requested and received comment on all of these inputs to its analysis and has addressed these comments in analyses conducted in this FEIS and will do so in the final rule.

Until 2002, when NHTSA began work on CAFE standards for light trucks sold during model years 2005-2007, the agency used tools such as spreadsheets to analyze regulatory options. For that rulemaking and ensuing rulemakings, the agency has supplemented such tools with a modeling system *developed specifically to assist NHTSA with applying technologies to thousands of vehicles and developing estimates of the costs and benefits of potential CAFE standards. The CAFE Compliance and Effects Modeling System, developed by DOT's Volpe National Transportation Systems Center and commonly referred to as "the Volpe model," enables the agency to efficiently, systematically, and reproducibly evaluate many more regulatory options, including attribute-based CAFE standards required by EISA, than was previously possible, and to do so much more quickly.*

The Volpe model needs the following types of information as input: (1) a forecast of the future vehicle market, (2) estimates of the availability, applicability, and incremental effectiveness and cost of fuel-saving technologies, (3) estimates of vehicle survival and mileage accumulation patterns, the rebound effect, future fuel prices, the social cost of carbon, and many other economic factors, (4) fuel characteristics and vehicular emissions rates, and (5) coefficients defining the shape and level of CAFE curves to be examined. The model makes no a priori assumptions regarding inputs such as fuel prices and available technology, and does not dictate the form or stringency of the CAFE standards to be examined. The agency makes those selections and, in the case of technology assumptions, has determined that confidential product plans are a vital source of information.

Using the inputs selected by the agency based on best available information and data, NHTSA projects a set of technologies each manufacturer could apply in attempting to comply with the various levels of potential CAFE standards to be examined. The model then estimates the costs associated with this additional technology utilization, as well as accompanying changes in travel demand, fuel consumption, fuel outlays, emissions, and economic externalities related to petroleum consumption and other factors.

NHTSA specifically sought comment on the estimates, which it had developed jointly with EPA, of the availability, applicability, cost, and effectiveness of fuel-saving technologies, and the order in which the technologies were applied. See 73 FR 24352, 24367. While NHTSA asked manufacturers to submit such information in the request for product plans, the agency also conducted its own independent analysis of the all the comments and data—including comments and information from entities outside the automobile manufacturing community—received through the rulemaking process. This involved hiring an international engineering consulting firm that specializes in automotive engineering, and that was used by the EPA in developing its recent Advance Notice of Proposed Rulemaking to regulate greenhouse gas emissions under the Clean Air Act.[5]

NHTSA and its consultants undertook a thorough review of the NPRM technology assumptions and all comments received on those assumptions, based on both old and new public and confidential manufacturer information. NHTSA and its consultants reviewed and compared comments on the availability and applicability of technologies, and the logical progression between them. NHTSA also reviewed and compared the methodologies used for determining the costs and effectiveness of the technologies as well as the specific estimates provided. Relying on the expertise of its consultants and taking into consideration all the information available, NHTSA revised its estimates of the availability and applicability of many technologies, and revised its estimate of the order in which the technologies were applied. In addition, the agency and its consultants generally agreed with commenters who said that in several cases, the technology related costs used in the NPRM and DEIS were underestimated and benefits were overestimated. The agency also agreed with commenters that both sets of estimates were not well differentiated by vehicle class and that the technology decision trees needed to be expanded and refined. Relying on the expertise of its consultants and taking into consideration all the information available, NHTSA revised its technology and effectiveness estimates and used them in analyzing all of the alternatives and scenarios presented in this FEIS. The agency believes that the representation of

[5] *73 FR 44354 (July 30, 2008).*

technologies—that is, estimates of the availability, applicability, cost, and effectiveness of fuel-saving technologies, and the order in which the technologies were applied—used in this action is the best available.

Recognizing the uncertainty inherent in many of the underlying estimates in the model, NHTSA has used the Volpe model to conduct both sensitivity analyses, by changing one factor at a time, and a probabilistic uncertainty analysis (a Monte Carlo analysis that allows simultaneous variation in these factors) to examine how key measures (e.g., mpg levels of the standard, total costs, and total benefits) vary in response to change in these factors. This type of analysis is used to estimate the uncertainty of the costs and benefits of a given set of CAFE standards.

Finally, the model can be used to fit coefficients defining an attribute-based standard, and to estimate the stringency that either (a) maximizes net benefits to society, (b) achieves a specified stringency at which total costs equal total benefits, (c) imposes a specified average required CAFE level, or (d) results in a specified total incremental cost. The agency uses this information from the Volpe model as a tool to assist in setting standards, consistent with the requirements of EPCA.

Model documentation, publicly available in the rulemaking docket, explains how the model is installed, how the model inputs and outputs are structured, and how the model is used. The model can be used on any Windows-based personal computer with Microsoft Office 2003 and the Microsoft .NET framework (the latter available without charge from Microsoft) installed. The executable version of the model, with all of its codes and accompanying demonstration files, is available upon request, and has been provided to manufacturers, consulting firms, academic institutions, nongovernmental organizations, research institutes, foreign government officials, and other organizations. The current version of the model was developed using Microsoft Development Environment 2003, and every line of computer code (primarily in C#.NET) has been made available to individuals who have requested the code. Many of these individuals have run the model using market forecast data that they estimated on their own.[6]

Given the comprehensive disclosure of information about the Volpe model and the fact that many entities and individuals have made use of it, the characterization of the Volpe model as a "black box" is not accurate.

Although NHTSA uses the Volpe model as a tool to inform its consideration of potential CAFE standards, the Volpe model does not determine the CAFE standards NHTSA will propose or promulgate as final regulations. The results it produces are completely dependent on inputs selected by NHTSA, based on best available information and data available at the time standards are set. In addition to identifying the input assumptions underlying its decisions, NHTSA provides the rationale and justification for selecting those inputs. NHTSA also determines whether to use the model to estimate at what stringency net benefits are maximized, or to estimate other stringency levels, such as the point where total costs equal total benefits. NHTSA also determines whether to use the model to evaluate the costs and effects of stringencies that fall outside of the scope of maximum feasible. For example, the standards for the "Technology Exhaustion" Alternative examined by NHTSA were estimated outside the model, which was subsequently used to estimate corresponding costs and effects.[7] *Finally, NHTSTA is guided by the statutory requirements of EPCA in ultimate selection of a CAFE standard.*

NHTSA does not agree with Public Citizen that the agency "does not establish what is technologically feasible and economically practicable based on an independent assessment of the current

[6] *Resources for the Future (RFF) has run the model and is working under contract with EPA to expand its capability.*
[7] *By definition, the "maximum technology" scenario far exceeds the maximum feasible CAFE standard.*

vehicle fleet and the available technology to improve the fleet, but rather accepts industry inputs, which are run through the black box of the Volpe model and a variety of 'optimization' factors, which are tied to maximizing industry-wide benefits." The manufacturers' plans are only the starting point for the agency's determination of how much technology can and should be required consistent with the statutory factors. NHTSA considers the results of analyses conducted by the Volpe model and analyses conducted outside of the Volpe model, including analysis of the impacts of carbon dioxide and criteria pollutant emissions, analysis of technologies that may be available in the long term and whether NHTSA could expedite their entry into the market through these standards, and analysis of the extent to which changes in vehicle prices and fuel economy might affect vehicle production and sales. Using all of this information—not solely that from the Volpe model—the agency considers the governing statutory factors, along with environmental issues and other relevant societal issues such as safety, and promulgates the maximum feasible standards based on its best judgment on how to balance these factors.

This is why the agency considered seven alternatives, only one of which maximizes net benefits. The others assess alternative standards that in many cases exceed the point at which marginal costs equal marginal benefits. These comprehensive NEPA analyses are intended to inform and contribute to the agency's consideration of the "need of the United States to conserve energy," as well as the other statutory factors. 49 U.S.C. § 32902(f). Additionally, within the model the agency considers the need of the nation to conserve energy by monetizing the economic costs of incremental CO_2 *emissions in the social cost of carbon.*

CEQ regulations state that the purpose of the EIS is to "provide full and fair discussion of significant environmental impacts and … inform decisionmakers and the public of the reasonable alternatives which would avoid or minimize adverse impacts or enhance the quality of the human environment." 40 CFR § 1502.1. Accordingly, the agency analyzed alternatives that capture a full spectrum of potential impacts, ranging from vehicles continuing to maintain MY 2010 fuel economy levels to standards based on the maximum technology expected to be available over the period. The technology assumptions used in the NPRM produced CAFE standards that went beyond EISA's statutory goal (at least 35 mpg by 2020) in 2015. As a further refinement, NHTSA has updated the fuel-saving technology cost and benefit assumptions that go into the Volpe model based on comments to the NPRM and DEIS and on updated manufacturer product plans. NHTSA acknowledges that these changes affect the CAFE standards.

<u>Volpe Model Input Estimates</u>

Several commenters asserted that NHTSA used inaccurate input variables in the Volpe model, resulting in an underestimation of the projected CAFE standards. Commenters questioned NHTSA's choice of fuel price, social cost of carbon, discount rate, and military costs. The agency recognizes that many of these variables are subject to change based on differing economic circumstances that may or may not exist during the period the CAFE standards are intended to cover, making the estimation process a difficult one. Taking this into account, the agency has expanded its evaluation of the alternatives to account for different valuations of these variables and made this information available in this FEIS. In Section 2.5, Section 3.4.4, and Section 4.4.4, the agency presents the standards and accompanying environmental impacts that occur when the Volpe model is run with varying economic input values.

10.2.2.1 Fuel Price Assumptions

Comments

Comment Number: 0595-1
Organization: Environmental Protection Agency
Commenter: Susan Bromm

The DEIS uses official 2008 AEO [Annual Energy Outlook] Early Release fuel price projections of $2.04- $3.37 per gallon in the relevant timeframe. EPA's work with the Volpe Model, as well as the High Fuel Price sensitivity analyses presented in Section IX of the Preliminary Regulatory Impact Analysis (PRIA) associated with the CAFE Notice of Proposed Rulemaking (NPRM), indicates that the Volpe model is very sensitive to fuel price projections. Using projections at the high end of the AEO range would change the base case (as the market reacts to higher fuel prices) and the projected net benefits, and it would likely increase the level of the "optimized" fuel economy standard. EPA urges NHTSA to carefully consider projections for fuel prices and notes the important nexus between this estimate and future projections for the Final EIS.

Commenter: Jim Derzon

I think it is unlikely that gas will be below $3.00 per gallon again in my lifetime, so get busy and strengthen fuel economy standards. Current standards are criminal.

Comment Number: 0535-1
Organization: Individual
Commenter: James Farrelly

As of today the average price per gallon of gas is 4.07 – not 2.25 or 2.60 a gallon. That was what maybe 2006? So auto manufacturers don't feel the need to change fuel efficiency standards when these sorts of numbers are given.

Comment Number: 0549-1
Organization: Individual
Commenter: Nancy Miller

I am writing to protest the ridiculous assertion that we will be paying between $2.25 to $2.60 per gallon for gas through 2020. DOT [Department of Transportation] is calling for fuel economy improvements only if they pay for themselves through fuel savings—the money saved from the gas the cars wouldn't use. This gas price fantasy allows automakers to shave three to four miles per gallon off of the historic new fuel economy requirements that became law in 2007. If accurate gas prices are used, the new requirements would further reduce global warming pollution equivalent to taking about 10 million cars off the road.

Comment Number: 0554-1
Organization: Individual
Commenter: James Adcock

EIA estimates of future gas prices are not rational estimates given the recent run-up in gas prices. The EIA estimates can be compared to the estimate of future gas prices implied in the short-term and long-term NYMEX [New York Mercantile Exchange] oil and gas futures. If the EIA estimates were correct estimates, and the NYMEX futures greatly differ (which they do) then that difference represents an arbitrage opportunity that traders can exploit, which in turn would drive NYMEX prices back to EIA Estimates. (Modem Arbitrage Theory) This hasn't happened. The conclusion is that EIA estimates cannot be current rational estimates. See attached graph. [See original comment document for graph.] Based on NYMEX future estimates of gas prices during the regulatory time frame I suggest that NHTSA adopt its "HOP - High Oil Price" scenario rather than its current "MOP - Moderate Oil Price" scenario. Or use NYMEX futures values directly rather than outdated EIA estimates.

Comment Number: 0557-7
Organization: The Natural Resources Defense Council
Commenter: Luke Tonachel, Brian Siu

NHTSA relies on the Energy Information Administration's Reference Case forecast for fuel prices. However, both the Reference and High Case forecasts have consistently underestimated fuel prices and NHTSA fails to use a reasonable forecast consistent with likely price trajectories.

Comment Number: 0559-8
Organization: The Northeast States for Coordinated Air Use Management (NESCAUM)
Commenter: Arthur Marin

NHTSA acknowledges that the price of gasoline has the greatest impact on the cost analysis for the standards. Yet, NHTSA assumes fuel prices ranging from $2.26 per gallon in 2016 to $2.51 per gallon in 2030. These numbers are unrealistically low. Currently, the average price of a gallon of gasoline exceeds $4.00 and the principal reason given is high global demand in a supply constricted market. There is little expectation that the gap between supply and demand will be narrowed in the foreseeable future. Therefore, assuming this reasoning is correct, the price of gasoline should remain high; certainly well above the mid-$2.00 range. We urge NHTSA to reevaluate the effect of a wider range of gasoline prices to the $4.00 per gallon level and above. We would expect the results to show that there are more fuel savings technologies capable of cost-effectively achieving greater overall average fuel economy, even according to NHTSA's conservative "net societal benefit" cost-analysis approach.

Comment Number: 0564-9
Organization: Consumer Federation of America
Commenter: Mark Cooper

[NHTSA] used gasoline prices that are far too low — a price of only $2.45 per gallon for 2015 (in 2008 dollars);

Comment Number: 0572-14
Organization: Center for Biological Diversity
Commenter: Brian Nowicki, Mickey Moritz, Kassie Siegel

Another major determinant of the output from the Volpe model is the cost of fuel. DEIS at 2-2. The NHTSA used the EIA's Annual Energy Outlook Early Release Forecast to select fuel prices, and assumes future fuel prices ranging from $2.26 per gallon in 2016 to $2.51 per gallon in 2030.Considering that national average gasoline prices are currently $3.81 per gallon [Footnote: See original comment document.] and over a dollar higher than one year ago, there is every indication that the price of oil will continue to increase over the short term, and there is every indication that the price of oil will continue to remain in the short term higher than projected by the administration, this estimate is impossible to justify. It is important to note that these price projections are based in 2006 dollars, and include Federal, State, and local taxes. However, the estimated 2008 fuel price of $2.69 per gallon of gasoline in 2006 dollars, adjusted by a 3% estimated annual inflation rate, is approximately $2.85 per gallon of gasoline, far below the current prices and projections. The use of an inappropriate gasoline price projection greatly skews the results, since the savings in fuel expenditures are by far the largest components of the cost-benefit analysis, accounting for $2.27 of the $2.51 in net benefits from each gallon of gasoline reduced, overwhelmingly drives the conclusions of the cost-benefit analysis as constructed by NHTSA.

Comment Number: 0572-57
Organization: Center for Biological Diversity
Commenter: Brian Nowicki, Mickey Moritz, Kassie Siegel

For the purposes of cost-benefit analysis, on page 24449 of the NPRM, NHTSA assumes future fuel prices "ranging from $2.26 per gallon in 2016 to $2.51 per gallon in 2030." Considering that national average gasoline prices are currently over $4.00 per gallon, there is every indication that the price of oil will continue to increase over the short term, and there is no indication that oil prices will subside in the long term, this estimate is impossible to justify. It is important to note that these price projections are based in 2006 dollars, and include Federal, State, and local taxes. [Footnote: See original comment document.] However, the estimated 2008 fuel price of $2.69 per gallon of gasoline in 2006 dollars, adjusted by a 3% estimated annual inflation rate, is approximately $2.85 per gallon of gasoline, far below the current prices and projections. The use of an inappropriate gasoline price projection greatly skews the results, since the savings in fuel expenditures are by far the largest components of the cost-benefit analysis, accounting for $2.27 of the $2.51 in net benefits from each gallon of gasoline reduced, overwhelmingly drives the conclusions of the cost-benefit analysis as constructed by NHTSA in the NPRM.

Comment Number: 0575-2
Organization: Union of Concerned Scientists
Commenter: Eli Hopson

While gasoline prices soared above $3 per gallon this winter and have hovered around $4 per gallon this summer, NHTSA relied on projections of $2.25-$2.50 per gallon.

Comment Number: 0575-29
Organization: Union of Concerned Scientists
Commenter: Eli Hopson

At around $2.50 or lower, the gasoline price projection used by NHTSA dramatically undervalues the savings associated with improved fuel economy. According to NHTSA's own analysis, the use of an undervalued gasoline projection, rather than the Energy Information Administration's High Oil Price projection (which itself falls below today's pump prices), robs the nation of an additional 3-4 mpg. At a minimum, NHTSA should use EIA's High Price projection.

Comment Number: 0575-9
Organization: Union of Concerned Scientists
Commenter: Eli Hopson

Between 2001 and 2008, inflation-adjusted gasoline pump prices nearly doubled [Footnote: See original comment document.], leaving consumers burdened with drastically increased vehicle operating costs. The auto industry, stagnant with a fleet average fuel economy comparable to that of the mid 1980s [Footnote: See original comment document.], offered consumers few fuel-efficient options, and even fewer options from the domestic automakers. Today, gasoline prices continue to break record levels; in late June, gasoline surpassed a national average of $4 per gallon, with the potential of $5 per gallon fuel in the near future. [Footnote: See original comment document.]

The above facts underscore the importance of properly assessing future fuel prices when setting smart energy policy. Indeed, as noted in the agency's NPRM, "projected future fuel prices are a critical input" (NPRM, p. 186) into the economic analysis used to assess economically practicable CAFE levels. The agency proposes using Annual Energy Outlook (AEO) Reference Case forecasts by the Energy Information Administration (EIA), because they "represent the EIA's most up-to-date estimate of the most likely course of future prices for petroleum products." (NPRM, p. 186) This appears to be a flawed assumption. Nowhere in the Annual Energy Outlook (2007 or 2008 edition) is the Reference Case projection referred to as a "most likely course." In fact, according to EIA, the reference case merely "assumes that current policies affecting the energy sector remain unchanged throughout the projection period." (EIA, 2008. AE02008 Overview, p. 2.)

NHTSA's decision to regard Reference Case gasoline price projections—which have substantially under-predicted the price of gasoline in recent years—as the most likely course of future prices is fundamentally flawed and undervalues the benefits of fuel saving technology in the determination of maximum feasible fuel economy standards. According to NHTSA's own sensitivity analysis, employing a High Price Case would enable application of additional fuel saving technologies on vehicles, increasing passenger car fuel economy between 6.1 – 6.7 mpg over the proposed standards, and increasing light truck fuel economy between 0.1 – 0.8 mpg over the proposed standards. (PRIA, Tables IX-5a and IX-5b) The use of EIA's High Price Case projections would be far more realistic assumption to employ (though, since 2003, even the High Price Case projections have dramatically underestimated the real price of gasoline). [Footnote: See original comment document.]

UCS does not stand alone in this opinion. Even Guy Caruso, Administrator of the EIA—the agency that authors and publishes the AEO—has publicly recommended that NHTSA use the High Price Case in setting fuel economy standards. At a hearing by the House Select Committee on Energy Independence and Global Warming, Mr. Caruso stated, in direct reference to NHTSA's rulemaking process, "We're on the higher price path right now. If you were to ask me today what I would use, I would use the higher price." [Footnote: See original comment document.]

As shown in Figure 1, EIA's Reference Case projections have substantially under-predicted the price of gasoline, falling short of the actual price by as much as 80 cents per gallon. Even near-term Reference Case assessments, such as the 2009 projection, fall well short of today's gasoline price. Moreover, as shown in Figure 2, EIA has consistently predicted a decline in gasoline prices when, in fact, gasoline has faced a precipitous price escalation. [See original comment document for figures and footnote.]

NHTSA points to recent increased fuel prices in AEO 2008 to justify use of AEO Reference Case data. Yet, as shown in Figure 2, even with the upward revision, EIA's 2008 Reference Case projection still falls well below current gasoline prices

NHTSA also points to a comparative assessment of fuel price projections, identifying EIA's Reference Case forecast as providing the highest publicly available estimates: "Comparing different forecasts of world oil prices also shows that EIA's Reference Case forecast reported in Annual Energy Outlook 2007 (AEO 2007) was actually the highest of all six publicly-available forecasts of world oil prices over the 2010-30 time horizon." (NPRM, p. 190)

However, this statement ignores the fact that the same EIA table referenced by NHTSA specifies the High Price Case forecast with oil prices 20 percent higher than the Reference Case in 2010, 60 percent higher than the Reference Case in 2015, and 71 percent higher than the Reference Case in 2020. (Only 5-year increments are shown.)

Given current gasoline market conditions, gasoline market trends, and the historical inaccuracy of EIA's Reference Case for much of this decade, UCS recommends that NHTSA employ the High Price Case forecast in its cost-benefit assessment. As shown in Figure 2, the High Price Case forecast remedies the predicted decline in gasoline prices. Yet even this projection still falls far below current gasoline prices which reside over $4 per gallon. Without question, the High Price Case is not a prediction of extreme, never-before-seen fuel costs, but rather a modestly more representative projection of the energy-dependent environment that we now live. UCS strongly suggests that NHTSA employ, at a minimum, EIA's High Price Case projection in its analysis.

Comment Number: 0576-18
Organization: Public Citizen
Commenter: Joan Claybrook

NHTSA has assumed retail gas prices of $2.31 per gallon for model year 2015, with a high estimate of $3.19. For 2030, the forecast price is $2.51 per gallon, and the high price is $3.76. (PRIA, X-5) Guy Caruso, administrator of the Energy Information Administration (EIA), recommended in a hearing of the House Select Committee on Energy Independence and Global Warming in June 2008 that NHTSA should use the high price estimate when setting fuel economy standards. [Footnote: See original comment document.] Public Citizen strongly urges NHTSA to base its final rulemaking on a more realistic estimate of future fuel price based on the high estimate and an at-the-pump price that pushes the standard in the direction of real-world gas prices.

Comment Number: 0576-9
Organization: Public Citizen
Commenter: Joan Claybrook

The future fuel price assumptions are unjustifiably low, assuming a 2030 price of gasoline at $2.51. The administrator of the Energy Information Administration has publicly stated that NHTSA should use the high-end estimate in setting fuel economy standards. [Footnote: See original comment document.]

Comment Number: 0588-4
Organization: New York State Department of Transportation
Commenter: Stanley Gee

NHTSA uses unrealistically low predictions of motor fuel prices, thereby underestimating economic benefits, and overestimates the rebound effect, which underestimates fuel savings and underestimates vehicle-related criteria and toxic pollutant emissions.

Comment Number: 0588-7
Organization: New York State Department of Transportation
Commenter: Stanley Gee

The DEIS (page 3-59) states that the Preliminary Regulatory Impact Analysis (PRIA) uses the Energy Information Administration reference price estimate for gasoline in the *AEO 2008 Early Release Forecast*, Please note that the EIA International Energy Outlook Highlights, June 2008 states, "Given current market conditions, it appears that world oil prices are on a path that more closely resembles the projection in the high price case than in the reference case." Therefore, NYSDOT [New York State Department of Transportation] believes that the analysis of alternatives analysis should use EIA's "high price case" scenarios. In addition, the Final Environmental Impact Statement should specifically explain why *current* market prices are excluded from the factoring process for economic practicability.

Comment Number: 0598-2
Organization: Sierra Club
Commenter: Caroline Keicher

NHTSA' s own analysis shows that between 2011 and 2015, significantly higher standards are technologically feasible and economically practicable when higher gas prices are used ($3.14 per gallon in 2016). NHTSA's final rule should be, at a minimum, consistent with the analysis provided in the PRIA. NHTSA's use of below-cost energy estimates is arbitrary and capricious and violates the agency's statutory charter to impose mandatory maximum feasible fuel economy standards based upon a review of economic and technological feasibility.

Comment Number: TRANS-02-2
Organization: Lee Auto Malls
Commenter: Adam Lee

NHTSA plays a real role in determining what our fuel economy will be. You analyze the impact of CAFE on Detroit. And I think that your assumptions are based on incorrect data. Gas costs $4 a gallon, not $2.

Comment Number: TRANS-08-14
Organization: Sierra Club
Commenter: Ann Mesnikoff

The proposed rule and the PRIA both show that the gas prices are major forces in setting fuel economy. NHTSA short changes America by using gas price assumptions that are far too low, a price for carbon that is randomly selected, and artificially constraining technologies.

Comment Number: TRANS-09-5
Organization: Individual
Commenter: Doug Molof

The agency's proposal assumes future gasoline prices to be only $2.25 per gallon in 2016, when American future gas prices – when American consumers are already paying prices nearly twice as much today. In fact, since NHTSA first released its draft CAFE rulemaking, the price of gasoline has jumped by over a dollar.

NHTSA's own analysis shows that between 2011 and 2015 significantly higher standards are technologically feasible and economically practical when higher gas prices are used. NHTSA's final rule should be, at a minimum, consistent with the analysis provided in the preliminary impact analysis that accompanied the notice of proposed rulemaking.

NHTSA's use of the low cost energy estimates is arbitrary and violates the agency's statutory charter to impose mandatory maximum feasible fuel economy standards based upon a review of economic and technological feasibility.

The high gas price scenario yields cost effective and technologically feasible standards that will help meet the nation's need to conserve energy, and will help lower gas prices for the average American consumer. NHTSA should ensure that final standards are set using this value at a minimum.

Comment Number: TRANS-10-4
Organization: Individual
Commenter: Matt Dernoga

I am baffled that our new CAFE standards are based on the presumption that the cost of a gallon of gas will be only $2.25 by 2016.

Comment Number: TRANS-12-2
Organization: Individual
Commenter: Sam Blodgett

Economists agree $2, even $3 gas price days are over. Your environmental impact statement must reflect this new reality. In your draft EIS you analyze two price projections for the cost of gasoline; one that predicts $2.25 gas prices by 2015, and another that predicts $3.14 gas prices by 2015.

In your EIS you chose to use the lower price estimation. Given current gas prices, this was an obvious misstep. It is only prudent to use the higher cost estimation. Even it undervalues gas by almost a dollar.

According to your analysis, if gasoline is $3.14 by 2015 then higher fuel economy standards are both technologically feasible and economically practicable. If true, then it is nonsensical to continue as planned.

Comment Number: TRANS-13-2
Organization: Individual
Commenter: Joseph Frewer

the current estimation of the price of a gallon of gas, which is, I think $2.25, not counting inflation in 2016, is unrealistic. I mean, we all prices right now, while they've been fluctuating, they're not going to drop back down to what they used to be. They are definitely staying above $3, and I think that's what most economists are saying. So we need to at least take this into account when coming up with what our standards need to be.

Comment Number: TRANS-14-6
Organization: U.S. Public Interest Research Group
Commenter: Annie Chau

NHTSA unrealistically predicts gasoline prices to be only $2.25 per gallon in 2016. But Americans are already paying nearly twice as much today. U.S. PIRG [Public Interest Research Group] research from squandering to stimulus shows that in the last five months American families have spent the entirety of their stimulus checks filling their tanks, while the cost of gasoline skyrocketed more than 40 percent.

Comment Number: TRANS-18-2
Organization: Individual
Commenter: Pamela Woodward

You need to use realistic gas prices, prices that are, that equal the current average, which is much higher than the $2 plus range. It's in the $4 plus range.

Comment Number: TRANS-22-3
Organization: Individual
Commenter: Julie Locascio

Nonetheless, many consumers will look first to the impact on their own finances in assessing the value of increased CAFE standards. A higher priced vehicle will be worth the extra cost to the consumer, if the consumer gets higher fuel efficiency. But if NHTSA is saying that such a consumer will only save about $2.50 for every gallon of gas longer needed, well into the next two decades, this analysis is completely distorted.

As everyone knows the price of gasoline at the pump is current hovering around $4 a gallon, and one would be hard pressed to find a cross-section of economists who would predict that the price of gasoline is going to drop back down below $3 a gallon in the two decades to come.

Indeed, even Guy Caruso, EIA administrator has testified that the CAFE cost benefit analysis should be using an oil price between $2.96 and $3.63 per gallon. I don't see how NHTSA can ignore the expert recommendation of the man responsible for ensuring that the statutory and regulatory requirements for legally performing the environmental impact assessment are fulfilled.

Comment Number: TRANS-23-4
Organization: Greater Washington Interfaith Power and Light
Commenter: Tara Morrow

Another matter for closer examination in the DEIS is the estimate of the price of gasoline used to determine what is cost effective. Many here have already referred to this, but I, too, was quite shocked to see an assumption of only in the $2 range for 2016, that's in terms of 2006 dollars, and it does seem quite unrealistic given current realities.

Comment Number: TRANS-24-2
Organization: Individual
Commenter: Heather Moyer

As others have said, I also was surprised and shocked to see the proposal assuming that future gas prices would be only $2.25 in 2016 using 2006 dollars. I found that shocking and saddening, and also laughable. And I urge you to use realistic gas prices.

Comment Number: TRANS-25-1
Organization: Individual
Commenter: Emanuel Figueroa

It doesn't make sense when we assume that the price of gasoline is $2 or $3, when we go outside and see the first, any gas station, doesn't matter if it's an Exxon, Mobile, Shell, any. You can choose your brand. You can choose the one that you like for your car, but it's way over $4 right now.

Comment Number: TRANS-28-2
Organization: Individual
Commenter: Jim Pierobon

So I urge you, just to quickly conclude here, to use more realistic assumptions about how high future gasoline prices could go. And looking back on how high they've been this year.

Comment Number: TRANS-29-1
Organization: Individual
Commenter: Allison Forbes

The figure you're considering right now for cost of gas is offensive to consumers. And I'm sure you know that, but we definitely need to be considering the higher cost of gas in our analysis. I paid $4.15 a gallon over the weekend driving around, and it's not easy. So please consider that in your rulemaking.

Comment Number: TRANS-30-1
Organization: Jewish Community Relations Council of Greater Washington
Commenter: Debbie Linick (for Ron Halber)

We must regulate fuel economy based on realistic assumptions about the likely future cost of fuel, and with an eye toward encouraging cleaner vehicles, and the pursuit of renewable and alternate sources of energy.

Comment Number: TRANS-33-2
Organization: Individual
Commenter: Fred Dobb

I'm no statistician, but as a citizen and clergy person it seems that whatever method yielded $2.25 or even $2.60 as an estimate for a decade out is an outlier at best, and a statistic beyond [expletive deleted] lies at worse.

Comment Number: TRANS-33-4
Organization: Individual
Commenter: Fred Dobb

I'm particularly concerned about calculations for the likely cost of gas in the future.

Comment Number: TRANS-34-3
Organization: Individual
Commenter: Fred Teal, Jr.

In summary, I wish to say that I disagree strongly with the arbitrarily low future gasoline prices contained in NHTSA's calculations. It's just incredible that you would use mileage figures for gas costs per gallon for gasoline that would be that low. It's just so impractical, considering our current situation.

Comment Number: TRANS-35-3
Organization: Individual
Commenter: Alina Fortson

Your analysis uses assumptions for future gas prices that are simply unrealistic. Today, Americans are paying nearly $4 per gallon and there's currently no reason to expect prices to drop as low as $2.25.

Comment Number: TRANS-36-3
Organization: Individual
Commenter: Matt Kirby

The unrealistic gas price of $2.25 assumption which is, frankly, an insult to my parents and an insult to the students who can't afford to eat.

Your own analysis shows that between 2011 and 2015 significantly higher standards can be achieved if you only up the presumed gas price at $3.14. So the use of these below cost energy estimates, it violates your own charter to impose mandatory maximum feasible fuel economy standards on a review of economic and technological feasibility.

Comment Number: TRANS-38-2
Organization: Environment America
Commenter: Ben Schreiber

You know, we're using a price of gasoline of $2.30 to justify doing the bare minimum on fuel economy standards, and yet at the same time the price of $4 is being justified to open up our very last protected wild spaces to more and more oil and gas exploration. And it's unacceptable.

Comment Number: TRANS-39-3
Organization: American Jewish Committee
Commenter: Ami Greener

Further, the current proposal relies on fanciful gas price assumptions, which result in insufficient fuel economy levels. The proposal assumes future gasoline prices of $2.25 per gallon, when American consumers are already paying prices nearly double that today.

Comment Number: 0599-2
Organization: Center for Biological Diversity
Commenter: Multiple Signatories

Your assumption that gas will cost $2.36 per gallon in 2020 is completely unsupportable and contributed to the ridiculously low proposed standards.

Response

As explained in Section 10.2.2 above, in response to all the comments NHTSA received pertaining to the fuel price forecast used in the Volpe model, this FEIS examines how the alternatives are affected by variations in the economic assumptions input into the Volpe model. Specifically, the agency calculated and analyzed mpg standards and environmental impacts associated with each alternative under both the "Reference Case" for key model inputs, which uses the U.S. Energy Information Administration's (EIA's) Reference Case fuel price forecast, a domestic social cost of carbon, and a 7-percent discount rate; and under a "High Scenario" set of input assumptions, which uses the EIA "High Case" for fuel price forecast, a global social cost of carbon, and a 3-percent discount rate. This FEIS also analyzes the impacts of various other combinations of economic assumptions inputs.

In the DEIS, NHTSA relied on the EIA's Annual Energy Outlook (AEO) forecasts for the estimate of fuel price during the period covered by the agency's action (EIA 2008a). Federal government agencies generally use EIA's projections in their assessment of energy-related policies. In the DEIS and NPRM, the agency selected the EIA's Reference Case fuel price forecast in performing the analysis. The EIA also includes a "High Price Case" and "Low Price Case" in AEO analyses that reflect uncertainties regarding future levels of oil production. Several commenters suggested that the agency apply the AEO "High Price Case" forecast to the Volpe model. In response to these comments, NHTSA has analyzed scenarios using the "High Price Case" and the "Reference Case." The agency declines to apply the current cost of gasoline to the Volpe model, as some commenters have suggested. Applying current fuel prices would be speculative. Indeed, at the time the DEIS was published, market prices for fuel were *generally rising. However, since that time commodity prices for light sweet crude oil have been declining. The current volatility in fuel prices gives NHTSA greater confidence in relying on EIA forecasts, rather than current prices in the marketplace.*

NHTSA's modeling incorporates the annual plans of the car manufacturers in the United States. Given the volatility and rapid movement of the market and the resulting decline in demand for large SUVs and pick-up trucks, the car manufacturers have moved quickly to adjust production of vehicles. EIA incorporates these and other economic trends in its AEO 2008 Forecast. In particular, AEO 2008 Forecast includes the impact of the Energy Independence and Security Act of 2007 (EISA 2007) that was enacted in December 2007, reflecting updates to the renewable fuel standard and the influences of higher CAFE standards for new light-duty vehicles. It also includes additional revisions that reflect historical data issued after the early release version of the AEO 2008 was completed, the EIA Short-Term Energy Outlook released in January 2008, a more current economic outlook, and updates to correct modeling problems in the early release version (EIA 2008d).

10.2.2.2 Rebound Effect

Comments

Comment Number: 0564-11
Organization: Consumer Federation of America
Commenter: Mark Cooper

Assumed that consumers irrationally burn up their fuel savings on increased driving, rather than using it to buy other goods and services, and applied this excessive "rebound" effect to analyses where it should not play a role.

Comment Number: 0575-11
Organization: Union of Concerned Scientists
Commenter: Eli Hopson

NHTSA assumes a rebound effect of 15 percent. Yet recent research from Small and Van Dender, [Footnote: See original comment document.] which NHTSA "attaches greater significance" (NPRM, p. 201], notes that the rebound effect in the U.S. is small and has been getting smaller.

"*...the rebound effect declined substantially over time*—which we confirmed by estimating the equation (without the three interaction terms) separately for time periods 1966-1989 and 1990-2004... the short-run rebound fell from 4.8% to 2.9%, while the long run rebound fell from 21.1% to 7.7%" (emphasis added)

Given the Small and Van Dender conclusions, there is no justification for NHTSA's 15 percent rebound effect, especially given the low gas prices used by the agency. [Footnote: See original comment document.] A rebound of up to 10 percent may be reasonable if NHTSA employs the high price gasoline projection (or today's fuel prices). UCS suggests that, in accordance with use of the High Price Case gasoline projection, NHTSA employ a rebound effect no higher than 10 percent.

Comment Number: 0575-31
Organization: Union of Concerned Scientists
Commenter: Eli Hopson

NHTSA assumes a rebound effect of 15 percent. This value is too high, based upon recent research which NHTSA "attaches greater significance to." Along with use of the High Price Case gasoline projection, NHTSA should employ a rebound effect no higher than 10 percent.

Comment Number: 0576-11
Organization: Public Citizen
Commenter: Joan Claybrook

NHTSA has assumed a very high rebound effect, which also influences its assumptions both in the appropriate level of standards and the potential environmental benefits of each of the range of alternatives.

Comment Number: 0576-23
Organization: Public Citizen
Commenter: Joan Claybrook

NHTSA has assumed a very high rebound effect – 15 percent – for this proposal. The rebound effect assumes that the amount of driving will increase as a result of decreased fuel consumption, which reduces the per mile cost of driving. (PRIA VIII-8) NHTSA looks at 29 estimates and attempts to reflect the current conditions; however according to the Small and Van Dender study, "most empirical measurements of the rebound effect rely heavily on variations in the fuel price," which raises again the question of whether NHTSA's assumptions about the rebound effect are colored by the estimates of future fuel price. [Footnote: See original comment document.]

Comment Number: 0588-10
Organization: New York State Department of Transportation
Commenter: Stanley Gee

The rebound effect is defined as an increase in Vehicle Miles Traveled (VMT) in response to decreased operating costs. Such an effect may occur as a result of higher fuel economy. Additional driving uses more fuel; thus, the rebound effect reduces the net fuel savings that accrue to vehicle owners, for a given increase in fuel economy. In chapter VIII of the PRIA, NHTSA summarizes the results of studies done on the rebound effect across the country, and chooses the study performed in 2005 by Dr. Kenneth Small at the University of California, Irvine. That study concluded that California would experience a dynamic rebound effect of 3 percent. NHTSA claims that updating this study for the country as a whole and for the period covered by this rulemaking would yield a rebound effect of at least 15 percent. It seems counterintuitive that the nation as a whole would see a rebound effect that is five times that of California, particularly in the face of significantly higher fuel costs. In a 2003 report, the Congressional Budget Office notes that the U.S. is a "mature market" and that as such, the rebound effect is small. The report also points out that even though the real cost of fuel per kilometer decreased in the U.S. by about 65 percent between 1982 and 1995, that decrease was not accompanied by a strong rebound in VMT. NHTSA's 15 percent downward adjustment to the economic benefits resulting from this fuel economy rulemaking is not warranted by economic research literature, or actual consumer behavior.

Comment Number: 0600-3
Organization: Centers for Disease Control and Prevention
Commenter: Sarah Heaton, Andrew Dannenberg

In Chapter 3, Affected Environment and Consequences, the assumption is stated that, "the tightened CAFE standards would create an incentive to drive more because they would decrease the vehicle's fuel cost per mile. The total amount of passenger car and light truck VMT would increase slightly due to this 'rebound effect'." There is substantial uncertainty in this argument and an insufficient analysis in the DEIS of variables affecting VMT projections, such as current and projected fuel costs. A sensitivity analysis is warranted to examine the implications of higher or lower assumptions about rebound effects.

Comment Number: TRANS-04-4
Organization: National Automobile Dealers Association
Commenter: David Westcott

Similarly, to the extent vehicles regulated by the CAFE proposal are used by NHTSA predicts after introduction into the fleet, the proposal will necessarily fail to achieve its expected level of environmental benefit. Due to the rebound effect, vehicles with lower operating costs predictably will be used more than the vehicles they replace. Environmental impacts that correlate with miles driven, traveled, such as those associated with greenhouse gases will be impacted to the degree of any such rebound effect, reducing any delay or forecast in environmental performance benefits.

Response

To derive an estimate of the rebound effect for use in assessing the fuel savings and other impacts of more stringent CAFE standards, NHTSA reviewed many studies (PRIA pp. VIII-6 and VIII-7). NHTSA then performed a detailed analysis of 66 estimates of the long-run rebound effect reported in these studies. The 66 estimates range from as low as 7 percent to as high as 75 percent, with a mean value of 23 percent. Approximately two-thirds of all 66 estimates reviewed range from 10 to 30 percent, as do two-thirds of all published estimates, and two-thirds of authors' preferred estimates.

In selecting a single value for the rebound effect to use in analyzing the fuel savings and other impacts of stricter CAFE standards for future model years, NHTSA attaches greater significance to studies that allow the rebound effect to vary in response to changes in the various factors that have been found to affect its magnitude. The agency also updated authors' originally reported estimates of variable rebound effects to reflect current conditions. Commenters referred to studies by Small and Van Dender, and NHTSA notes that it considered two papers by Small and Van Dender (2005a & b); however, NHTSA informs its decision with many studies rather than relying on a select few.

Considering the empirical evidence on the rebound effect as a whole, while according greater importance to the updated estimates from studies allowing the rebound effect to vary, NHTSA uses a rebound effect of 15 percent (with a range of uncertainty extending from 10 percent to at least 20 percent) to evaluate the fuel savings and other effects resulting from stricter fuel economy standards for future model year vehicles.

10.2.2.3 Social Cost of Carbon

Comments

Comment Number: 0557-8
Organization: The Natural Resources Defense Council
Commenter: Luke Tonachel, Brian Siu

The social cost of carbon used by NHTSA is based on an arbitrary range of values and incorrectly relies on a central estimate of $7 per metric ton of CO_2. Unmitigated, costs of dangerous climate change are very likely much higher than estimates in standard literature, and NHTSA must use a reasonable risk premium in its calculations.

Comment Number: 0572-15
Organization: Center for Biological Diversity
Commenter: Brian Nowicki, Mickey Moritz, Kassie Siegel

The NHTSA's methodology for the selection of an estimate of the value of reducing greenhouse gas emissions is arbitrary and designed to minimize the estimate. The Volpe model assumes that the value of CO_2 reductions is the midpoint between a so-called "high" of $14/ton CO_2 and a "low" of $0/ton CO_2. DEIS Appx. C at VIII-30. This valuation is flawed because: (1) it is based on an out-dated and otherwise flawed analysis; (2) the use of a $0 low value is unjustified; and (3) simply splitting the difference between two values does not take into account the distribution of economic projections for the cost of carbon.

The NHTSA relies entirely on the 2005 *Energy Policy* article, Tol (2005), as the source for the estimate of $14 per ton of CO_2, but fails to address the much higher estimates also reported by Tol. Tol (2005) states that "The marginal damages caused by a metric ton of carbon dioxide emissions in the near future were estimated in the [IPCC] Second Assessment Report at US$5-125 per tC." In addition, the NHTSA overlooks the fact that the studies cited in the Tol (2005) survey dated back as much as 18years, to 1991, and 25 of the 28 studies cited were published more than five years ago. Considering that the understanding of climate change has expanded dramatically in the past five years, and that impacts of climate change are progressing much more rapidly than were previously projected, this represents a fatal flaw in the analysis. Of the 28 papers cited by Tol (2005), only three were published since 2003, only one of which was peer reviewed. That paper estimated the social cost of carbon as high as $14 per ton of CO_2. (Pearce 2003).

The Fourth Assessment Report of the Intergovernmental Panel on Climate Change also refers to the Tol (2005) survey, but is careful to point out, on page 813 of Yohe (2007), that "[it] is likely that the globally-aggregated figures from integrated assessment models underestimate climate costs because they do not include significant impacts that have not yet been monetized…," and, on page 17 of Adger (2007), that "taken as a whole, the range of published evidence indicates that the net damage costs of climate change are likely to be significant and to increase over time." The NHTSA concedes this point: "[taken] as a whole, recent estimates of the SCC may underestimate the true damage costs of carbon emissions because they often exclude damages caused by extreme weather events or climate response scenarios with low probabilities but potentially extreme impacts, and may underestimate the climate impacts and damages that could result from multiple stresses on the global climatic system." DEIS Appx. C at VIII-28.

In fact, the IPCC, on page 813 of Yohe (2007), estimates the cost of carbon as high as $350 per ton of carbon ($97.67/ton CO_2), and states that "It is virtually certain that the real social cost of carbon and other greenhouse gases will increase over time; it is very likely that the rate of increase will be 2% to 4% per year."

The DEIS places great weight on the fact that the IPCC Fourth Assessment report cites to Tol (2005). Yet, the DEIS does not acknowledge the many other studies that the IPCC refers to. For example, the IPCC contrasted the Tol estimate of carbon costs with that of Downing (2005), which indicated that the lower benchmark of $50/tC ($13.95/t CO_2) was reasonable. Most importantly, the IPCC gives great weight to the estimates in the Stern Review 2007. As the most recent and most comprehensive analysis of the costs of climate change, the Stern Review is the best available information. As the IPCC notes, the Stern Review 2007 estimates the cost of carbon at $85/t CO_2. The NHTSA must re-calibrate the Volpe model results to reflect the actual range of values in the current literature.

The NHTSA also uses an impermissible value for the lower bound on the cost of carbon dioxide reductions. The DEIS acknowledges that the IPCC indicates that the costs of global climate change will be non-zero. DEIS Appx. C at VIII-30. But then it jumps to the amazing and illogical conclusion that "it does not necessarily rule out low or zero values for the benefit to the U.S. itself from reducing emissions." DEIS Appx. C at VIII-30. This statement is completely erroneous. The evidence is clear that the U.S. will be severely adversely affected by climate change. Just a few examples: some of the most expensive real estate and most densely populated regions are along our expansive coastlines; the desert Southwest is gripped by drought and projected to continue to be; much of our fresh water is supplied by annual snowpack, which is already declining; forest fires are raging through most of the forested regions of the country; and human health, especially in the Southwest where there are large retired populations, will be affected by extreme heat events and in many other ways. Furthermore, our economy depends heavily on imports and exports from other countries. If the rest of the world is economically harmed by climate change, the U.S. will undoubtedly pay. There is no doubt that the U.S. will suffer severe impacts along with the rest of the world: the cost of carbon is most certainly non-zero.

Finally, the DEIS uses an impermissible method for reducing the range of potential carbon costs to a single value. The DEIS takes the midpoint between its chosen "upper" and "lower" bound. But as emphasized by the IPCC there are numerous estimates of carbon cost. This constellation of carbon costs will have some distribution. It is very likely that the estimated values do not fall along a normal "bell" curve. Consequently, taking the midpoint between the extreme values does not reflect the true "consensus" value for the cost of carbon.

The NHTSA must first re-analyze the available and current estimates of the cost of carbon, with particular attention to the leading analyses in the Stern Review 2007. Next, the NHTSA must ascertain a proper non-zero lower bound for its estimates. Finally, the distribution of estimated values should be taken into account when a single value is selected for use in the Volpe model.

Comment Number: 0572-22
Organization: Center for Biological Diversity
Commenter: Brian Nowicki, Mickey Moritz, Kassie Siegel

Furthermore, the NHTSA makes the mistake of elevating the decisional process over the substantive character of the alternatives. As the court in *California v. Block* noted with regard to an EIS prepared under NEPA, "[a]lthough it is worthwhile to consider a broad range of variables in constructing policy alternatives, the procedure becomes meaningless if the variables are assigned numerical values such that only a limited range of outcomes result." 690 F.2d 753, 769 (9th Cir. 1982) Here, NHTSA has limited its consideration, and range of alternatives, to the results of the model, yet those results are meaningless for a number of reasons, including the fact that the input values were simply incorrect. Thus, the range of values used as inputs to the Volpe model has unreasonably constrained the universe of alternatives under NEPA.

Moreover, as discussed above, the Volpe model arbitrarily constrains the universe of NEPA alternatives. The purpose of NEPA is to inform decision-making, but application of a specialized tool designed for cost-benefit analysis indicates that a decision has already been made by the agency. If the cost-benefit analysis is applied to select alternatives, there is no potential for considering alternatives that may carry less environmental impact. Yet, the Volpe cost-benefit analysis was employed to define all alternatives, including the maximal technology alternative. This alternative was based on what the NHTSA "considered to be available" and based on market penetration rates defined in the Volpe model DEIS at 2-10.

Comment Number: 0572-55
Organization: Center for Biological Diversity
Commenter: Brian Nowicki, Mickey Moritz, Kassie Siegel

Like the Volpe model, this analysis uses an estimate of the economic costs of global climate change, set in the proposed rule at $7 per ton of CO_2. However, this cost-benefit analysis fails to incorporate the full economic costs of global climate change, values that are difficult to monetize, and costs to the world outside the boundaries of the United States. In general, the estimate of the social costs of climate change fails to incorporate the loss of biodiversity, complex and large-scale ecosystem services, and the disproportionate impacts of global climate change on the developing world.

Comment Number: 0572-56
Organization: Center for Biological Diversity
Commenter: Brian Nowicki, Mickey Moritz, Kassie Siegel

NHTSA's methodology for the selection of an estimate of the value of reducing greenhouse gas emissions is arbitrary and designed to minimize the estimate. The proposed rule, on page 24414, explains that NHTSA "elected to use the midpoint of the range from $0 to $14 (or $7.00) per metric ton of CO_2 as the initial value for the year 2011..." However, the range of estimates extends much higher than $14; there is no justification for a value of $0; and simply splitting the difference between two points is not a defensible methodology, particularly when the low point of the range is not part of a valid range but simply an arbitrary selection of zero as an endpoint.

NHTSA relies entirely on the 2005 *Energy Policy* article, Tol (2005), as the source for the estimate of $14 per ton of CO_2, but fails to address the much higher estimates of $95 per ton of CO_2 reported in Tol (2005). Tol (2005) states that "The marginal damages caused by a metric ton of carbon dioxide emissions in the near future were estimated in the [IPCC] Second Assessment Report at US$5-125 per tC." In addition, NHTSA overlooks the fact that the studies cited in the Tol (2005) survey dated back as much as 18 years, to 1991, and 25 of the 28 studies cited were published more than five years ago. Considering that the understanding of climate change has expanded dramatically in the past five years, and that impacts of climate change are progressing much more rapidly than were previously projected, this is a serious limitation. Of the 28 papers cited by Tol (2005), only three were published since 2003, and only one, Pearce (2003), was peer reviewed, and that paper estimated the social cost of carbon as high as $14 per ton of CO_2.

The Fourth Assessment Report of the Intergovernmental Panel on Climate Change also refers to the Tol (2005) survey, but is careful to point out, on page 813 of Yohe (2007), that "[it] is likely that the globally-aggregated figures from integrated assessment models underestimate climate costs because they do not include significant impacts that have not yet been monetized...," and, on page 17 of Adger (2007), that "taken as a whole, the range of published evidence indicates that the net damage costs of climate change are likely to be significant and to increase over time." [Footnote: See original comment document.] In fact, the IPCC, on page 813 of Yohe (2007), estimates the cost of carbon as high as $350 per ton of carbon, and states that "It is virtually certain that the real social cost of carbon and other greenhouse gases will increase over time; it is very likely that the rate of increase will be 2% to 4% per year."

The IPCC, on page 821 of Yohe (2007), specifically refers to the findings of Stern (2007) with regard to the economics of climate change. Stating, "[most] recently, Stem (2007) took account of a full range of both impacts and possible outcomes (i.e., it employed the basic economics of risk premiums) to suggest that the economic effects of unmitigated climate change could reduce welfare by an amount equivalent to a persistent average reduction in global per capita consumption of at least 5%. Including direct impacts on the environment and human health (i.e., 'non-market' impacts) increased their estimate of the total (average) cost of climate change to 11 % GDP [gross domestic product]; including evidence which indicates that the climate system may be more responsive to greenhouse gas emissions than previously thought increased their estimates to 14% GDP." Ultimately, Stern (2006) estimates the social cost of climate change at $25 to $30 per ton of CO_2, or much higher. In fact, as Stern points out "If consumption falls along a path, the discount rate can be negative. If inequality rises over time, this would work to reduce the discount rate, for the social welfare functions typically used. If uncertainty rises as outcomes further into the future are contemplated, this would work to reduce the discount rate, with the welfare functions typically used." A negative discount rate would dramatically increase the cost of climate change in the cost-benefit analyses in the proposed rule.

For the lower end of the range of values for reducing global warming, NHTSA proposes an estimate of $0 per ton of CO_2. NHTSA, on page 24414 of the NPRM, states, "Although this finding suggests that the *global* value of economic benefits from reducing carbon dioxide emissions is unlikely to be zero, it does not necessarily rule out low or zero values for the benefit to the U.S. itself from reducing emissions..." Presumably, this is meant to imply that the United States might benefit economically by letting other countries bear the costs of unabated American greenhouse gas emissions. Setting aside the tremendous ethical implications of such a position, NHTSA provides absolutely no evidence to support the claim. Furthermore, only one study surveyed in Tol (2005) included central estimates below $0.00; and that was a non-peer-reviewed article, also authored by Tol.

NHTSA, on page 24413of the NPRM, offers a justification for the low valuation by stating, "many studies fail to consider potentially beneficial impacts of climate change, and do not adequately account for how future development patterns and adaptations could reduce potential impacts from climate change or the economic damages they cause." Although this statement is paraphrased from page 2067 of Tol (2005), it is important to note that this is not cited by Tol (2005) as a finding, and is not reported by Tol as one of the factors contributing to the range of estimates. In fact, the sum of the findings of the IPCC, Tol (2005), and the Stern Review, shows that NHTSA's selection of $14 per ton of CO_2 is unreasonably low and completely unsupported by the literature and by reality. In fact, NHTSA itself concedes this point, on page 24413, with the statement that, "[taken] as a whole, recent estimates of the SCC may underestimate the true damage costs of carbon emissions because they often exclude damages caused by extreme weather events or climate response scenarios with low probabilities but potentially extreme impacts, and may underestimate the climate impacts and damages that could result from multiple stresses on the global climatic system."

Comment Number: 0572-61
Organization: Center for Biological Diversity
Commenter: Brian Nowicki, Mickey Moritz, Kassie Siegel

NHTSA, on page 24414 of the NPRM, states that, "[in] order to be consistent with NHTSA's use of exclusively domestic costs and benefits in prior CAFE rulemakings, the appropriate value to be placed on changes climate damages [sic] caused by carbon emissions should be one that reflects the change in damages to the United States alone. Accordingly, NHTSA notes that the value for the benefits of reducing CO_2 emissions might be restricted to the fraction of those benefits that are likely to be experienced within the United States."

This statement indicates that NHTSA fails to fully understand the tremendous threats and challenges posed by global climate change, and the fundamental challenges global climate change presents in comparison to previous approaches to addressing pollution reductions. Unlike other pollutants, the air basin for greenhouse gases, and CO_2, in particular, is the global atmosphere. The impacts of global warming are local, regional, national, international, and global. The cost-benefit analysis should incorporate the social costs of climate change, and the economic benefits of reducing greenhouse gas emissions, wherever those impacts or benefits are experienced. The alternative, in which only the impacts and costs experienced in United States territory are considered, would lead to a dramatic underestimation of the aggregate costs of climate change. In addition, it would carry the terrible and arrogant implication that the people of the United States believe that people in other countries should bear the environmental and economic burdens caused by American consumer preferences. Nothing in EPCA, NEPA, or other applicable law allows NHTSA to artificially constrain the analysis or under report the costs of global warming in this manner.

Comment Number: 0575-13
Organization: Union of Concerned Scientists
Commenter: Eli Hopson

In its NPRM, NHTSA proposes the use of a 2011 value of carbon between $0 and $14 per metric ton. Even the upper end of this range, selected by NHTSA based on a 2005 Tol study, is an unacceptably low valuation of the pollutant. The European Climate Exchange, which provides a futures market value for global warming pollution in Europe's carbon constrained market, indicates 2011 contracts for carbon dioxide at approximately $45 (U.S.) per metric ton – well above the figure cited by NHTSA. [Footnote: See original comment document.]

Further, NHTSA proposes a 2011 value of carbon at $7 per metric ton CO_2, a computed mean average of the proposed $0 and $14 boundaries. This computation places as much weight on the $0 per metric ton value as it does on the $14 per metric ton value. Valuing carbon at $0 was declared by the ninth circuit court to be arbitrary and capricious – and implies the possibility that climate change won't have any negative consequences. This is unrealistic and stands in stark contrast to recent government study findings on U.S. climate change effects and findings from the International Panel on Climate Change and the Academies of Science for the G8+5. [Footnote: See original comment document.]

NHTSA includes a sensitivity analysis using varied valuation of CO_2 emissions, and concludes that "the results of the sensitivity analyses indicate that the value of CO_2... has almost no impact on the level of the standards." (NPRM, p. 364). NHTSA juxtaposes this seemingly insignificant impact with that of a gasoline price sensitivity analysis, which shows significantly higher sensitivity. It is not surprising that NHTSA came to such conclusions. The dollar per gallon price equivalent of a $0-$14 per metric ton CO_2 range is (assuming full in-use and upstream emissions of 24 lbs. of CO_2/gallon consumed) a mere $0.00-

$0.15 per gallon. A sensitivity analysis examining such a confined range will of course arrive at such an erroneous conclusion.

UCS recommends that NHTSA employ a value of at least $45 per metric ton CO_2, the value currently trading on the European Climate Exchange. This value represents a predicted marginal abatement cost (the cost of avoiding global warming pollution), and is likely a conservative estimate of the benefit of reducing global warming pollution since the cost of avoiding climate change is lower than the cost of fixing the damage after it occurs.

The value recommended by UCS for use in this 2008 rule is generally consistent with other recent allowance price estimates, such as the EPA' s assessment of GHG allowance prices under Lieberman-Warner: $22 – $40 in 2015 and $28 – $5 1 in 2020 (EPA figures are in 2005 dollars per ton of CO_2-equivalent). [Footnote: See original comment document.]

Comment Number: 0575-3
Organization: Union of Concerned Scientists
Commenter: Eli Hopson

While carbon dioxide futures are currently trading at more than $40 per metric ton in Europe, NHTSA used a value of $7 per ton. NHTSA even considered $0 per ton to be in the range of possible values. In the face of numerous economic analyses which indicate that combating global warming will greatly reduce the cost of adapting to climate change, factoring a $0 value into the rule is unacceptable.

Comment Number: 0576-10
Organization: Public Citizen
Commenter: Joan Claybrook

NHTSA has set the price of CO_2 arbitrarily and too low. The agency chose a value of $7/ton CO_2 based on a 2005 meta-analysis of estimates of the price per ton of carbon by Richard S. J. Tol, from which NHTSA estimated prices per ton of carbon, and NHTSA converted the range to $0-14 per ton CO_2. In comments to NHTSA's NPRM, Tol commented that NHTSA has improperly indexed the values in the Tol paper, as they were in 1995 dollars instead of 2005 dollars, and also that a 2007 paper he authored found larger estimates than the 2005 paper. [Footnote: See original comment document.]

Comment Number: 0576-21
Organization: Public Citizen
Commenter: Joan Claybrook

NHTSA's estimate for the value of CO_2 is arbitrary and too low. The agency's estimate for the price of CO_2 examines a range of values from $0-14 per metric ton CO_2, based on a 2005 meta analysis of CO_2 valuation. Emissions allowances have recently been trading on the European Climate Exchange at around €30 per allowance (one metric ton CO_2 equivalent). [Footnote: See original comment document.] An analysis done by EPA in March 2008 for the Senate Committee on Environment and Public Works for S. 2191, America's Climate Security Act, estimated the value of CO_2 in 2015 between $22 and $40 per metric ton of CO_2, and cited two other analyses with higher estimates of $48 and $50 per metric ton CO_2. [Footnote: See original comment document.] The agency should extend the range of CO_2 prices considered at least as high as EPA's estimates, which are more recent than the Tol estimate cited in NHTSA's notice. All of the estimates EPA cited for its analysis of Lieberman-Warner exceed the $14 ceiling on carbon price.

The agency provides no justification for selecting the midpoint of the range it took from the Tol study. NHTSA should weight the credibility of each estimate. Averaging the results of multiple studies can substantially skew the result, especially if the estimates are not parallel comparisons. Estimating the value of something like CO_2 requires careful selection of factors considered, and requires subjective determination of assumptions. Failure to make "apples to apples" comparisons by looking at studies based on their assumptions can produce a result that does not reflect the actual value.

In discussing monetized value of CO_2, it is also important to take into consideration the costs of inaction on reducing greenhouse gas emissions and the resultant consequences of global warming. In the EPA notice on the California waiver denial, the agency outlines some of these consequences:

> …along with exacerbating ozone impacts and increasing wildfires. . . declining snowpack and early snowmelt and resultant impacts on water storage and release, sea level rise, salt water intrusion, and adverse impacts to agriculture (e.g., declining yields, increased pests, etc.), forests, and wildlife. . . .In addition, some commenters specifically point to a direct threat to public health (e.g., asthma) since increased temperatures due to increased GHG emissions will lead to increased levels of ozone and other pollutants. [73 *FR* 12156, 12169 (March 6, 2008) at 12164.]

A recent report from the University of Maryland found that economic impacts of global warming will be far-reaching, unevenly distributed, and will put a significant strain on public sector budgets. [Footnote: See original comment document.] It is therefore important that when considering any policy relevant to reducing global warming pollution that the costs of inaction be factored into the decision. NHTSA has not made such an estimate in its proposal or the accompanying economic analysis.

Comment Number: 0588-3

Commenter: Stanley Gee

NHTSA also uses an arbitrary low value for the benefits of avoided greenhouse gas emissions, reducing estimated benefits.

Comment Number: 0588-8
Organization: New York State Department of Transportation
Commenter: Stanley Gee

Under NHTSA's cost-benefit based standard setting methodology, the values assigned to benefits are critical. Higher value benefits justify more stringent standards. NHTSA arbitrarily chose $7.00 per metric ton of carbon dioxide avoided as the benefit of reduced fuel consumption, rather than $13.60 per metric ton of carbon dioxide ($50 per metric ton of carbon) recommended by the National Academy of Sciences Committee on which NHTSA says it relies for this analysis.

Comment Number: 0595-22
Organization: Environmental Protection Agency
Commenter: Susan Bromm

Also, the social cost of a non-CO_2 GHG can be quite different from the social cost of carbon dioxide emissions (IPCC WGII, 2007). NHTSA should estimate the global changes in non-CO_2 GHG emissions and apply, or at least acknowledge, non-CO_2 marginal benefits estimates.

Comment Number: 0595-3
Organization: Environmental Protection Agency
Commenter: Susan Bromm

NHTSA selected a single marginal benefits value of \$7.00/tCO_2 to represent the social cost of carbon (SCC) for their main analysis. This value and the \$0-14/tCO_2 range NHTSA considers are characterized as domestic SCC estimates. While OMB [Office of Management and Budget] guidance instructs Agencies to consider benefits that accrue to U.S. residents, it does allow for the additional consideration of global benefits. Given that U.S. emissions have global externalities, NHTSA should analyze global SCC estimates in addition to any domestic estimates to more fully capture all of the externalities. This could be justified from the fact that U.S. citizens may value impacts felt outside our borders. Moreover, to the extent that the United States regards the CAFE standards as a component of its contribution to a global effort to address climate change, a global SCC is needed to accurately characterize that contribution. It is also important that NHTSA recognize that the current monetized estimates of marginal benefits are incomplete and very likely underestimated.

Therefore, EPA recommends that NHTSA do Volpe runs with a range of domestic and global SCC estimates that capture the uncertainty in estimates and the potential risks of significant climate change impacts. The ranges and growth rates should be based in the peer reviewed literature and should cover a substantial range, given the wide uncertainties in estimates of the SCC. For example, see the estimates and discussion in the "Technical Support Document on the Benefits of Regulating GHG Emissions" developed in support of EPA's Advanced Notice of Proposed Rulemaking (found at www.regulations.gov; search on "Technical Support Document – Benefits").

It should also be noted that SCC estimates are only a partial accounting of the social costs of carbon. NHTSA does not currently account for the non-monetized impacts and potential catastrophic risks of climate change in its decision-making approach. The IPCC WGII [Work Group II] (2007) report states that SCC values are "very likely" underestimated, where the report defines "very likely" as a greater than 90% probability. The models used to generate the SCC estimates cited by NHTSA leave out major types of climate change damage that have been identified by the IPCC.

Furthermore, most SCC estimates exclude the value of avoiding or reducing the risk of potential catastrophic effects of climate change, due to scientific and economic uncertainties. It is noteworthy that the risk of such effects is one of the major policy considerations for Congress, the public, and the executive branch in developing a climate change mitigation policy, yet is excluded in most economic analysis. Risk increases with increases in the rate and magnitude of climate change, due to a greater chance to stress systems. NHTSA should clearly note in the DEIS that emissions reductions reduce the probability of higher climate outcomes and therefore reduce the level of associated risk and acknowledge that benefits estimates do not include a risk premium, i.e., the value people have for greater certainty and the reduced risk of more extreme outcomes.

Commenter: Caroline Keicher

NHTSA should first use more accurate values for gasoline prices and carbon values and more realistic assumptions about hybrid penetration and an accelerated introduction of PHEVs [plug-in hybrid electric vehicles] and EVs [electric vehicles] – all of which will justify a standard of at least 35 mpg in 2015. NHTSA should then recalibrate its alternative scenarios to reflect these changes.

Commenter: Tara Morrow

While I was glad to see that the DEIS does assign a dollar value greater than zero to CO_2 reductions, I ask you to take another look at the value range and price carbon more accurately given the most recent analysis, as others have referred to here today.

Response

As commenters noted and as shown by a significant body of literature, there is a wide range of values associated with the social cost of carbon (SCC) and extremely wide variations in published estimates for SCC. However, NHTSA has taken a hard look at this issue and the associated literature, and believes its analysis falls within the mainstream views on the issue.

Emissions of CO_2 and other GHGs occur throughout the process of producing and distributing transportation fuels, and from fuel combustion itself. By reducing the volume of fuel consumed by passenger cars and light trucks, higher CAFE standards will reduce emissions generated by fuel use, and throughout the fuel-supply cycle. Quantifying and monetizing the benefits from reducing these emissions first requires an estimate of the resulting effect on the projected pace and extent of future changes in the global climate, and then an estimate of the value of any resulting reduction in future economic damages that changes in the global climate would otherwise have caused.

If projected future changes in the global climate ultimately exceed critical thresholds in the dynamics of global geophysical or biophysical systems, those changes might also lead to large-scale events, such as a sudden large rise in sea levels or irreversible alteration of critical regional ecosystems. By reducing the probability that climate changes with potentially catastrophic economic or environmental impacts will occur, reducing GHG emissions might also confer benefits that extend beyond their resulting reduction in the expected future economic costs caused by more gradual changes in Earth's climatic systems.

The environmental impacts of GHG emissions differ in several important ways from those of conventional air pollutants. Most important, as the IPCC has noted, CO_2 and other GHGs are chemically stable, and therefore remain in the atmosphere for periods of a decade to centuries, or even longer, becoming well-mixed throughout Earth's atmosphere. As a consequence, current emissions of these gases have extremely long-term effects on the global climate, and emissions from the United States *are expected to contribute to changes in the global climate that will affect many other nations. Similarly, emissions occurring in other countries will contribute to changes in Earth's future climate that are expected to affect the well-being of the United States.*

Researchers usually estimate the economic benefits from reducing GHG emissions in several steps; the first is to project future changes in the global climate and the economic damages that are expected to result under a baseline projection of net global GHG emissions. These projections are usually developed using models that relate concentrations of GHGs in Earth's atmosphere to changes in summary measures of the global climate, such as temperature and sea levels, and in turn, estimate the reductions in global economic output that are expected to result from changes in climate. Because the effects of GHG emissions on the global climate occur decades or even centuries later, and there is considerable inertia in Earth's climate systems, changes in the global climate and the resulting economic impacts must be estimated over a comparably long future period.

Next, this same modeling process is used to project future climate changes and resulting economic damages under the assumption that GHG emissions will be reduced by some increment beginning in a stated future year. The reduction in projected global economic damages resulting from the lower future trajectory of GHG emissions, which also occurs over a prolonged period extending into the distant future, represents the estimated economic benefit from the assumed reduction in emissions. Discounted to its equivalent present value and expressed per unit of GHG emissions (usually per ton of carbon emissions, with non-CO_2 *GHGs converted to their equivalents in terms of carbon emissions), the resulting value represents the global economic benefit from reducing GHG emissions by one unit beginning in a stated future year. This value is often referred to in published research and debates over climate policy SCC.*

This process involves multiple sources of uncertainty, including those in scientific knowledge about the effects of varying levels of GHG emissions on the magnitude and timing of changes in the functioning of regional and global climatic and ecological systems. In addition, sunstantial uncertainty surrounds the anticipated extent, geographic distribution, and timing of the resulting impacts on the economies of nations in different regions of the globe. Because the climatic and economic impacts of GHG emissions are projected to occur over the distant future, uncertainty about the correct rate at which to discount these future impacts also substantially affects the estimated economic benefits of reducing GHG emissions.

Finally, researchers have not yet been able to quantify many of the potentially substantial effects of GHG emissions and their continued accumulation in Earth's atmosphere on the global climate. Researchers also have not developed complete models to represent the anticipated impacts of changes in the global climate on economic resources and the productivity with which they are used to generate economic output. As a consequence, the estimates of economic benefits from reducing GHG emissions produced by integrated models of climate and economic activity are likely to exclude some potentially substantial sources of benefits that will result from lower emissions.

Some researchers are concerned that the combination of multiple sources of uncertainty in estimating climate damages and the omission of some potentially substantial economic impacts of climate change limits the usefulness of deterministic estimates of SCC for valuing the economic impacts of GHG emissions and developing policies that are intended to reduce their emissions. They argue that the modeling approach typically used to monetize the impacts of climate change and value reductions in GHG emissions does not appropriately represent or account for risks posed by the possibility of catastrophic changes in climate and the correspondingly large economic damages. This could lead the conventional approach to substantially underestimate the economic benefits resulting from policies that reduce GHG emissions.

While conventional probabilistic uncertainty analysis might be useful in identifying the range of uncertainty surrounding estimates of SCC derived using the typical modeling approach, a risk management approach might be more appropriate in these circumstances. Instead of using estimates of SCC to value reductions in GHG emissions, this approach would specify a maximum acceptable extent of climate change (as measured, for example, by a maximum increase in global mean temperature), and derive from it the maximum permissible level of GHG emissions over the foreseeable future.

Estimates of the costs of achieving the emissions reductions necessary to limit emissions to this maximum level – and thus prevent climate change from proceeding beyond its maximum acceptable extent – would then be developed. The estimated incremental costs for achieving the final emissions reductions necessary to keep emissions below their maximum permissible level would then be used to estimate the value of reducing GHG emissions via policies or regulations.

In developing the fuel economy standards proposed in the NPRM and evaluated in the DEIS, NHTSA used an initial estimate of $7 per metric ton for the value of reducing U.S. CO_2 *emissions from fuel production and use. This figure was intended to represent the amount by which the economic value of damages to the United States from potential climate change effects in the United States was likely to be reduced for each ton of* CO_2 *emissions that would be avoided by producing and consuming less fuel. NHTSA also examined the sensitivity of the optimized CAFE standards and their accompanying environmental impacts to a range of values for reducing* CO_2 *emissions extending from zero to $14 per metric ton of* CO_2*.*

As discussed in detail in the NPRM, these values were based on Tol's (2005) extensive survey of published estimates of the global economic damage likely to be caused by changes in climate resulting from increased carbon emissions, often referred to as the social cost of carbon (SCC)[8] *(Tol 2005). Specifically, NHTSA's estimate of $7 per metric ton for the domestic value of reducing* CO_2 *emissions, which was intended as an estimate of the reduction in climate-related economic damages that occur within the United States as a consequence of lower* CO_2 *emissions, was based on Tol's calculation that the mean value of peer-reviewed estimates of the global SCC included in his survey was $43 per metric ton of carbon. Tol's estimate corresponds to a global value for the economic benefits from reducing* CO_2 *emissions of $14 per metric ton (Tol 2005, Yohe et al. 2007).*[9]

NHTSA's estimate implicitly reflected the assumption that approximately half of the global economic damages resulting from climate change would be borne within the United States, thus resulting in the figure of $7 per metric ton of CO_2 *emissions. The range from zero to $14 per metric ton used in the NPRM sensitivity analysis reflected the additional assumption that the range of uncertainty surrounding the likely economic benefits to the United States from reducing the threat of climate change extended from a low estimate of zero benefits to a high estimate equal to 100 percent of the $14 per metric ton value derived from Tol's analysis.*

NHTSA received numerous comments on the value of reducing CO_2 *emissions it employed to develop the standards proposed in the NPRM and DEIS. This FEIS examines how the alternatives are affected by variations in the economic assumptions input into the Volpe model. Specifically, NHTSA*

---

[8] *Richard S. J. Tol, The marginal damage costs of carbon dioxide emissions: an assessment of the uncertainties, Energy Policy 33 (2005), 2064-2074.*

[9] *Carbon itself accounts for 12/44, or about 27 percent, of the mass of carbon dioxide (12/44 is the ratio of the molecular weight of carbon to that of carbon dioxide). Thus, each ton of carbon emitted is associated with 44/12, or 3.67, tons of* CO_2 *emissions. Estimates of SCC are typically reported in dollars per ton of carbon, and must be divided by 3.67 to determine their equivalent value per ton of* CO_2 *emissions.*

calculated and analyzed mpg standards and environmental impacts associated with each alternative under both the "Reference Case" for key model inputs, which uses the U.S. Energy Information Administration's (EIA's) Reference Case fuel price forecast, a domestic SCC, and a 7 percent discount rate; and under a "High Scenario" set of input assumptions, which uses the EIA "High Case" for fuel price forecast, a global SCC, and a 3 percent discount rate. This FEIS also analyzes the impacts of various other combinations of economic assumptions to illustrate the variations in environmental impacts and mpg stringency that result from using various combinations of Volpe model inputs. See Sections 3.2.4, 3.3.4, 3.4.5, 4.2.3, 4.3.4, and 4.4.3.

In response to new research on the potential economic costs of climate change that has become available since publication of the recent NPRM, and the many comments NHTSA received, we have evaluated in this FEIS the environmental impacts resulting from standards associated with a substantially higher global estimate of the value of reducing CO_2 emissions. Specifically, this FEIS analyzes environmental impacts under the assumption that the global value of reducing CO_2 emissions is $33 per metric ton, and conducts a sensitivity analysis using a value of $80 per metric ton. This FEIS also presents the environmental impacts resulting from a revised domestic SCC assumption of $2 per metric ton of CO_2 emissions. To develop these new estimates, NHTSA has relied on Tol's (2008)[10] expanded and updated survey of 211 published estimates of SCC, which was published after the completion of the analysis NHTSA performed to develop CAFE standards it proposed in the NPRM.

Tol's 2008 survey encompasses a substantially larger number of estimates for the global value of reducing carbon emissions than its previously published counterpart. Like that author's earlier survey, it represents the only recent, publicly available compendium of peer-reviewed estimates of SCC that has been peer-reviewed and published itself. Thus, NHTSA believes that it is the most reliable source on which to base our own updated estimate of the global value of reducing CO_2 emissions from fuel production and use.

As indicated previously, the long-lived nature of atmospheric GHGs means that emissions of these gases from any location or source can affect the global climate over a prolonged period, and can thus result in economic damage to many nations and over multiple generations. Reducing GHG emissions to an economically efficient level, or one that maximizes the difference between the benefits from limiting the extent of climate change and the costs of achieving the emissions reductions necessary to do so, therefore requires individual nations to limit their own domestic emissions to the point where their domestic costs for further reducing emissions equal the global value of reduced economic damages that result from limiting climate change.

In its Technical Support Document on the Benefits of Regulating GHG Emissions referenced in its comments on the DEIS, EPA argued that if individual nations consider only the domestic benefits they each receive from limiting the pace or extent of climate change, they will each reduce their emissions only to the point where their respective domestic costs for achieving further reductions equal the benefits to their own domestic economies from limiting the impacts of climate change. Because no individual nation is likely to experience a large share of total global damages from climate change, however, none will capture a substantial share of the benefits from limiting it. Thus, the combined global reduction in emissions resulting from individual nations comparing their domestic benefits from limiting climate change to their domestic costs for reducing emissions will likely be inadequate to substantially slow or limit the progress of climate change.

[10] *Richard S.J. Tol (2008), "The Social Cost of Carbon: Trends, Outliers, and Catastrophes," Economics – the Open-Access, Open-Assessment E-Journal, 2 (25), 1-24.*

Tol's updated survey reports that the mean value of the 125 estimates of SCC published in peer-reviewed journals through the year 2007 is $71 per ton of carbon emissions. All of these estimates are intended to represent the global value of reduced economic damage from climate change that would be likely to result from lower carbon emissions. In direct communications with Tol, NHTSA staff confirmed that this value applies to carbon emissions occurring during the mid-1990s, and is expressed in approximately 1995 dollars (Tol 2008, Table 1). The $71 per metric ton estimate of the social cost of increased carbon emissions corresponds to a global value of $19 per metric ton of CO_2 *emissions reduced or avoided, also expressed in 1995 dollars.*

Separately, the IPCC notes that the climate-related economic damage resulting from an additional ton of carbon emissions is likely to grow at a rate of 2.4 percent annually (Yohe et al. 2008). This growth occurs because the increase in the expected pace and degree of climate change – and thus in the resulting economic damage – caused by growth in emissions rises in proportion to the existing concentration of CO_2 *in Earth's atmosphere.*

Several comments on the NPRM asserted that the IPCC intended the 2.4-percent growth rate it reports for SCC to instead read "2-4 percent." NHTSA staff reviewed the underlying references from which this figure was derived, and those sources clearly report the growth rate in the future value of SCC as 2.4 percent, rather than the 2-4 percent asserted in various comments (Hope 2006, Hope and Newberry 2006). Applying the 2.4-percent annual rate of increase to the $19 per ton mean value for mid-1990s CO_2 *emissions, and expressing the result in 2007 dollars, results in a global value of $33 per metric ton of* CO_2 *for emissions occurring during 2007. In this FEIS, NHTSA uses this global value for SCC in the Mid-1 and High Scenario combinations of economic assumptions. See Table 2.3-2 and Appendix B.*

NHTSA uses this figure, which is assumed to continue increasing from its 2007 value at the 2.4-percent annual rate specified by the IPCC, to estimate the global economic benefits from reducing future CO_2 *emissions by establishing higher CAFE standards for MY 2011-2015 cars and light trucks. Continuing growth in the value of reducing* CO_2 *emissions over the expected lifetimes of those vehicles, which extend through approximately 2050, means that the value of eliminating each ton of* CO_2 *emissions by reducing fuel production and use averages approximately twice its $33 value during 2007.*

Like the underlying estimate from which it is derived, the $33 per metric ton of CO_2 *figure represents the estimated world-wide or global economic benefits from reducing U.S.* CO_2 *emissions during 2007. As indicated previously, there are important reasons for individual nations to take these world-wide benefits into account when deciding the extent of reductions in their domestic emissions to seek or require, because reducing their domestic emissions confers substantial benefits on the large number of other nations for which potential economic damages from climate change are also reduced as a result.*

The substantial magnitude of these "external" benefits (EPA estimates that 90 to 95 percent of the total global benefits from reducing U.S. CO_2 *emissions will be experienced by other nations) implies that a globally efficient level of total emissions reduction can only occur if individual nations base their respective decisions about how extensively to reduce their own domestic emissions on a comparison of the global benefits from reducing the threat of climate change to their respective costs for reducing domestic emissions. Basing its decisions about emissions reductions on this comparison is particularly likely to be required for the U.S. to achieve reductions that are efficient from a global perspective, since as much as 90-95% of the total global benefits from reducing U.S. CO2 emissions may be experienced by other nations (EPA 2008i; calculated from Table 1).*

NHTSA notes that there is a risk for nations that unilaterally attempt to reduce emissions by adopting policies, regulations, or taxes to reduce the threat of climate change. The potential risk is that they will economically disadvantage the domestic industries those policies affect. There is also the possibility of unintended consequences. By doing so, they could induce economic activity – particularly production by emissions-intensive industries – to shift to nations that adopt less stringent or no regulations on emissions. This shift could take either the form of industries relocating production capacity to other nations or the loss of market share by domestic industries to overseas producers.

In either case, the result is likely to be reductions in domestic economic output and employment. Thus, nations attempting to reduce emissions to the levels called for by considering the global benefits from doing so could bear substantial costs, without resulting in comparably valuable reductions in the potential economic damages they face from climate change.

In the specific context of this rulemaking, establishing CAFE standards partly on the basis of the global benefits projected to result from lower GHG emissions would likely impose higher costs on automobile manufacturing activity to serve the U.S. vehicle market, regardless of whether that activity occurs within the U.S. or overseas. If vehicle manufacturers located in the U.S. respond by reducing production, the U.S. economy could bear substantial costs, without resulting in a measurable net reduction in global GHG emissions.

Recognizing this prospect, NHTSA has estimated the economic damage from climate change effects that is likely to be borne within the United States, and employed this value to estimate the domestic benefits to the United States from reducing GHG emissions. NHTSA constructed this value using estimates of U.S. domestic and global benefits from reducing greenhouse gas emissions developed by EPA and reported in that agency's Technical Support Document accompanying its Advance Notice of Proposed Rulemaking on motor vehicle CO_2 emissions[11] (EPA 2008i). Specifically, NHTSA applied the ratio of domestic to global values of reducing CO_2 emissions estimated by EPA using its Climate Framework for Uncertainty, Negotiation, and Distribution (FUND) integrated assessment model to the $33 per metric ton estimate of the global value of reducing CO_2 emissions, which was developed as described above.

EPA's central estimates of domestic and global values for reducing GHG emissions from the FUND model using a 3 percent discount rate are $1 and $17 per metric ton (in 2006 dollars) (EPA 2008i; Table 1, p.12). Applying EPA's ratio to NHTSA's $33 per metric ton estimate of the global value of reducing CO_2 emissions, developed as described above, produces an estimate of $2 per metric ton for the domestic benefit from reducing U.S. CO_2 emissions in 2007. NHTSA have employed this estimate as an alternative to the global value of reducing U.S. CO_2 emissions in establishing CAFE standards for MY 2011-2015 and evaluating their economic benefits.

NHTSA has also applied the 2.4 percent rate of growth to calculate the annual increase in its estimate of the domestic benefits from reducing CO_2 emissions. Over the lifetimes of cars and light trucks subject to the CAFE standards for MY 2011-15, the resulting value averages $4 per metric ton of CO_2 emissions avoided by reducing fuel production and consumption.

In its Technical Support Document, EPA argues that the most appropriate estimate of SCC that can be derived from Tol's 2008 survey is the mean value of the estimates from only those studies that

[11] *EPA Technical Support Document on Benefits of Reducing GHG Emissions, June 12, 2008. EPA Docket No. EPA-HQ-OAR-2008-0318* (http://www.regulations.gov/fdmspublic/component/main?main=DocumentDetail&o=0900006480669358).

were published after 1995 and that do not employ so-called equity weighting.[12] *Further, Tol notes that estimates of SCC vary substantially with the rate used to discount increased future economic damages resulting from climate change to the date that the emissions causing that increased damage are assumed to occur.*

EPA also suggests that estimates of benefits from reducing emissions should employ the mean of only those estimates of SCC that are derived using the specific rate that will subsequently be used to discount CO_2 emissions from the date they occur to the present.[13] *Because NHTSA uses a rate of 3 percent to discount future benefits from reducing CO_2 emissions (see Section 10.2.2.8), EPA's Technical Support Document appears to suggest that the most appropriate estimate of SCC from Tol's 2008 survey for use in NHTSA's analysis of benefits from reducing fuel consumption corresponds to a value of $40 (in 2007 dollars) per metric ton of CO_2 emissions occurring today (EPA 2008i; Table 1, p 12).*

However, NHTSA's view is that the mean value of all 125 SCC estimates from peer-reviewed studies reported by Tol provides a more appropriate basis for valuing reductions in CO_2 emissions. This is because NHTSA believes that excluding pre-1995 studies and those that employ equity weighting (which would eliminate 40 of the 125 estimates) could eliminate many studies that produced sound, defensible estimates of SCC, particularly recognizing that those studies have been published in peer-reviewed journals. Including those studies improves the reliability of the resulting average value by reducing the uncertainty surrounding it.

NHTSA also believes that its estimate of the value of reducing CO_2 emissions should not be based solely on estimates developed using a 3-percent discount rate. Instead, NHTSA recognizes that the varying discount rates employed by different researchers are an important source of variation in their resulting estimates of SCC. The discount rate is a parameter about which there is substantial disagreement, analogous to the uncertainty surrounding the many other parameters involved in modeling future climate change and the resulting economic damage.

Thus, NHTSA believes that incorporating estimates of SCC that employ varying discount rates increases the extent to which the resulting average value fairly incorporates the many sources of uncertainty that complicate researchers' attempts to identify the correct value. Another more practical reason for not restricting the sample of estimates to those using a 3-percent discount rate is that this would reduce the number of estimates on whichNHTSAbases the estimate of the value of reducing CO_2 emissions to only 10 of the 125 peer-reviewed estimates included in Tol's recent survey (Tol 2008, Table 1).

The agency also conducted sensitivity analysis using $80 per ton as an estimate of the global value for reducing CO_2 emissions to illustrate the resulting stringencies, fuel savings, and CO2 reductions that result from higher estimates of the global social cost of CO_2 emissions. In his updated survey of SCC estimates, Tol reports that the standard deviation associated with the mean value from 125 peer-reviewed estimates of the global SCC of $71 per ton of carbon emissions is $98 per ton. Like Tol's original $71 estimate, this value applies to mid-1990s emissions of carbon (rather than carbon dioxide), and is expressed in approximately 1995 dollars.

[12] *Equity weighting assigns higher weights per dollar of economic damage from climate change that are expected to be borne by lower-income regions of the globe, in an attempt to make the welfare changes corresponding to those damages more comparable to the damages expected to be sustained by higher-income world regions.*
[13] *Tol notes that estimates of SCC vary substantially with the rate that is used to discount increased future economic damages resulting from climate change to the date that the emissions causing those increased damages are assumed to occur.*

Thus, a range of one standard deviation above and below the $71 mean value extends from minus $27 (i.e., $27 per ton benefit for each ton of carbon emitted) to $169 per ton of carbon. Converting this range to 2007 dollars per ton of CO_2 *and applying the same 2.4-percent annual growth rate to these values produces a range of minus $13 to $80 around the $33 per ton mean estimate of the global benefit from reducing* CO_2 *emissions in 2007.*

While NHTSA uses the $80 per ton benefit of reducing CO_2 *emissions in its sensitivity analysis, the agency has elected not to employ the minus $13 per ton figure, in part because, based on information from the U.S. Climate Change Science Program and the IPCC, it views the implication that there are measurable economic benefits from climate change as implausible. NHTSA believes that the range extending from the $2 per ton estimate of the domestic value of reducing* CO_2 *emissions to the $80 per ton upper estimate of the global value is sufficiently broad to illustrate the sensitivity of fuel savings and resulting environmental impacts to differing SCC values.*

Comments

Comment Number: 0550-8
Organization: Individual
Commenter: Sarah Larsen

NHTSA proposes to raise the fuel economy of cars and light trucks to a combined average of 31.6 mpg for Model Year 2015. While this increase is more than half of what is required to meet the mandate of 35 mpg by 2020, I believe NHTSA fails to take full advantage of available fuel saving technologies, and fails to fully and fairly evaluate the benefits of greenhouse gas emission reductions.

Comment Number: 0554-9
Organization: Individual
Commenter: James Adcock

Plug-in hybrids. Given GM commitment to delivering a plug-in hybrid (Chevy Volt) in this time frame, NHTSA's assumption that plug-in technology will not exist during the regulatory period is troubling, and will lead to higher GHG.

Start/stop mild hybrid on small cars. NHTSA's assumption that this technology is not available for small cars is troubling given that it has already been implemented in Europe (Smart Fortwo mhd.) This assumption results in higher GHG.

Comment Number: 0557-11
Organization: The Natural Resources Defense Council
Commenter: Luke Tonachel, Brian Siu

NHTSA set arbitrary limits on technology availability in the Volpe Model, which biased toward setting a weaker fuel economy standard. Two specific examples include an arbitrary constraint on the use of lightweight materials substitution to improve fuel economy and the exclusion of plug-in hybrid electric vehicles from consideration in the Volpe Model.

Comment Number: 0559-7
Organization: The Northeast States for Coordinated Air Use Management (NESCAUM)
Commenter: Arthur Marin

We urge NHTSA to reevaluate its proposal, taking more of a technology forcing approach to setting standards. Further, we urge NHTSA to consider fuel consumption reducing technologies that by virtue of NHTSA's conservative cost-analysis approach have not been given due consideration. For example, NHTSA notes that "some manufacturers have made public statements regarding hopes to offer plug-in HEVs [hybrid electric vehicles] before MY 2015, but such vehicles are not represented in our analysis." We contend that the prospect for widespread deployment of plug-in HEVs in the near term is more than a simple hope. For example, both Toyota and Chevrolet have announced plans for plug-in HEVs to be available around 2010. [Footnote: See original comment document.]

Comment Number: 0572-18
Organization: Center for Biological Diversity
Commenter: Brian Nowicki, Mickey Moritz, Kassie Siegel

The potential technologies for improving fuel economy are unreasonably limited. The extent to which the technology is unreasonably limited is amply illustrated by the fact that the "technology exhaustion" alternative barely reaches the current fuel economy standards in Japan and Europe, much less the projected fuel economy standards in Europe and Japan for 2015. [Footnote: See original comment document.] A model that predicts maximal technology implementation to be unable to reach even current market standards in other countries is clearly not considering all available technologies.

Concrete examples of technologies that are unreasonably excluded are: electric vehicles, plug-in hybrids, and power-split hybrids. Electric vehicles are entirely excluded from the Volpe model. (73 *Fed. Reg.* at 24381, Table III-3) This is absurd considering that a major U.S. auto manufacturer produced and placed such vehicles on the road in the year 1996. [Footnote 6: See original comment document.] These vehicles were pulled from the market for commercial reasons over loud protests of drivers in 1999, and destroyed in 2003 (Biederman 2005). An auto manufacturer's commercial decision does not render a technology unsuitable for implementation – the only concern should be physical capability, which has been clearly demonstrated. Plug-in hybrids are also categorically excluded on the basis that they are not "market-ready" (73 *Fed. Reg.* at 24381), despite the fact that Toyota is planning to introduce plug-in hybrids by MY 2010 (Maynard 2008). The major U.S. auto manufacturers are also planning to offer similar vehicles around the same time. (Maynard 2008) Power split hybrids, like the Toyota Prius, are considered advanced technology that will not be available under 2014. (73 *Fed. Reg.* at 24381, Table III-3) This assumption is ludicrous given that the Toyota Prius has been sold in the U.S. since MY 2001 and is a top-selling vehicle.

Other technologies that are not yet commercially available, but could be if economy standards were sufficiently high, include replacement of spark-plugs with laser-pulse injection systems and engines that can switch between two-stroke and four-stroke modes (Graham-Rowe 2008). Furthermore, the DEIS makes no mention of alternatives such as compressed-air vehicles (Green Car Congress 2008).

There are abundant potential technologies for improving fuel economy that have not been included in the Volpe model. This leads to misleading and factually incorrect outputs from the model, and a failure to disclose basic relevant information under NEPA.

Comment Number: 0598-5
Organization: Sierra Club
Commenter: Caroline Keicher

NHTSA should first use more accurate values for gasoline prices and carbon values and more realistic assumptions about hybrid penetration and an accelerated introduction of PHEVs and EVs – all of which will justify a standard of at least 35 mpg in 2015. NHTSA should then recalibrate its alternative scenarios to reflect these changes.

Comment Number: TRANS-06-7
Organization: Public Citizen
Commenter: Lena Pons

All of the regulatory alternatives that are considered in the draft environmental impact statement are the result of modeling using the Volpe model. This is problematic because the Volpe model does not completely look at all of the available technologies. It does not look at, and it applies various optimization factors which do not reflect what the most aggressive possible control regulations would be.

Additionally, the Volpe model bars certain types of techniques, such as down weighting and performance reduction, which may seem like strange things to do, because we've traditionally considered them to be problematic. However, given the significant dangers to the environment as a result of global warming, it's important to consider these things as well.

Comment Number: TRANS-08-14
Organization: Sierra Club
Commenter: Ann Mesnikoff

The proposed rule and the PRIA both show that the gas prices are major forces in setting fuel economy. NHTSA short changes America by using gas price assumptions that are far too low, a price for carbon that is randomly selected, and artificially constraining technologies.

Comment Number: TRANS-08-4
Organization: Sierra Club
Commenter: Ann Mesnikoff

NHTSA should first use more accurate values for gasoline prices and other inputs to justify a 35 in 2015 standard, and increases beyond that with greater hybrid penetration, accelerated introduction of plug-in electric hybrid vehicles, and other technologies.

The DEIS is premised upon a flawed proposed standard and the scenarios that must be addressed should be fixed before a final standard is issued and a final EIS is issued.

Comment Number: TRANS-20-7
Organization: Sierra Club
Commenter: Caroline Keicher

NHTSA proposes to raise fuel economy of cars and light trucks to a combined average of 31.6 miles per gallon for model year 2015. While this increase is more than half of what is required to meet the floor set by the EISA, NHTSA fails to take full advantage of the fuel saving technologies, and fails to fully and fairly evaluate the benefits of greenhouse gas emission reductions.

Comment Number: TRANS-39-2
Organization: American Jewish Committee
Commenter: Ami Greener

In proposing a combined average of 31.6 miles per gallon for model year 2015, NHTSA is failing to acknowledge the current technology that could safely and cost effectively make all vehicles reach state-wide fuel economy average of at least 35 miles per gallon by that year.

Comment Number: TRANS-15-4

Organization: Union of Concerned Scientists
Commenter: Eli Hopson

One of the peculiar findings of the NPRM is light trucks' lack of sensitivity compared to that of passenger cars. The sensitivity analysis using high fuel prices, for example, yields up to a 6.7 mpg difference from NHTSA's proposed scenario for cars, and only a 0.8 mpg difference from the proposed scenario for light trucks. The only explanation given by NHTSA for this lack of truck sensitivity is that marginal technologies for trucks are too expensive to "bring them over the cost-benefit threshold." (NPRM, p. 364-365).

However, that explanation is inconsistent with the technology costs laid out in Table III-1 of the NPRM. Even the 2002 National Academies study, on which NHTSA claims to have based some of its technology costs, show only slightly (approx. 15% to 25%) lower technology expenses for passenger cars than for light trucks [Footnote: See original comment document.] Moreover, given that incremental energy savings are greater at the low end of the fuel economy spectrum (i.e., that a 1 mpg increase from 14 to 15 mpg saves more energy than a 1 mpg increase from 24 to 25 mpg), one would presume that trucks would have an even *easier* time making the marginal cost-effective case.

Based on the opaqueness of the cost-effective judgment criteria, UCS cannot determine with certainty what might be constraining application of fuel saving technologies to light trucks in the Volpe model. However, the explanation provided by NHTSA that light truck technology has tapped out its cost-effectiveness seems highly unlikely.

Comment Number: 0576-33
Organization: Public Citizen
Commenter: Joan Claybrook

This approach to vehicle weight ignores the role of advanced materials to reduce vehicle weight without compromising safety, it discourages manufacturers from considering more aggressive vehicle redesigns, which could achieve a broad range of fuel economy and safety goals, and it preserves the dangerous incompatibility between the heaviest and lightest vehicles. In setting aggressive new fuel economy standards, the agency should encourage manufacturers to rethink how vehicles are built. New standards should promote innovation that drives safety and fuel economy forward. Instead, with the Volpe Model's approach of merely requiring that the industry do what it was planning to do, there is little to no motivation to make much-needed bold shifts.

Comment Number: 0588-6
Organization: New York State Department of Transportation
Commenter: Stanley Gee

As global warming trends continue, NYSDOT encourages NHTSA to work with the industry to expedite the production of more fuel efficient vehicles, as well as those capable of using alternative fuels, such as compressed natural gas (CNG), liquefied natural gas (LNG), and advanced biofuels. NHTSA should also promote hybrid-electric, battery electric, cleaner diesel, and fuel cell technology.

Comment Number: 0575-21
Organization: Union of Concerned Scientists
Commenter: Eli Hopson

The source of the data for NHTSA's manufacturer-specific learning curves is not provided and the approach appears fundamentally flawed. First, by applying learning curves on a manufacturer-specific basis, NHTSA ignores the fact that many manufacturers engage in joint-venture efforts to produce new technologies. The recent 2-mode hybrid technology enabling more fuel efficient trucks, for example, was the product of a joint venture between Chrysler, General Motors, and BMW. Even when joint ventures are not in practice, manufacturers learn from each other through the standard practice of tearing down competitors products. NHTSA's proposed learning curve methodology does not account for any of these practices.

Further, treating car and truck sales volumes separately when estimating learning curves makes little sense. While certain components will invariably be unique to cars or light trucks separately, that is far from an industry-wide rule of thumb. It makes little sense to assume that the experience gained from, for example, the use of lower cost materials would not subsequently be used in other products. This is especially true today where many "trucks" are, in fact, car-like crossover vehicles with shared components of many sedans and wagons.

In its technical report, *Cost and Effectiveness Estimates of Technologies Used to Reduce Light-duty Vehicle Carbon Dioxide Emissions*, EPA suggests use of a learning curve factor of 20%, with the limited exception of diesel. [Footnote: See original comment document.] UCS recommends that NHTSA remedy the flaws associated with its learning curve assumptions, and adopt EPA's suggestion of a 20% learning factor, to help account for the market realities noted above.

Comment Number: 0559-12
Organization: The Northeast States for Coordinated Air Use Management (NESCAUM)
Commenter: Arthur Marin

Information from a 2004 NESCCAF (NESCCAF is the Northeast States Center for a Clean Air Future, an affiliate organization of NESCAUM) study entitled "Reducing Greenhouse Gas Emissions from Light-Duty Motor Vehicles" is cited in the NHTSA proposal. Some of this information is reported in a way that is either confusing or incorrect. For example, NHTSA applies a 1.5 retail price equivalent (RPE) factor to the manufacturer costs presented in Appendix C of the NESCCAF report, and at other times uses a 1.4 RPE — and presents both costs as NESCCAF costs. In the report, NESCCAF only used a 1.4 RPE. The reporting of costs using the 1.5 multiplier as NESCCAF costs is incorrect and leads to uncertainty as to how the costs were developed. A specific case is the cost of a turbocharger. NHTSA states the NESCCAF turbocharger cost is $600. In this case, NHTSA applied a 1.5 RPE factor to manufacturer costs presented in Appendix C of the NESCCAF report to arrive at the $600 cost. This is different from the cost that NESCCAF developed. Conversely, on page 24369 of the Federal Register notice, NHTSA accurately states the NESCCAF cylinder deactivation costs ranged from $161 to $210. This cost accurately reflects manufacturer costs presented in Appendix C of the NESCCAF report, multiplied by the 1.4 retail price equivalent used by NESCCAF.

In some cases, information about what specific components were included in the NESCCAF study assumptions is reported incorrectly by NHTSA. For example, the NESCCAF study did not conclude that an air pump is required as part of a turbocharged system, in contrast to NHTSA's statement that NESCCAF assumed a $90 air pump is needed with the turbocharger.

Another example is the statement on p. 24375 of the *Federal Register* notice that the NESCCAF study included costs for high efficiency generators ($56) but failed to account for costs for the electrification of other accessories. In reality, Appendix C of the NESCCAF report assigns a cost of $70 for electrified accessories for a total cost of $126, which is within the range of costs for these technologies cited from a National Academy of Sciences report and used by NHTSA.

We recommend that all reported costs and benefits, attributed to NESCCAF by NHTSA, be reviewed carefully for errors and amended accordingly.

Comment Number: 0572-16
Organization: Center for Biological Diversity
Commenter: Brian Nowicki, Mickey Moritz, Kassie Siegel

Fleet mix is a central component of average fuel economy and yet is absent from the Volpe model cost-benefit analysis. For instance, the Volpe model "does not attempt to account for…intentional over-compliance…" Another possibility NHTSA and Volpe staff have considered but do not yet know how to analyze, is the potential that manufacturers might "pull ahead" the implementation of some technologies in response to CAFE standards that they know will be steadily increasing overtime." Proposed CAFE Standards MY 2011-2015 at 73 *Fed. Reg.* 24352, 24393 (May 2, 2008).

Comment Number: 0575-19
Organization: Union of Concerned Scientists
Commenter: Eli Hopson

In Table 111-3, the NPRM specifies "year of availability" assumptions for various technologies. (NPRM, p. 112) It is unclear where the hybrid technology assumptions come from. Further, the assumptions used do not appear to make sense. All hybrid technologies—ranging from start/stop-based systems to the 2-mode and power-split "full" hybrid systems-are assumed not to appear until 2014, despite the fact that these technologies are on the road today (*i.e.*, Saturn VUE "mild" hybrid, GMC Yukon "2-mode" hybrid, and Toyota Prius "full" hybrid). It is unrealistic to assume, as it appears NHTSA has done, that automakers have cleared their product plans of any other hybrid models until the 2014 model year. This is especially egregious considering that the Toyota Prius is the 9th best selling car in the U.S.

Hybrid Adoption Rates

UCS is concerned about the technology phase-in caps or, as described by NHTSA, "overall constraints on the rates at which each technology can penetrate a manufacturer's fleet." (NPRM, p. 131-132) While many of the caps range from a 4-6 year fleet penetration, NHTSA assumes that hybrid and diesel technologies would see phase-ins as low as 3 percent.

UCS sees no valid reason to assume it will take 33 years for hybrid technology to become ubiquitous. First, and most fundamental, NHTSA applies the same cap to all types of hybrids, from mild start-stop hybrids to full PHEVs alike, despite the fact that the cap is employed “to reflect the major redesign efforts and capital investments required to implement these technologies.” (NPRM, p. 132) In contrast, an EPA technical report on which NHTSA relied said the following about integrated starter-generators with idle-off: “their low cost and easy adaptability to existing powertrains and platforms can make them attractive for some applications.” [Footnote: See original comment document.]

While hybrids currently only account for about three percent of the U.S. market, they are seeing a dramatic increase in interest from consumers seeking ways to find relief from high gas prices. Furthermore, with more than 10 years of experience from leading manufacturers, hybrids can no longer be considered niche technology. UCS (among numerous other groups and market analysts) expects significant growth in the hybrid market over the coming years.

It appears that, lacking any support to back their decision, NHTSA’s hybrid adoption rate was arbitrarily selected, as opposed to based on specific technological findings. Given the fuel savings potential of hybrid-electric technology, limiting its application in this manner is inappropriate. UCS recommends that NHTSA accelerate its hybrid technology adoption rate to 5-7 percent, equivalent to a 15-20 year full market penetration.

Comment Number: TRANS-19-9
Organization: Union of Concerned Scientists
Commenter: Eli Hopson

The recent proposed notice rulemaking actually assumed that hybrids wouldn’t be on the road until 2014. Let me just reiterate that. Despite the fact that there are more than 1 million hybrids on the road today, despite the fact that the Toyota Prius is the ninth best selling car in America, the announcements that NHTSA used assume hybrids won’t be on the market until 2014.

People are not sitting around waiting for a hybrid to show up on a dealer’s lot in six years. They’re on six month waiting lists, as we heard today, because they are already that popular.

Comment Number: TRANS-28-3

Commenter: Jim Pierobon

I hope you’ll recognize how fuel efficient hybrids, as one dramatic example, are becoming more valuable and how quickly and efficiently they can deeply penetrate, especially the consumer automobile market.

Comment Number: TRANS-34-4
Organization: Individual
Commenter: Fred Teal, Jr.

I disagree with your belief that we’re not going to have any substantial amount of hybrid vehicles introduced until 2014. They’ve been around for years, and Ford and General Motors, Honda, Toyota, are making them and selling them today in large quantity. I disagree with your assumption that the rate of adoption of hybrids is going to be as low as you say it is.

Comment Number: 0572-7
Organization: Center for Biological Diversity
Commenter: Brian Nowicki, Mickey Moritz, Kassie Siegel

As discussed in our July 1, 2008 comments on the NPRM, the Volpe model makes a number of assumptions that are unreasonable and conflict with the EPCA statutory scheme. For example, the NHTSA assumes that the U.S. fleet mix will not change in response to consumer demand for more fuel efficient vehicles or due to a change in regulatory requirements. (73 *Fed. Reg.* 24394) This assumption is particularly outrageous. First, auto manufacturers who have for decades deliberately manipulated the market with advertising, incentives, financing schemes, and other methods towards the least fuel efficient vehicles, continue to do so. (See, *e.g.* Chevrolet Tahoe Hybrid website; GreenCar.com 'Chevrolet Tahoe Hybrid Green Car of the Year;' Chrysler $3 gas banner; KCRA.com 'Chrysler $3 gas;' Ford Escape Hybrid website; Lyons 'Ford Guilt Free SUV.') Consumer preferences, nonetheless, are now shifting dramatically towards more fuel efficient vehicles in response to higher gas prices. (Cooper 2008). For a manufacturer to change its fleet mix in response to regulation is a method of compliance that must be considered in both the EPCA and NEPA analyses. Any precedent to the contrary is inapposite.

The NHTSA also assumes that manufacturers will not update their vehicle models more frequently than once every 5 years, and, "in most instances" has simply "accepted the projected redesign periods from the companies who provided them through MY 2013" (73 *Fed. Reg.* 24386) In other words, the underlying analysis for a fuel economy standard which is supposed to conserve energy by pushing manufacturers to develop new technology and innovate to meet challenging standards which may even "appear impossible" today, is constrained by the assumption that manufacturers will do <u>nothing other than what they are already doing</u>, at least for a period of five years. This clearly violates both EPCA and NEPA.

Comment Number: 0576-30
Organization: Public Citizen
Commenter: Joan Claybrook

For this rulemaking, NHTSA has added two more factors that impede transparency, and erode consumer confidence in the Volpe Model: technology phase-in caps and manufacturer learning curves. Public Citizen acknowledges that manufacturers cannot deploy all technologies in all vehicles at once, and that lead-time is necessary for manufacturers to make necessary changes. However, the agency's decision to gear technology additions to the redesign and refresh cycle is unnecessarily lenient. The agency has given the industry over two years of lead time before the 2011 model year. [Footnote: See original comment document.] EISA only requires only 18 months of lead time. For the 2012 to 2015 model years, the agency will have provided ample lead time for automakers to adjust. The industry is already changing plans, and closing plants or stopping work to adjust to changing consumer demand. [Footnote: See original comment document.]

NHTSA claims that it relaxed phase-in caps based on rising fuel prices and rising forecast fuel prices. (PRIA V-50). The agency should re-evaluate the assumptions about phase-in caps, especially with regard to technologies that require a more substantial redesign. NHTSA has given ample lead time for the industry to reconsider its redesign schedule to reflect tumultuous changes in consumer preferences. Public Citizen suggests that NHTSA not constrain the use of technology to achieve the maximum feasible fuel economy level.

Comment Number: 0576-41
Organization: Public Citizen
Commenter: Joan Claybrook

Public Citizen requests that NHTSA rethink its position on dealing with "outliers," or vehicles that get vastly better fuel economy. The agency position is that excluding hybrid electric vehicles "yields initial curves of shapes similar to those proposed, but displaced slightly in the direction of lower fuel consumption. The similarity of the shapes of these curves suggests that optimization against the full fleet (with HEVs) would produce standards whose stringency is similar to that of those proposed today." (73 *FR* 24440) However, automakers will be credited for producing hybrid vehicles which will count for compliance, but not in the stringency of how the curves are set. In an economy-wide standard, the pressure from manufacturers that build more efficient vehicles set the stringency of the economy-wide level of standards. Removing that pressure by excluding highly-efficient vehicles undercuts the maximum feasible level of fuel economy.

Comment Number: 0572-8
Organization: Center for Biological Diversity
Commenter: Brian Nowicki, Mickey Moritz, Kassie Siegel

Volpe model generally does not apply a new technology until a given vehicle is due for a "redesign or refresh," and assumes that some technologies, such as hybrid vehicles, already in use today cannot yet be adopted. (73 Fed. Reg. 24386)

Comment Number: 0575-20
Organization: Union of Concerned Scientists
Commenter: Eli Hopson

Vehicle Redesign Rates

NHTSA assumes that vehicles will be redesigned on five-year cycles, which is inconsistent with recent trade publication information. As reported in Ward's Automotive. Ford intends to shorten its redesign period to three-year cycles. [Footnote: See original comment document.] Given this and past performance from other automakers, NHTSA's product cycle duration assumptions are too long. UCS recommends that NHTSA shorten its modeled redesign period to three-year cycles.

Comment Number: TRANS-02-3
Organization: Lee Auto Malls
Commenter: Adam Lee

The new technologies are coming down in price.

Comment Number: 0572-64
Organization: Center for Biological Diversity
Commenter: Brian Nowicki, Mickey Moritz, Kassie Siegel

both the Volpe model and the economic analyses fail to account for the potential for technologies developed within the automobile industry to be exported to other economic sectors. This exclusion overlooks the potential for technologies developed in the automobile industry to bring significant benefits to the larger economy, resulting in financial returns to the developers of the technologies within the automobile industry, as well as the multiplied economic benefits of increased efficiency in other sectors, and the social and economic benefits of the greenhouse gas reductions. These considerations, by incorporating additional benefits to both society and to the automakers, would significantly alter the calculation of the CAFE standards and the cost-benefit analyses.

Response

Many commenters stated that NHTSA failed to take full advantage of available fuel saving technologies and that optimization factors used in technology application do not reflect the most aggressive possible regulations. NHTSA specifically sought comment on the estimates, which it had developed jointly with EPA, of the availability, applicability, cost, and effectiveness of fuel-saving technologies, and the order in which the technologies were applied, as well as cost learning curves. See 73 FR 24352, 24367. While NHTSA asked manufacturers to submit such information in the request for product plans, the agency also conducted its own independent analysis of the all the comments and data – including comments and information from entities outside the automobile manufacturing community – received through the rulemaking process. This involved hiring an international engineering consulting firm that specializes in automotive engineering, and that was used by the EPA in developing its recent Advance Notice of Proposed Rulemaking to regulate greenhouse gas emissions under the Clean Air Act.[14]

NHTSA and its consultants undertook a thorough review of the NPRM technology assumptions and all comments received on those assumptions, based on both old and new public and confidential manufacturer information. NHTSA and its consultants reviewed and compared comments on the availability and applicability of technologies, and the logical progression between them. NHTSA also reviewed and compared the methodologies used for determining the costs and effectiveness of the technologies as well as the specific estimates provided. Relying on the expertise of its consultants and taking into consideration all the information available, NHTSA revised its estimates of the availability and applicability of many technologies, and revised its estimate of the order in which the technologies were applied. In addition, the agency and its consultants generally agreed with commenters who said that in several cases, the technology related costs used in the NPRM and DEIS were underestimated and benefits were overestimated. The agency also agreed with commenters that both sets of estimates were not well differentiated by vehicle class and that the technology decision trees needed to be expanded and refined. Relying on the expertise of its consultants and taking into consideration all the information available, NHTSA revised its technology and effectiveness estimates and used them in analyzing all of the alternatives and scenarios presented in this FEIS. The agency believes that the representation of technologies—that is, estimates of the availability, applicability, cost, and effectiveness of fuel-saving technologies, and the order in which the technologies were applied, as well as cost learning curves—used in this action is the best available.

NHTSA appreciates NESCAUM's attention to detail on the retail price equivalents and component inclusion. NHTSA has noted the inaccuracies NESCAUM identified, and will correct them in the final rule.

As to the multitude of comments on hybrid penetration/phase-in rates, there is a general misperception that the technology is cost-effective. The waiting lists for popular hybrid cars are due to limitations in the supply chain, especially in battery production. At present, manufacturers are not able to produce numbers that justify the cost of production. The model incorporates technologies when they are expected to reach the point of cost-effectiveness, but this does not prevent manufacturers from applying the technologies if they choose to do so.

NHTSA has considered comments that we should include advanced materials and allow manufacturers to downweight vehicles; however, NHTSA's analysis still supports our position that

[14] 73 FR 44354 (July 30, 2008).

downweighting vehicles under 5,000 pounds carries unacceptable risks to public safety. See Section 10.3.6.4 for detailed responses to downweighting and safety comments.

Regarding levels of fuel economy in other countries, there are several important reasons why a direct comparison to U.S. standards is not possible. First, the United States, the European Union (EU), and Japan all use different testing methods to determine a vehicle's mpg. Second, the EU standard is voluntary, and the Japanese fines are minimal. Third, the Japanese standard is weight-based (a practice the United States moved away from for safety reasons). Fourth, the fleet mix is different. Fuel taxes and other incentives are credited with shrinking the average vehicle size in both the EU and Japan, so higher fuel economy standards cannot be attributed to technology alone, as the commenter appears to suggest. Fifth, the EU and Japanese emissions standards are not as stringent as those in the United States with respect to some pollutants (e.g., NO_x). To facilitate the fast penetration of diesel vehicles into its market, Europe made a policy decision not to require fast reductions in NO_x emissions. Diesel vehicles in the United States are more costly because of the higher emissions requirements and the need for installing pollution abatement devices, which are not required in Europe.

10.2.2.5 Fleet Turnover

Comments

Comment Number: 0574-10
Organization: Alliance of Automobile Manufacturers
Commenter: Julie Becker

As Attachment #14 to its substantive comments on NHTSA's CAFE NPRM for MY 2011-2015 (NHTSA Document ID: NHTSA-2008-0089-0170.1), the Alliance submitted the June 15, 2007 study performed by NERA, Sierra Research, and Air Improvement Resource ("AIR") entitled *Effectiveness of the California Light Duty Vehicle Regulations as Compared to Federal Regulations*, which was originally submitted to EPA in connection with its consideration of whether to grant California a waiver of preemption under the Clean Air Act for that State to set its own greenhouse gas emission standards for new vehicles. This study demonstrates how increases in fuel economy standards can, through the fleet turnover effect, delay new vehicle purchases, thereby prolonging the period that vehicles emitting greater levels of traditional criteria and toxic pollutants will be driven on the roads. [Footnote: See original comment document.]

The NERA/Sierra/AIR [Air Improvement Resources, Inc.] study compared the real-world emissions control levels achieved by the California program to the federal program for light-duty vehicles. The analysis compared emissions of the five key pollutants (VOC, NO_x, $PM_{2.5}$, CO, and SO_x), plus effects on an aggregation of five air toxics (acetaldehyde, benzene, 1,3 butadiene, formaldehyde, and acrolein) under the two programs from 2009 through 2023. The study concluded that increases in the relative stringency of fuel economy standards as adopted by California would significantly drive up most criteria pollutant and air toxics emissions levels.

By contrast, NHTSA's analysis in its DEIS concludes that the more stringent CAFE standards become, the fewer criteria pollutants and air toxics are emitted from the vehicle fleet. See DEIS at 2-15 (Table 2.5-2) (moving from right to left on that table, which corresponds to increased CAFE stringency, criteria and toxic emissions generally are shown to decrease). This can only be inconsequence of NHTSA failing to properly take account of the fleet-turnover effect. Failure to rectify this error would be arbitrary and capricious. See *Motor Vehicle Mfrs. Ass'n v. State Farm Mut. Auto. Ins. Co.*, 463 U.S. 29, 43 (1983) ("agency rule would be arbitrary and capricious if the agency has . . . offered an explanation for its decision that runs contrary to the evidence . . . .").

Indeed, NHTSA's discussion in the DEIS makes clear that the agency is refusing to consider fleet-turnover effects. See DEIS at 1-18 ("As these issues [including fleet turnover] raised by the AAM . . . do not relate to the effects on the physical environment, they are not addressed in this document."). This entirely misunderstands the NERA/Sierra/AIR study and the nature of the fleet turnover effect. This effect will cause NHTSA's proposed CAFE standards to increase various criteria pollutant and air toxic emissions. These are direct physical effects on the environment. It is difficult to understand what NHTSA means when it attempts to call the effect on pollutant levels caused by the fleet turnover effect a non-physical effect on the environment. If NHTSA means that it can ignore some physical effect on the environment whenever such an affect occurs based on economic cause and effect, then NHTSA surely errs. If that were the case, NHTSA's use of the Volpe model in connection with NEPA analysis would also be flawed, because the Volpe model is intended as a cost-benefit tool for comparing different fuel economy mandates, and the Volpe model is integral to NHTSA's NEPA analysis.

In fact, agencies are often compelled to consider environmental outcomes resulting from behavioral changes due to economic factors. See *generally Mid States Coalition for Progress v. STB*, 345 F.3d 520, 548-49 (8th Cir. 2003) (STB erred by failing to consider claimed increases in CO_2 emissions by power plants associated with the STB's approval of a new rail line based on a lengthy chain of economic reasoning to the effect that the new rail line would lower the price and increase the availability of low-sulfur coal, and thereby increase emissions from power plants expected to consume the coal being carried). In the case of EISA, the consideration of economic factors is a particularly critical element of the statutory design. It would be nonsensical for NHTSA to ignore technically sound studies demonstrating a direct connection between the economic effects of CAFE standards and resulting environmental impacts.

Comment Number: 0574-5
Organization: Alliance of Automobile Manufacturers
Commenter: Julie Becker

NHTSA finds that more stringent CAFE standards will reduce criteria pollutant and air toxics emissions. Such a conclusion is demonstrably incorrect and ignores the fleet-turnover effect and the study of that effect submitted by the Alliance to EPA in 2007 to explain how California CO_2 emissions standards that represent increases in stringency over the MY 2010 CAFE baseline would increase emissions of most criteria pollutant and air toxics. NHTSA has a duty to consider that submission and revise its analysis accordingly.

Comment Number: TRANS-01-5
Organization: Alliance of Automobile Manufacturers
Commenter: Julie Becker

[T]he draft EIS incorrectly disregards the environmental impact of the fleet turnover effect, and this was explained in our scoping comments. The Alliance asks NHTSA to consider the fleet turnover effect, and the air quality impacts that will result from heightened CAFE standards. Instead, NHTSA is treating this as an economic impact and an indirect one, which we don't think is appropriate.

Response

Under NHTSA's analysis, any effect of higher vehicle prices resulting from stricter CAFE standards on fleet turnover is not likely to have substantial consequences for criteria pollutant emissions. First, NHTSA's research indicates that prices for new vehicles are only one of many factors that vehicle buyers consider in their purchase decisions. Others are likely to include fuel prices, vehicle maintenance and repair costs, household income levels, loan rates for financing new-vehicle purchases, and *macroeconomic cycles. Because all of these factors are likely to change in the future, the potential effect of higher prices for new vehicles on fleet turnover is difficult to anticipate.*

Second, there is evidence that manufacturers cannot pass on to buyers the full costs of complying with higher CAFE standards, which would limit their effect on fleet-wide emissions of criteria pollutants. Finally, the dramatic reduction in the rates of tailpipe emissions for late-model vehicles that has resulted from technological advances in emissions controls has substantially narrowed the differences in emissions rates between new and older vehicles, and further reductions emissions rates in new-vehicles will continue to do so over the foreseeable future.[15] *This continued narrowing of the difference between emissions from older vehicles and the new vehicles with which they would be replaced has substantially reduced the likely impact of any slowing in fleet turnover on fleet-wide emissions.*

10.2.2.6 Consumer Demand/Behavior

Comments

Comment Number: 0564-1
Organization: Consumer Federation of America
Commenter: Mark Cooper

In light of the new evidence on the swift changes by consumers to embrace more fuel- efficient vehicles, we believe that the standard should be set at the highest level in NHTSA's analysis that was economically practicable. (This is the point in the initial analysis where total benefits equal total costs. When NHTSA corrects the many flaws in its approach benefits from this level of fuel economy will far exceed the costs.) This would raise the standard for 2011 to 30.6 miles per gallon, from the proposed level of 27.8 mpg. The attached report shows that consumers are more than willing to purchase such vehicles and the dramatic changes that the automakers have announced in their product plans indicate they can deliver the vehicles necessary to achieve this level of fuel economy.

Comment Number: 0564-3
Organization: Consumer Federation of America
Commenter: Mark Cooper

NHTSA's approach to setting fuel economy standards is to start with automaker product plans, assert that consumers undervalue fuel economy by demanding unrealistic economic returns from fuel saving technologies and assume that automakers are severely constrained in their ability to incorporate new fuel-saving technology into the vehicle fleet. Neither the product plans, nor the assumptions about consumer and automaker behavior relied on in NHTSA's analysis bear any relationship to reality.

- Consumers are looking for higher mileage in the new vehicles today than NHTSA has mandated for seven years from now.

- The product plans on which NHTSA based its rule seven years into the future have already been torn up by the automakers who have belatedly recognized the strong shift in consumer behavior.

[15] *In 1990, for example, NHTSA's estimates indicate that average VOC emissions for a 10-year-old gasoline automobile were 4.75 grams per mile larger than those for a new model-year 1990 car, but by 2005 this difference had narrowed to 1.31 grams per mile; it is projected to decline to 0.23 grams per mile by 2015. These emissions factors were computed using EPA's MOBILE6.2 motor vehicle emissions factor model using the procedures described elsewhere in this FEIS.*

- The mix of cars and trucks that NHTSA projects bears no relationship to the vehicles that consumers are buying.

- Not only did NHTSA assume that consumers are unwilling to buy fuel economy beyond a very narrow economic assumption, but it also assumed that higher fuel economy has no value in the marketplace (particularly in resale value), which is contrary to what is happening in the market.

Our market behavior analysis and public opinion polling show that consumers want more fuel-efficient cars than the automakers are offering them.

Comment Number: 0564-8
Organization: Consumer Federation of America
Commenter: Mark Cooper

The attached study of consumer attitudes and auto market behavior prepared by the Consumer Federation of America has a series of findings that call into question the fundamental approach that NHTSA took to set the standard and compel NHTSA to thoroughly reconfigure its analytic approach before it issues a final rule.

Consumers are deeply concerned about rising gasoline costs and the national security implications of our dependence on foreign oil and are prepared to take actions to remedy these problems. Neither the auto industry in its marketing plans nor NHTSA in its proposed rule has fully comprehended the current state of consumer attitudes toward fuel efficiency and the state of the auto market.

- Eighty-four percent of respondents say they are concerned about rising gasoline prices (70 percent very concerned) and eighty-four percent say this rise in price has placed a financial burden on their household budgets (63 percent say severe).

- Seventy-four percent of respondents say they are concerned about Mid Eastern oil imports (57 percent very concerned).

- Among those who drive and intend to purchase a vehicle, the current average fuel economy of their vehicle is reported at about 24.1 mpg, but they intend to get 32.7 mpg in their next vehicle.

- Thus, the average goal for consumers in the market today is 32.7 mpg above the standard of 31. 6 mpg that NHTSA has set for 2015.

- There is a huge mismatch between consumer demand and models offered by automakers in 2008. Whereas 59 percent of the respondents say they want to get more than 35 mpg in their next vehicle, only 1 percent of the models offered by automakers in the first half of 2008 achieve that mileage.

- About 60 percent of the poii respondents say they are willing to consider major changes to achieve higher fuel economy, including switching to four cylinder engines, small cars and hybrids.

Moreover, as the attached report shows, consumers are not merely considering these measures to achieve higher fuel economy; they are acting on their attitudes.

- Four cylinder engines have increased their market share dramatically.
- Smaller cars are in exceptionally high demand, while trucks and SUVs languish on the lots.
- Hybrids are flying out of the show rooms.

However, in direct contradiction to these market trends, NHTSA's proposed rule restricts the level of the standard because it makes assumptions about consumer behavior or automaker ability to incorporate fuel-saving technology that fail to reflect this market reality. NHTSA refuses to consider vehicle downsizing or different performance characteristics as a means of increasing fuel efficiency. NHTSA's underlying assumptions are so out of touch with reality that they are arbitrary and capricious, resulting in a rule that is unreasonable.

The change in consumer attitudes and purchasing patterns has deeply affected the resale value of vehicles, yet NHTSA's proposed rule does not recognize the impact of fuel economy on the resale value of vehicles. NHTSA erroneously assumes that a gas guzzling SUV has the same resale value (as a percentage of the original purchase price) as a fuel sipping small car.

- Contrary to this assumption, SUVS and pickups are piling up on dealer lots across the country.

- SUVs and trucks, both new and used, have plummeted in value, while small cars have increased sharply.

- The Big 3 U.S. automakers announced plans to discontinue leasing these vehicles precisely because the value at the end of a lease is so much lower than the price they have to pay.

The faulty assumptions on resale value play a critical role in NHTSA's analysis by undervaluing fuel efficiency in its consumer payback analysis and preventing NHTSA from including more fuel savings in the fleet in its evaluation of standards.

The analysis of auto market behavior in the attached report shows that these consumer attitudes and trends were not a sudden development in the early part of 2008. They have been evident and progressing for several years. The auto industry and NHTSA have simply ignored the clear evidence.

- The shift in sales was not sudden, nor is it only the result of a shift from trucks to cars. Consumers have also been demanding greater fuel economy within vehicle categories.

- The structural shift to fuel economy occurred in 2004 for trucks and 2006 for cars.

- The effect has built over time so that by the first half of 2008, the level of fuel economy of a car model accounts for over 40 percent of the variance in the change in sales.

- Simply put, it did not take $4/gallon gas to cause the change in consumer behavior, it started at least three years ago when gas was $2.50 per gallon and has been growing progressively.

The automakers not only missed the shift in consumer behavior, they actually tried to resist it by continuing to pump out gas-guzzlers and trying to bribe consumers to buy them with rebates and low interest. However, the trend has proven too powerful and fundamental to resist. Now that the automakers have recognized that they must change, they are rapidly shifting their operations, retooling plants and adopting new technologies at a pace that is far greater than NHTSA had assumed possible. Thus, NHTSA's auto market model erroneously assumes a slow incorporation of fuel savings technology into the vehicle fleet for several reasons. Not only were the product plans on which NHTSA based its proposed rule thoroughly outdated, but also the ability of automakers to change was vastly underestimated by NHTSA. A rule based on data that is so out of touch with reality is arbitrary and capricious and unreasonable.

Commenter: Eli Hopson

As one of the components in assessing sales impacts of increased fuel economy, NHTSA estimates the 5-year resale value of vehicles. First, NHTSA's explanation for choosing five years as the evaluation timeline, namely that "this is the average length of time of a financing agreement" (PRIA, p. VII-41), is unfounded—as that would presume that consumers sell their vehicles as soon as their car and truck loans are paid off.

Moreover, NHTSA computes the resale value of a vehicle as a flat 32.8% of its original value. This assumption ignores the fact that fuel efficient vehicles are valued more than inefficient vehicles on the used vehicle market. According to a 2008 Congressional Budget Office study:

"Average prices of fuel-efficient used vehicles have been rising, and those of less-efficient vehicles have been falling. That is as expected: In both [new and used vehicle markets, consumers' preferences for fuel-efficient vehicles should be similarly affected by rising gasoline prices—which should affect prices similarly in both markets." [Footnote: See original comment document.]

UCS recommends that NHTSA modify its resale value estimate to reflect greater consumer preference for fuel efficient vehicles in the new and used vehicle markets.

Commenter: Brian Nowicki, Mickey Moritz, Kassie Siegel

A recent report by the Consumer Federation of America indicates that the NHTSA's assumed fleet mix does not represent what consumers are actually buying (Cooper 2008). Furthermore, the average consumer desires a car that gets at least 32.7 mpg today (Cooper 2008), yet even the "technology exhaustion" alternative would only require an average fuel economy of 31.1 mpg in 2011.Including this shift in consumer demand in the Volpe model is essential to properly assess the potential for increased fuel economy in the U.S.

The NHTSA does not address the potential implications of a changing automobile market and to embrace its technology forcing mandate. The possibility that increasing consumer demand for more fuel efficient vehicles may affect the calculation of an individual automaker's CAFE under Reformed CAFE, and the opportunities available for individual automakers to take advantage of those changing demands through CAFE credits. (73 Fed. Reg. at 24393 & 24443). However, the proposed CAFE standards completely fail to consider the significant market advantage experienced by automakers that "pull ahead" to offer higher-efficiency vehicles.

In such a market, "over-compliance" can result in significant gains in market share and economic returns for innovative automakers. By failing to consider shifting consumer demand, NHTSA and the Volpe model significantly underestimate the economic benefits of increased efficiency vehicles, and artificially and inappropriately skew the cost-benefit analysis of developing and implementing efficiency technologies. Stated another way, NHTSA has illegally constrained its analysis by locking itself into the assumption that a manufacturer's fleet mix need not, and will not, change in response to the nation's need to conserve energy.

Comment Number: 0572-46
Organization: Center for Biological Diversity
Commenter: Brian Nowicki, Mickey Moritz, Kassie Siegel

The inadequacy of the proposed CAFE standards is perhaps most clearly seen in comparison to vehicles already available on the market today with fuel efficiencies of 35 mpg and higher. The NPRM, on page 24394, states that the Volpe model, in the development of the CAFE standards, does not account for shifting demand by consumers for higher efficiency vehicles. Thus, the proposed CAFE standards were developed within the context of the automakers current product lines and business plans, and thus rejected or delayed larger increases in fuel efficiency in deference to previous business decisions the automakers have made that have favor lower efficiency vehicles.

Organization: Center for Biological Diversity
Commenter: Brian Nowicki, Mickey Moritz, Kassie Siegel

NHTSA, on page 24393 of the NPRM, states that the Volpe model does not attempt to account for…intentional over-compliance....Another possibility NHTSA and Volpe staff have considered but do not yet know how to analyze, is the potential that manufacturers might "pull ahead" the implementation of some technologies in response to CAFE standards that they know will be steadily increasing over time."

These statements display NHTSA's fundamental failure to understand the potential implications of a changing automobile market and to embrace its technology forcing mandate. The NPRM on page 24393 and 24443 mentions the possibility that increasing consumer demand for more fuel efficient vehicles may affect the calculation of an individual automaker's CAFE under Reformed CAFE, and the opportunities available for individual automakers to take advantage of those changing demands through CAFE credits. However, the proposed CAFE standards completely fail to consider the significant market advantage experienced by automakers that "pull ahead" to offer higher-efficiency vehicles. In such a market, "over-compliance" can result in significant gains in market share and economic returns for innovative automakers. By failing to consider shifting consumer demand, NHTSA and the Volpe model significantly underestimate the economic benefits of increased efficiency vehicles, and artificially and inappropriately skew the cost-benefit analysis of developing and implementing efficiency technologies. Stated another way, NHTSA has illegally constrained its analysis by locking itself into the assumption that a manufacturer's fleet mix need not, and will not, change in response to the nation's need to conserve energy.

The Volpe model does not estimate market shifts, and therefore cannot predict the experience of recent months, where sales of light trucks have plummeted and sales of small cars have skyrocketed in response to high oil prices (73 FR 24394). The vehicles automakers are offering do not achieve a level of fuel economy consumers want, and vehicles that comply with the 2011-2015 standards will not achieve a level of fuel economy that consumers want. [Footnote: See original comment document.] NHTSA's failure to effectively regulate the industry has resulted in a market that offers too few choices to consumers, and the

Volpe model will exacerbate this problem rather than correct it, by relying on outdated information from the automakers.

Organization: Public Citizen
Commenter: Joan Claybrook

This country is in crisis because of high gas prices, the attendant rise in the price of food and other goods, and the looming prospect of catastrophic consequences of global warming. Failure by the agency to adequately plan for future predictable fuel price increases has contributed to the current fuel price situation. NHTSA must not exacerbate this condition further by failing to ask for the most aggressive implementation of available technology to give consumers the fuel economy they want and need." [Footnote: See original comment document.] In a March 2008 survey, "[s]ixty-one percent of those interviewed said lawmakers should require better fuel efficiency for new cars, trucks and SUVs; 56 percent said the government should increase funding for alternative fuel research." [Footnote: See original comment document.] This came just three months after Congress passed a law to raise fuel economy standards and expand research funding for alternative fuels. This is a strong signal to NHTSA to reconsider the pace and level of these new standards, which will, of course, inform the standards set for model years 2016-2020 and beyond.

Importantly, CAFE standards equate the greenhouse gas emissions in that CAFE compliance is measured by capturing greenhouse gases emitted by regulated motor vehicles. Thus the draft EIS appropriately suggests that model year 2011 through '15 proposal likely will result in the overall motor vehicle greenhouse gas emission reduction below what will occur without standards.

Of course, this conclusion assumes that purchasers will buy new vehicles covered by CAFE proposal, and hereby bring them into the fleet at the rate assumed by NHTSA and that once introduced into the fleet, they will be driven to the same degree that NHTSA has assumed.

To that extent, purchasers do not buy – to the extent that purchasers do not buy vehicles regulated by the CAFE proposal and bring them into the fleet as predicted, whether due to their higher cost or lack of desirability, the CAFE proposal will necessarily fail to achieve this hoped for level of environmental performance.

This jalopy affect phenomenon recently was demonstrated by the failed introduction of the '07 model year medium and heavy-duty truck rules governed by the new EPA emissions mandates that increase their costs and arguably compromise their fuel economy and reliability.

Comment Number: TRANS-05-7
Organization: Consumer Federation of America
Commenter: Mark Cooper

Consumers are looking for higher mileage in new vehicles today than NHTSA has mandated for seven years from now. The product plans on which NHTSA based its rule seven years in the future have already been torn up by the automakers, but belatedly recognize the shift in consumer behavior.

The mix of cars and trucks that NHTSA projects, there's no relationship to the vehicles that consumers are buying. Rules that are not connected to reality violate the act and the administrative procedures act.

If you don't think that people will buy and drive more fuel efficient vehicles, you must be living under a rock.

As one of the components in assessing sales impacts of increased fuel economy, NHTSA estimates the 5-year resale value of vehicles. First, NHTSA's explanation for choosing five years as the evaluation timeline, namely that "this is the average length of time of a financing agreement" (PRIA, p. VII-41), is unfounded—as that would presume that consumers sell their vehicles as soon as their car and truck loans are paid off.

Moreover, NHTSA computes the resale value of a vehicle as a flat 32.8% of its original value. This assumption ignores the fact that fuel efficient vehicles are valued more than inefficient vehicles on the used vehicle market. According to a 2008 Congressional Budget Office study:

"Average prices of fuel-efficient used vehicles have been rising, and those of less-efficient vehicles have been falling. That is as expected: In both [new and used vehicle markets, consumers' preferences for fuel-efficient vehicles should be similarly affected by rising gasoline prices—which should affect prices similarly in both markets." (Congressional Budget Office, 2008. Effects of Gasoline Prices on Driving Behavior and Vehicle Markets, p. 20.)

UCS recommends that NHTSA modify its resale value estimate to reflect greater consumer preference for fuel efficient vehicles in the new and used vehicle markets.

Response

NHTSA considers product plans and other data from auto manufacturers, which it believes to be the most accurate source of information about manufacturer capability and future production. In NHTSA's judgment, there is no more accurate source for this information. <u>See</u> *the response in Section 10.2.2 for more information. Many factors are considered in these product plans, including fuel-price projections and shifts in buyers' preferences toward higher fuel efficiency. Commenters who pointed to NHTSA's use of out-of-date product plans can be reassured that the recently revised Volpe model relies on updated product plans received after publication of the NPRM.*

Regarding comments that the popularity of fuel-efficient vehicles among consumers is justification for promulgating more stringent standards, commenters fail to recognize the influence of economic practicability. The demand might exist, but the supply might not exist if manufacturers cannot realistically be expected to meet it.

While higher fuel prices are currently affecting consumer behavior, NHTSA's assumptions about consumer undervaluation of fuel economy are well supported by peer-reviewed literature. The study that the Consumer Federation of America used to support its arguments relies on a survey in which the consumers are not actually purchasing a vehicle, and that likely overvalues consumer preferences.

Regarding resale value, estimates of resale value are used, not in the Volpe model but in the Regulatory Impact Analysis, to try to predict how the increase in price and fuel economy of vehicles would affect sales. These estimates of resale value have no direct impact on the levels of the CAFE standard, and their indirect impact was negligible because NHTSA did not find a large impact on sales.

Further, NHTSA does not presume that consumers would all sell their cars at the end of the loan period, an average of 5 years. NHTSA uses that as a proxy measure of how consumers make purchasing decisions; that is, how do consumers value increased fuel economy? NHTSA assumes that the average purchaser thinks about how much money he might save in fuel over a 5-year period. In the Regulatory Impact Analysis, NHTSA conducts a marginal cost-benefit analysis. This commenter appears to imply that resale value would increase by more than 32.8 percent of incremental costs because of the improved fuel economy. This implies that first purchasers believe that a second purchaser would place a value on the improvement in fuel economy over the remaining life (beyond the initial first 5 years) of the vehicle. If NHTSA made this assumption, then for the first purchaser who keeps a vehicle, we should value fuel economy savings over the lifetime of the vehicle (or some period longer than 5 years), not just over the first 5 years. However, NHTSA does not believe that the average consumer thinks about payback periods past 5 years; that is, a first purchaser would not consider the second purchaser's payback period. When NHTSA performs the Volpe model cost-benefit analysis, considering costs and benefits from a societal perspective, NHTSA uses fuel economy savings over the lifetime of the vehicle.

However, NHTSA does not believe that the average consumer thinks about payback periods past 5 years; that is, a first purchaser would not consider the second purchaser's payback period. When

NHTSA performs the Volpe model cost-benefit analysis, considering costs and benefits from a societal perspective, the agency uses fuel economy savings over the lifetime of the vehicle.

10.2.2.7 Fleet Composition Assumption

Comments

Commenter: Luke Tonachel, Brian Siu

NHTSA fails to adhere to standard economic practice and governmental guidelines when it used a discount rate of 7 percent. The agency should use a discount rate that does not exceed 3 percent and should conduct sensitivity analysis for even lower values.

Comment Number: 0559-11
Organization: The Northeast States for Coordinated Air Use Management (NESCAUM)
Commenter: Arthur Marin

NHTSA's stated intent is to use a 7 percent rate for discounting future benefits from increased CAFE standards. We believe this rate is too high and therefore inappropriately devalues the technologies designed to achieve increased fuel economy. In contrast, for the rulemaking on Tier 2 Motor Vehicle

Emissions Standards (*FR*/Vol. 65, No. 28, February 10, 2000). EPA used a discount rate of 5 percent. We recommend that NHTSA use a discount rate of no greater than 5 percent and perhaps consider an even lower discount rate if appropriate.

Comment Number: 0564-10
Organization: Consumer Federation of America
Commenter: Mark Cooper

Discounted the value of fuel savings at an unnecessarily high rate; *i.e.*, after identifying two possible discount rates: 1) a high rate based on the automaker view of capital costs and 2) a low rate based on the consumer view of consumption expenditures. NHTSA failed to choose a rate between the two, instead applying the high "capital" rate.

Comment Number: 0572-13
Organization: Center for Biological Diversity
Commenter: Brian Nowicki, Mickey Moritz, Kassie Siegel

One of the primary flaws is the use of a 7% discount rate. The DEIS acknowledges that discount rate and gasoline price have a significant impact on the cost-benefit analysis. Yet the DEIS adopts a 7% discount rate and does not present even the results for a 3% or lower discount rate. The significant influence of discount rate alone is reflected in the fact that the "optimized" fuel economy standard with a 3% discount rate is more than 50% higher than the "optimized" alternative presented in the DEIS. (PRIA Appx. A at A-2, Table A-1) This important information is only available in the Preliminary Regulatory Impact Assessment (PRIA), which is insufficient. *Grazing Fields Farm v. Goldschmidt*, 626 F.2d 1068,1072 (1st Cir. 1980) ("no indication in the [NEPA] statute that Congress contemplated that studies or memoranda contained in the administrative record, but not incorporated in any way into an EIS, can bring into compliance with NEPA an EIS that by itself is inadequate").

The choice of a 7% discount rate is not supported by the evidence. As the DEIS states, OMB suggests the use of both 3% and 7% discount rates, with the 3% discount rate appropriate where the costs of regulations are likely to be passed on to consumers. (DEIS at 3-60) The Volpe model assumes that costs will be passed to consumers. For instance, the cost of new technology is limited by consumer pay-back periods and willingness to pay higher vehicle prices. See, *e.g.*, DEIS 2-1 (discussing "retail price equivalent"); DEIS Appx. C at V11-41 (discussing impact of higher costs on sales).

Other agencies have assumed discount rates of 3% in similar analyses. The EPA in its recent advance notice of proposed rule making for regulating greenhouse gas emissions under the Clean Air Act noted that changes in GHG emissions are "essentially long-run investments" that "yield returns in terms of avoided impacts over a period of one hundred years and longer. Furthermore, there is a potential for significant impacts from climate change, where the exact timing and magnitude of these impacts are unknown. These factors imply a highly uncertain investment environment that spans multiple generations." [73 Fed. Reg. 44354, 44414 (July 30, 2008)] When there are important benefits or costs that affect multiple generations of the population, EPA and OMB allow for low but positive discount rates (*e.g.*, 0.5–3% noted by U.S. EPA, 1–3% by OMB)."

In recent testimony before the House of Representatives Energy Committee, Sir Nicholas Stern notes the inappropriateness of pure-time discounting in which future generations are valued less than the current generation (Stern 2008). He goes on to distinguish between current market rates, which reflect only near-term benefits, versus the value of "young or unborn" generations.

The DEIS thus makes several crippling errors in its choice of discount rate. First, the NHTSA assumes that a substantial portion of the costs of the regulation will come from foregone capital investments by the auto industry. This is simply incorrect. All capital costs will be passed onto consumers in short order. Furthermore, the largest costs from the regulation come in the form of impacts from catastrophic climate change. This will most certainly be felt by consumers, both in this generation and the next. The choice of a 7% discount rate is based in part on assumptions regarding loan rates. (DEIS Appx. C at VIII-2). Yet, this short-sighted context is entirely inappropriate. Given that the impacts of the alternatives are analyzed out to year 2100, the discount rate must also reflect this long time horizon for impacts.

Comment Number: 0572-50
Organization: Center for Biological Diversity
Commenter: Brian Nowicki, Mickey Moritz, Kassie Siegel

The NPRM, on page 24393 and footnote 7 on page 24355, describes using a 7% and 3% discount rate for societal benefits. While essentially conceding that the 7% discount rate is far too high, NHTSA then appears to use the 7% figure in calculations for the proposed rule. However, the NPRM on page 24393, discusses the Volpe model calculation of societal costs and benefits without identifying which discount rate is used.

In fact, both the 7% and 3% are too high, artificially reducing the value of the future benefits of increasing fuel efficiency. For example, Stern (2007) sets the rate at lower than 1% per year. NHTSA proposes 3% versus 7%. For the purposes of the rulemaking, any calculations performed under a selected discount rate for societal benefits must be compared to the same calculations under standard inflationary discount, but without discounting societal benefits to future generations.

The discount rate is an extremely important factor in determining the "socially optimal" fuel economy level as defined by NHTSA. Use of a 3% discount rate would have resulted in fuel economy standards 2 mpg higher than the proposed standards in MY 2015. NHTSA should have run the calculations with a reasonable range of values and disclosed the outcomes, and should have selected a lower discount rate for primary use in its analysis.

Comment Number: 0575-12
Organization: Union of Concerned Scientists
Commenter: Eli Hopson

As noted in comments from UCS to NHTSA on the 2006 light truck rule, the discount rate used to calculate the present value of future costs and benefits is among the most important factors in determining a fuel economy target. NHTSA's use of a 7% discount rate to determine the proposed standards is inappropriate and contrary to OMB recommendations. A discount rate of 3%, corresponding to the social rate of time preference, should instead be used. While OMB Circulars A-4 and A-94 direct that the default interest rate should be 7%, Circular A-4 advises that:

"The effects of regulation do not always fall exclusively or primarily on the allocation of capital. *When regulation primarily and directly' affects private consumption (e.g., through higher consumer prices for goods and service), a lower discount rate b appropriate*. The alternative most often used is sometimes called the "social rate of time preference." . . . *Over the last thirty years, this rate has averaged around 3 percent in real terms on a pre-tax basis.*" (Office of Management and Budget, 2003. Circular A-4)

This guidance is cited by NHTSA multiple times throughout the NPRM and PRIA, and indeed NHTSA itself acknowledges that "direct benefits to consumers, including fuel savings" account for 84%-85% of the gross consumer benefits resulting from increased passenger car and light truck CAFE. (PRIA, p. VIII-36 and VIII-37).

A smaller effect of the proposed regulation will be for automakers to invest capital to build cars with more advanced technologies. While automakers will need to allocate some capital to help meet the proposed regulations, the amounts involved will be markedly smaller than the benefits realized by private consumers. The primary effect of the regulation, therefore, will be on private consumption.

It is clear that the proposed regulation will directly affect private consumption of vehicle fuels, and that this benefit is by far the primary effect. Since the regulation "primarily and directly affects private consumption," much more so than the allocation of capital, the regulation should be based on discounting using the social rate of time preference. UCS recommends that a real rate of 3% – as noted in Circular A-4 – be employed.

Comment Number: 0588-2
Organization: New York State Department of Transportation
Commenter: Stanley Gee

NHTSA should also correct several errors in its analysis that artificially reduce the stringency of the proposed CAFE standards by underestimating benefits arid overestimating costs. In particular, NHTSA inflates costs relative to benefits by failing to apply a discount rate to future costs.

Comment Number: 0588-5
Organization: New York State Department of Transportation
Commenter: Stanley Gee

In its analysis, NHTSA discounts economic benefits, but not costs. In any cost-benefit analysis, both future benefits and costs should be discounted using the same discount rate, or time-value of money, to correct for the difference in the value of money in hand today versus money in the future, based on the interest rate and inflation. The Office of Management and Budget specifically instructs NHTSA to discount both costs and benefits, and provides recommended interest rates for that purpose.

Comment Number: 0595-2
Organization: Environmental Protection Agency
Commenter: Susan Bromm

NHTSA uses a 7 percent discount rate to future benefits in determining the "optimized" fuel economy standard. The sensitivity analysis performed in the DEIS using a discount rate of 3 percent shows that a lower discount rate has a substantial effect on future carbon dioxide reductions. As such, using a 3 percent discount rate significantly increases the projected societal benefits, as shown in Section IX of the PRIA, indicating a higher "optimized" fuel economy standard. EPA recommends that NHTSA consider using a 3 percent discount rate for GHG benefits as part of its primary analysis. While a 7 percent discount rate may be reasonable to apply to the cost savings realized by consumers who invest in fuel economy, EPA questions whether such a high discount rate can be justified for the long-term benefits associated with GHG reductions.

Response

Discounting represents the conversion of the economic values of expected future benefits and costs to their equivalent values today, or present values. Discounting is intended to account for the fact that most individuals attach lower values to economic outcomes that are not expected to occur until some *future date, than to equivalent outcomes that are expected to occur sooner. It is particularly important to discount the future values of benefits or costs when they are expected to vary from year to year, or when the time profiles of benefits and costs are not expected to be similar. Discounting enables a consistent comparison of benefits to costs across time, and enables consistent comparison of expected future costs or benefits to those in the present.*

In proposing CAFE standards for MY 2011-2015, NHTSA employed a rate of 7 percent to discount future benefits and costs resulting from increased fuel economy to their present values. Discounting the value of future fuel savings and other benefits that result from higher fuel economy, and future costs from added driving due to the fuel-economy rebound effect, accounts for the fact that they will occur over the future lifetimes of MY 2011-2015 vehicles. The discount rate expresses the rate at which the value of these future benefits and costs, as viewed from today's perspective, declines for each year they are deferred into the future.

NHTSA received many comments on the discount rate it employed in analyses in the NPRM and DEIS. Many of these comments suggested that NHTSA use a rate as low as 3 percent to discount future benefits from reduced fuel consumption, and that even lower rates be used to discount the reductions in the future costs of climate change expected to result from reduced emissions of GHGs from fuel production and consumption. In contrast, other comments argued that vehicle buyers discount the value of future fuel savings resulting from higher fuel economy at rates of 12 percent or higher, and suggested that NHTSA should employ a similarly high discount rate to evaluate the fuel savings and other benefits resulting from higher CAFE standards.

In response to these comments, NHTSA has carefully reviewed published research and Office of Management and Budget (OMB) guidance on appropriate discount rates, including "inter-generational" discount rates that should be applied to benefits that are expected to occur in the distant future and, thus, be experienced mainly by future generations. On the basis of this review, NHTSA has have elected to apply separate discount rates to the benefits resulting from reduced emissions of CO_2 *and other GHGs, which are expected to reduce the rate or intensity of climate change that will occur 100 or more years in the future, and the economic value of fuel savings and other benefits resulting from lower fuel consumption that will be experienced in the comparatively near future.*

In support of this decision, NHTSA notes that OMB guidance on discounting permits the use of lower rates to discount benefits that are expected to occur in the distant future (OMB 2003). The main rationale for doing so is that although most individuals demonstrate a clear preference for current consumption over consumption they expect to experience later within their own lifetimes, it might not be appropriate for society to exercise a similar preference for present over distant-future consumption when developing actions that affect the relative income levels of present and future generations. In addition, while market interest rates provide useful guidance about the rates that should be used to discount future benefits that will be received by present generations, no comparable market rates are available to guide the choice of rates for discounting benefits to be received by future generations.

Specifically, NHTSA has elected to use a rate of 3 percent to discount the benefits resulting from reduced emissions of CO_2 *and other GHGs projected to result from decreased fuel production, distribution, and consumption. These benefits, which include reductions in the expected future economic damages caused by increased global temperatures, a rise in sea levels, and other projected impacts of climate change, are anticipated to extend over a period from approximately 50 to 200 or more years in the future.*

The 3-percent rate is consistent with those used to develop many of the estimates of the economic costs of future climate change that form the basis for NHTSA's estimate of the economic value of *reducing CO_2 emissions (see Section 10.2.2.3) (Tol 2008). Of the 125 peer-reviewed estimates of SCC included in Tol's 2008 survey, which provides the basis for NHTSA's estimated value of reducing CO_2 emissions, 83 used assumptions that imply discount rates of 3 percent or higher. Moreover, the 3-percent rate is consistent with widely used estimates of the appropriate rate-of-time preference for present versus distant-future consumption, expected future growth in real incomes, and the rate at which the additional utility provided by increased consumption declines as income increases.[16]*

The remaining future benefits and costs anticipated to result from higher fuel economy are projected to occur primarily within the lifetimes of vehicles affected by the CAFE standards for MY 2011-2020 vehicles, which extend up to a maximum of 35 years from the date they are manufactured. Thus, a conventional or intra-generational discount rate is appropriate to use in discounting these benefits and costs to their present value when analyzing the benefits and costs of establishing higher CAFE standards.

The correct discount rate to apply to these nearer-term benefits and costs depends on how the costs to vehicle manufacturers of CAFE compliance will ultimately be distributed. If manufacturers are unable to recover their costs for increasing fuel economy in the form of higher selling prices for new vehicles, those outlays will displace or alter other productive investments that manufacturers could make. In this case, the appropriate discount rate is their opportunity cost of investment capital. OMB estimates that the real before-tax rate of return on private capital investment in the U.S. economy averages approximately 7 percent per year, and recommends this figure for use as a real discount rate in cases where the primary effect of a regulation is to displace private capital investment (OMB 2003).

However, if vehicle manufacturers are able to raise selling prices for new vehicles to recover their costs for improving fuel economy, those costs will ultimately affect private consumption rather than capital investment. Under this assumption, a lower discount rate might be appropriate. Specifically, the rate-of-time preference for current versus future consumption, or the annual rate at which consumers must be compensated for deferring current consumption to the future, will be the appropriate rate for discounting future benefits from improved fuel economy.

OMB notes that the real rate of return on long-term government debt, which has averaged about 3 percent over recent decades, provides a reasonable measure of the rate at which typical savers discount future consumption (OMB 2003). The 3-percent rate reflects consumers' average rate-of-time preference, and thus provides an appropriate rate for discounting future benefits of higher CAFE standards if manufacturers are able to recover their costs for complying with those standards by charging higher prices for new vehicles.

Uncertainty about future developments in the international oil market, the U.S. economy, and the U.S. market for new cars and light trucks make it extremely difficult to anticipate the extent to which vehicle manufacturers will be able to recover costs (in the form of higher prices for new vehicles) for complying with higher CAFE standards. If buyers of new vehicles expect fuel prices to remain higher than those NHTSA used to establish CAFE standards for MY 2011-2015, they might be willing to pay the

---

[16] The Ramsey discounting rule is widely employed in studies of potential economic damages from climate changes in the distant future; see Tol (2008, p. 3). The Ramsey rule states that $-r = \delta + \eta g$, where r is the consumption discount rate, δ is the pure rate of time preference (the marginal rate of substitution between current and future consumption under the assumption that they are initially equal), g is the expected (percentage) rate of growth in future consumption, and η is the elasticity of the marginal utility of consumption with respect to changes in the level of consumption itself. Commonly used values in climate studies appear to be $\delta = 1$ percent per year, $\eta = -1.0$, and g = 2 percent per year, which yield a value for r of 3 percent per year.

higher prices necessary for manufacturers to recover their costs for complying with those standards.[17] *However, potential buyers who expect future fuel prices to be lower than these levels are likely to resist manufacturers' efforts to raise new vehicle prices sufficiently to recover their costs for compliance with CAFE standards.*

From the manufacturer's perspective, the current financial condition of some car and light-truck producers suggests that they are likely to find it difficult to absorb the costs of complying with higher CAFE standards. Some analysts speculate that because CAFE standards apply to all manufacturers, establishing higher standards provides a ready opportunity for all producers to raise prices for cars and light trucks. However, this opportunity might be restricted if producers that face very low compliance costs (because of higher CAFE standards in their planned model offerings) compete aggressively with others that face substantial costs for increasing their fuel-economy levels in their product plans to comply with higher CAFE standards.

Because the ultimate incidence of the costs for complying with higher CAFE standards is inherently uncertain, NHTSA has employed both the 3-percent and 7-percent rates to discount future benefits from higher CAFE standards other than those benefits resulting from lower CO_2 emissions. Accordingly, NHTSA has analyzed the mpg stringencies associated with varying combinations of discount rates. See Table 2.3-6.

10.2.2.9 Creation of a Backstop

Comments

Comment Number: 0575-15
Organization: Union of Concerned Scientists
Commenter: Eli Hopson

The Ninth Circuit Court of Appeals ruled that, in their recent fuel economy rulemaking for 2008-2011 light trucks, NHTSA was "arbitrary and capricious" in failing to set a backstop, a mechanism that would ensure that the benefits NHTSA's standards provide would not be eroded by a shift in sales to larger, lower fuel economy vehicles. The court also found that the agency failed to address petitioners' "well-founded concerns (given the historical trend) that a floating fleet-mix-based standard would continue to permit upsizing—which is not just a function of consumer demand, but also a function of manufacturers' own design and marketing decisions." [*Center for Biological Diversity v. National Highway Traffic Administration*. No. 06-7 1891 (9th Cir. 2007).]

In NPRM documentation, NHTSA argues that no further action is required of the agency with respect to backstops, as Congress has spoken directly on this issue, and called for an attribute-based system.

It is true that the 35 mpg minimum standard required in 2020 is a backstop of sorts. However, if maximum feasible fuel economy levels are found to exceed 35 mpg, the legislated minimum will not ensure those levels (and, thus, maximum feasible energy savings) are achieved. In essence, the same concerns of the Ninth Circuit court persist, and NHTSA can not be too deferential to the market in the setting of fuel economy standards.

[17] *Whether they will be willing to do so, however, depends partly on how the combined value of the economic and environmental externalities used to determine the standards compares to current fuel taxes. It also depends on whether buyers of new vehicles consider the value of fuel savings resulting from higher fuel economy over the entire expected lifetimes of the vehicles they purchase, or over only some part of that lifetime (such as the period they expect to own new vehicles).*

It is also true that Congress implied an interim-year backstop by requiring ratable increases in the average fuel economy standard from 2011 through 2020. However, it is NHTSA's obligation to ensure that these interim-year backstops are instituted. In effect, NHTSA has failed to follow through on its legal obligations, because while the proposed average fuel economy standards appear to be at or above a ratable level, there is no mechanism to ensure the market does not undermine those standards. For these reasons, UCS recommends that NHTSA implement a regulated backstop that addresses the concerns first raised by the Ninth Circuit Court of Appeals.

Comment Number: 0576-34
Organization: Public Citizen
Commenter: Joan Claybrook

Congress mandated a *minimum* increase in fuel economy standards for passenger cars and light trucks to 35 mpg; however, Congress entrusts the agency to determine the maximum feasible level of fuel economy for cars and trucks. In *Center for Biological Diversity v. NHTSA*, the court held that NHTSA must set a backstop to prevent the erosion of fuel savings due to up sizing of vehicles and manipulation of the fleet mix. (*Center for Biological Diversity v. NHTSA*. at 14841). NHTSA says "[a] relatively flat standard for larger vehicles acts as a de facto 'backstop' for the standard in the event that future market conditions encourage manufacturers to build very large vehicles. Nothing prevents manufacturers from building larger vehicles. With a logistic curve, however, vehicles upsizing beyond some limit face a flat standard that is increasingly difficult to meet." (73 *FR* 24418). Public Citizen is not convinced this approach is sufficient, particularly since NHTSA has chosen not to reevaluate the regulatory definitions.

Response

A "backstop," as NHTSA described it in the NPRM, is a minimum fixed CAFE standard that does not change in response to changes in a manufacturer's vehicle mix. As noted in the NPRM, Congress' enactment of EISA resolved the backstop issue by, among other things, requiring each manufacturer to meet a minimum fuel economy standard for domestically manufactured passenger cars in addition to meeting the standards set by NHTSA. The minimum standard "shall be the greater of (a) 27.5 miles per gallon; or (b) 92 percent of the average fuel economy projected by the Secretary [of Transportation] for the combined domestic and non-domestic passenger automobile fleets manufactured for sale in the United States by all manufacturers in the model year…." 49 U.S.C. § 32902(b)(4). Congress expressly mandated that CAFE standards for automobiles be attribute based. That is, they must be based on an attribute related to fuel economy (e.g., footprint), and they must adjust in response to changes in vehicle mix. Taken by itself, this mandate precludes NHTSA from adopting a fixed minimum standard. The only exception to that mandate is the provision in which Congress mandated a fixed and flat minimum standard for one of the three compliance categories. It required one for domestic passenger cars, but not for either non-domestic passenger cars or light trucks. Congress could have, but did not, enact one for foreign passenger cars or light trucks. Congress was aware of this issue from the MY 2008-2011 light-truck CAFE rulemaking and the Ninth Circuit Center for Biological Diversity case, but it chose not to act.

Given the clarity of the requirement for attribute-based standards and the equally clear narrow exception to that requirement, NHTSA reasonably concludes that had Congress intended backstops to be established for either of the other two compliance categories, it would have specified them. Absent explicit statutory language that provides NHTSA authority to set flat standards, we continue to believe that setting a supplementary minimum flat standard for the other two compliance categories would be contrary to the requirement under EISA to set an attribute-based standard.

NHTSA notes that the minimum 35-mpg requirement in and of itself serves as a backstop. Indeed, the Union of Concerned Scientists concedes in its comments that "[i]t is true that the 35 mpg minimum standard required in 2020 is a backstop of sorts." Under this backstop, NHTSA must set the standards high enough to ensure that the average fuel economy level of the combined car and light-truck fleet achieves the statutory requirement of at least 35 mpg by 2020. If we find that this requirement might not be achieved, we may set standards for MY 2016-2020 early enough (consistent with EPCA's 18-month lead time requirement), and at the appropriate level of stringency to ensure reaching the 35-mpg requirement.

Regarding NHTSA's discussion of why the attribute-based standards would make a backstop unnecessary even without Congress' having spoken to this issue, UCS and Public Citizen appear to argue that the statutory requirement of a combined fleet fuel economy of at least 35 mpg in MY 2020, combined with NHTSA's anti-backsliding measures for the target curves and the inherent lower asymptotic bound of the target curves for each model year, are not sufficient to guarantee that manufacturers will either (1) achieve fuel economy levels higher than 35 mpg in 2020 or (2) be prevented from upsizing their vehicles.

NHTSA reiterates, however, that the 35-mpg minimum statutory requirement for 2020 is absolute. Even if manufacturers so drastically change their fleet mix (by upsizing most or all of their vehicles to gain the benefits of lower targets) to achieve substantially lower fuel economy levels for the model years covered by this rulemaking, NHTSA must still set maximum feasible standards for MY 2016-2020 such that the combined fleet reaches at least the 35-mpg minimum requirement in 2020. Further, NHTSA has the authority to revise standards set in the current rulemaking if necessary to ensure that requirement is met, as long as the statutory minimum lead-time of 18 months is observed. See 49 U.S.C. § 32902(c).

10.2.2.10 Oil Import Externalities

Comments

Comment Number: 0557-10
Organization: The Natural Resources Defense Council
Commenter: Luke Tonachel, Brian Siu

The economic value of military security to protect oil supplies should be non-zero and positive. When NHTSA used zero it ignored the U.S. military security-related benefits of reduced oil consumption, such as enhanced flexibility to respond to supply threats and move the country in the direction of oil being a non-strategic resource.

Comment Number: 0564-5
Organization: Consumer Federation of America
Commenter: Mark Cooper

NHTSA takes a fundamentally flawed approach to its externality analysis. This was evident in the analysis of the military and strategic externalities in the proposed rule, where NHTSA engaged in reasoning that can, at best, be described as blind incrementalism.

Rather than see improvements in fuel economy as a part of a broader solution to the national oil addiction, NHTSA argues that because this rule alone cannot solve the problem, it does not deserve to be counted as making a contribution to the solution.

Implementing a law entitled the Energy Independence and Security Act, NHTSA concluded that oil consumption has no military or strategic value whatsoever.

Comment Number: 0575-4
Organization: Union of Concerned Scientists
Commenter: Eli Hopson

NHTSA left out the military and strategic costs of America's oil addiction.

Comment Number: TRANS-43-3
Organization: Individual
Commenter: Charles Yoder

I've noticed that your EIS puts your actions, proposed actions and alternatives in the context of the world. That was addressed by someone as I came into the hall earlier, in the context of the entire planet, not just in terms of the U.S. If you choose to do that, then I think we need to look at the implications of our national addiction to oil in a world context, in a world wide context. Our country invests enormous treasure and enormous numbers of lives ensuring our access to oil.

Comment Number: 0576-22
Organization: Public Citizen
Commenter: Joan Claybrook

Public Citizen also objects to the zero valuation of military security costs associated with oil consumption. NHTSA states "that while costs for U.S. military security may vary over time in response to long-term changes in the actual level of oil imports into the U.S., these costs are unlikely to decline in response to any reduction in U.S. oil imports resulting from raising future CAFE standards for passenger cars and light trucks." (See PRIA V-90 and 73 *FR* 24411.) NHTSA justifies this claim by stating that there are other national security and foreign policy objectives served by military actions in the Middle East. NHTSA used similar logic to justify assigning zero value to reducing CO_2 emissions in the light truck rule. The Ninth Circuit Court of Appeals rejected this justification in *Center for Biological Diversity v. NHTSA*, finding that uncertainty about how to assign a value was not a justification for setting the value at zero. [*Center for Biological Diversity et al., v. NHTSA*. 508 F. 3d 508 (November 15, 2007).]

Comment Number: TRANS-03-4
Organization: Individual
Commenter: Dennis McGinn

Our continued dependency on oil constitutes a clear and present danger to our national security, economically, militarily, and diplomatically. These dangers involve real, quantifiable costs, and these costs do not appear to be adequately included in your assumptions for the proposed fuel economy rule.

As a result, your draft environmental impact statement is at best incomplete, and more importantly, fundamentally flawed by its reliance on outdated data and unsupported assumptions about the real costs of this nation's ever growing consumption of oil. Erroneous assumptions based on old data inevitably leads to fundamentally flawed conclusions.

Ignoring these costs is just not a mistake. It is a threat to our national security because it precludes fuel savings our citizens and nation critically need at this moment in our history.

Our burgeoning demand for oil weakens U.S. diplomatic leverage around the globe, burdens our armed forces, and leaves the United States' economy vulnerable to unpredictable price spikes and an ever growing trade imbalance.

Taken together, these dynamics create a daunting national security challenge that must be met immediately. With oil at over $130 dollars a barrel, over a million dollars each minute is draining out of our economy, increasing our trade deficit, creating huge opportunity costs, and most significantly, putting money in the hands of regimes that are hostile to our interests.

OPEC [Organization of Petroleum Exporting Countries] recently warned that prices, oil prices would experience an unlimited increase in the event of a military conflict involving Iran over its nuclear program. A very real consequence of such confrontation is that Iran, in a bid to preempt or respond to U.S. military action would close the Straight of Hamus through which 20 percent of the world's oil supply passes. The impact would be swift and sure. Unprecedented spikes in oil costs, and a deep and lasting effect on the U.S. and world economy.

The ongoing impact of our oil dependency already threatens our national security economically. We lose over 35 billion dollars from our economy every month, and oil imports now account for over half of our annual trade deficit. We are exposed on a daily basis to oil price shocks and supply disruptions.

Regardless of how they are caused, by global market dynamics, natural disasters, terrorist attacks, or politically motivated oil embargos, the trends of our growing oil demand in a business as usual mode will make those price shocks much more frequent, deeply felt, and longer lasting.

In addition, there are national security costs and risks involved in addressing climate change. Last year top retired three and four star military leaders in a report from the Center on Naval Analysis, global warming poses a "serious threat to America's national security," acting as a threat multiplier for instability in some of the world's most volatile regions, adding tension to stable regions, worsening terrorism, and likely dragging the U.S. into fights over water and other resource shortages.

Comment Number: TRANS-05-3
Organization: Consumer Federation of America
Commenter: Mark Cooper

The second problem in the draft environmental impact statement stems from the fact that NHTSA takes a fundamentally flawed approach to its externality analysis. This was evident in the analysis of the military and strategic externalities in the proposed rule. There NHTSA engaged in reasoning that can at best be described as blind incrementalism.

Rather than see improvements in fuel economy as part of a broader solution to the national oil addiction, NHTSA argues that the cost to rule alone cannot solve the problem, it does not deserve to be counted as making a contribution to the solution.

Implementing a law entitled the Energy Independence and Security Act NHTSA arrived at the outrageous conclusions that oil consumption has no military or strategic value whatsoever.

Comment Number: TRANS-43-2
Organization: Individual
Commenter: Charles Yoder

But if the U.S. is going to continue our addiction to oil, then we need to address the impacts on a worldwide basis, and the environmental costs of any standard other than the strictest possible standard are enormous simply because there are powerful nations, not just the U.S., there are many powerful nations seeking access to a limited supply of a resource that overwhelmingly is located in an unstable part of the world.

And I think it's only reasonable to assume that there will be additional conflicts over the next generation, and that those conflicts will have enormous environmental impacts.

So if you're going to consider things in a world context, you need to consider the environmental impact of future wars, and those impacts must weight on the balance as you make your decision of the alternatives available to you in this rulemaking process.

Comment Number: TRANS-44-3
Organization: Individual
Commenter: Emily Spear

My second main concern is about America's dependence on oil, as it is a national security issue. Our country feeds off of foreign oil, which causes us to be in the pockets of many non-democratic governments. Increasing our fuel economy standard to 35 miles per gallon by 2015 would save us 300,000 gallons of oil per day by 2020.

Taking this simple and achievable action would help us decrease our dependence on oil, would allow us to take back control, and would help stabilize some issues with security.

Response

One possible component of the external economic costs of importing oil into the United States includes government outlays for maintaining a military presence to secure the supply of oil imports from potentially unstable regions of the world.[18]

In the NPRM, NHTSA tentatively concluded that:

> *[W]hile the costs for U.S. military security may vary over time in response to long-term changes in the actual level of oil imports into the U.S., these costs are unlikely to decline in response to any reduction in U.S. oil imports resulting from raising future CAFE standards for passenger cars and light trucks. U.S. military activities in regions that represent vital sources of oil imports also serve a broader range of security and foreign policy objectives than simply protecting oil supplies, and, as a consequence are unlikely to vary significantly in response to changes in the level of oil imports prompted by higher standards.*

73 FR 24352, 24411. Some commenters took issue with this tentative conclusion, and recommended that NHTSA assign a value to the reduction in military spending or other costs related to energy security that is likely to result from lower U.S. petroleum imports. NHTSA disagrees with commenters who asserted that there is a measurable relationship among higher CAFE standards, U.S. petroleum imports, and energy security costs.

The objective of "U.S. energy security," that reductions in U.S. petroleum imports might help to achieve is primarily a reduction in national political and military risks associated with a failure to adequately defend the Persian Gulf. Although NHTSA agrees that by reducing fuel consumption and U.S. petroleum imports from the Persian Gulf region, higher CAFE standards might reduce these military and political risks to some degree, the agency does not believe there is convincing evidence that this would reduce U.S. military expenditures in the Persian Gulf (or elsewhere). No commenter has presented any

[18] *Oil import externalities encompasses military security costs. For further discussion of what constitutes "oil import externalities," see page 24410 of the NPRM.*

evidence that this would occur, nor do any of the references included in their comments provide such evidence.

NHTSA does not agree with Public Citizen's analogy between energy security and "global warming costs." Although the economic valuation of climate-related benefits from reducing carbon dioxide emissions is uncertain, there is nevertheless a direct causal link between changes in U.S. oil consumption and changes in U.S. carbon dioxide emissions. In contrast, no such causal link – either scientific or empirical – exists between changes in U.S. oil consumption or imports, and changes in U.S. military expenditures in the Persian Gulf or anywhere in the world.

Although one recent economic analysis cited widely by commenters did estimate the value of U.S. military spending attributable to securing oil imports from the Persian Gulf region, this study does not estimate the extent to which U.S. military spending is likely to vary in response to changes in U.S. imports of Persian Gulf oil. Nor does it estimate the potential savings in U .S. military outlays that might result from reductions in U.S. oil imports of the magnitude likely to result from higher CAFE standards.[19]

The study argues that its purpose is to develop "the military cost of highway transportation." Broadly, the authors attempt to do this in four steps:

- *Estimate the amount spent annually to defend all U.S. interests in the Persian Gulf;*
- *Deduct the cost of defending interests other than oil in the Persian Gulf;*
- *Deduct the cost of defending against the possibility of a worldwide recession due to the effects of an oil price shock or supply interruption originating in the Persian Gulf on other countries; and*
- *Deduct the cost of defending the use of oil in sectors of the U.S. economy other than highway transportation.*

This analysis yields an estimate of the annual "military cost of oil use by motor vehicles" in the United States ranging from $5.8 billion to $25.4 billion in 2004. The authors then divide these figures by 2004 U.S. gasoline and diesel consumption by on-road motor vehicles, to arrive at an average "military cost of highway transportation" ranging from $0.03 to $0.15 per gallon of fuel.[20]

However, the authors do not argue that U.S. military spending would be reduced by this – or any other – amount as a consequence of incremental reductions in domestic consumption of transportation fuels. Instead, they describe their estimate in the following terms: "The bottom line of our analysis is that if all motor vehicles in the US (light-duty and heavy-duty) did not use oil, Congress might reduce defense spending by $6–$25 billion annually in the long run. This amounts to about $0.03–$0.15 per gallon ($0.01–$0.04 per liter) of all gasoline and diesel motor fuel in 2004." Id.

Thus, the values they report are clearly intended as estimates of the total and average per-gallon costs of U.S. military activities in the Persian Gulf that might reasonably be related to petroleum consumption by U.S. motor vehicles, and not as estimates of the extent to which those costs might be reduced as a consequence of lower fuel consumption by U.S. motor vehicles. The authors speculate that the proportional reduction in these outlays might be larger than any proportional reduction in U.S. petroleum imports from the Persian Gulf region, but provide no empirical support for this hypothesis.[21]

[19] *See Mark A. DeLucchi & James J. Murphy, US Military Expenditures to Protect the Use of Persian Gulf Oil Imports, 36 Energy Policy 2253 (2008) (assigning a cost of between $0.03 and $0.15 per gallon).*
[20] *Delucchi and Murphy, p. 2260.*
[21] *Delucchi and Murphy, pp. 2261-62.*

Nor does this study attempt to demonstrate any causal or empirical linkage between domestic consumption of transportation fuels and the level of U.S. military activities or spending in the Persian Gulf (or elsewhere). As the authors clearly acknowledge, achieving any reduction in U.S. military spending that might be facilitated by lower U.S. oil imports would require specific actions by Congress, and would not result automatically or necessarily. However carefully their analysis might be done, defining some fraction of U.S. military expenditures as being allocated to the defense of oil interests in the Persian Gulf, and then dividing the resulting figure by some quantity of petroleum, does not demonstrate any causal linkage between changes in the numerator and denominator of this calculation.

The analysis described above is irrelevant to NHTSA's analysis of fuel economy standards, because NHTSA's cost-benefit analysis is properly concerned with comparing two alternative states of the world: (1) the world as the agency expects it to exist over the next few years, in the absence of any new CAFE standards, compared with (2) an alternative world that is identical in every respect except that new CAFE standards are in place. NHTSA should, therefore, consider how U.S. defense expenditures might vary between these two states of the world. The relevant question for a cost-benefit analysis is: How much would U.S. military expenditures change if U.S. passenger-car and light-truck fuel consumption is several percent lower in the next decade than it otherwise would have been?

Neither the Congress nor the Executive Branch has ever attempted to calibrate U.S. military expenditures, force levels, or deployments to any oil market variable, or to some calculation of the projected economic consequences of hostilities in the Persian Gulf. Instead, changes in U.S. force levels, deployments, and thus military spending in that region have been largely governed by political events, emerging threats, and other military and political considerations, rather than by shifts in U.S. oil consumption or imports. NHTSA thus concludes that the levels of U.S. military activity and expenditures are likely to remain unaffected by even relatively large changes in light duty vehicle fuel consumption.

Nevertheless, the agency decided to conduct a sensitivity analysis of the potential effect of assuming that some reduction military spending would result from fuel savings and reduced petroleum imports in order to investigate its impacts on the standards and fuel savings. Assuming that the preceding estimate of total U.S. military costs for securing Persian Gulf oil supplies is correct, and that approximately half of these expenses could be reduced in proportion to a reduction in U.S. oil imports from the region, the estimated savings would range from $0.02 to $0.08 (in 2007 dollars) for each gallon of fuel savings that was reflected in lower U.S. imports of petroleum from the Persian Gulf. If the Persian Gulf region is assumed to be the marginal source of supply for U.S. imports of crude petroleum and refined products, then each gallon of fuel saved might reduce U.S. military outlays by $0.05 per gallon, the midpoint of this range.

This FEIS analyzes the stringencies of alternative CAFE standards, the resulting fuel savings, and their associated environmental impacts that would result from assuming that each gallon of fuel saved as a consequence of higher fuel economy would reduce U.S. military outlays by $0.05 per gallon, representing the midpoint of the estimated savings range in 2007 dollars. These results are included as part of the Sensitivity Analysis reported in Section 3.4.4.2 of this FEIS.

10.2.3 ALTERNATIVES

10.2.3.1 Introduction

NHTSA received a substantial number of comments related to the choice of the range of alternatives analyzed in the DEIS. These comments are related enough to provide a general response, but also unique enough to warrant individual attention. For this reason, the following paragraphs review *and generally respond to a common element in the comments regarding NEPA alternatives in the context of this rulemaking under EPCA. Following this section, NHTSA provides responses to individual comments.*

Commenters specifically suggested that NHTSA did not consider a reasonable range of alternatives. Commenters also suggested that NHTSA use different estimates of various economic inputs to the Volpe model when developing CAFE standards. Several commenters stated that the No Action Alternative was not properly selected. Some commenters also suggested that the Optimized Alternative did not accurately reflect the point at which marginal costs equal marginal benefits because incorrect economic assumptions were input into the Volpe model. In addition, commenters recommended that NHTSA select the Total Costs Equals Total Benefits Alternative as its Preferred Alternative. Commenters also criticized NHTSA's Technology Exhaustion Alternative. As a new alternative, commenters suggested that NHTSA consider GHG regulations as potential alternatives under CAFE. In addition, some commenters stated that NHTSA needs to survey consumer demand and dictate what vehicle fleets manufacturers offer based on those trends. Some commenters further stated that the agency must adopt the "environmentally preferable" alternative as its preferred alternative. Other commenters stated that NHTSA must take into account the looming threat of global warming on the environment and assign further emphasis to energy conservation, thereby setting the CAFE standards at a higher level. Some commenters also asserted that NHTSA did not prioritize the need of the United States to conserve energy. Finally, NHTSA received comments urging the adoption of more "aggressive" fuel economy standards.

Where there is a federal action requiring an EIS, NEPA requires an agency to develop "alternatives to the proposed action." 42 U.S.C. § 4332(2)(C)(iii). CEQ regulations state that consideration of alternatives is the "heart" of an EIS. 40 CFR § 1502.14. However, under CEQ regulations and applicable case law, NHTSA is not required to include every conceivable "alternative" in an EIS, nor necessarily other hypothetical "alternatives" submitted by commenters. Rather, an agency is to consider "reasonable" alternatives. The purpose of and need for the rulemaking determines the range of reasonable alternatives under NEPA. As one circuit court has framed the issue, "an agency must look at every reasonable alternative, with the range dictated by the nature and scope of the proposed action, and sufficient to permit a reasoned choice." Alaska Wilderness Recreation and Tourism Ass'n v. Morrison, 67 F.3d 723, 729 (9th Cir. 1995). NHTSA believes its NEPA analysis of alternatives satisfies this standard.

The CEQ regulations state that the alternatives "should present the environmental impacts of the proposal and the alternatives in comparative form, thus sharply defining the issues and providing a clear basis for choice among options by the decisionmaker and the public." 40 CFR § 1502.14. CEQ guidance also instructs that "[w]hen there are potentially a very large number of alternatives, only a reasonable number of examples, covering the full spectrum of alternatives, must be analyzed and compared in the EIS." Forty Most Asked Questions Concerning CEQ's National Environmental Policy Act Regulations, 46 FR 18026, 18027 (March 23, 1981). The CEQ regulations for EISs further provide that the alternatives section must:

(a) Rigorously explore and objectively evaluate all reasonable alternatives, and for alternatives which were eliminated from detailed study, briefly discuss the reasons for their having been eliminated.

(b) Devote substantial treatment to each alternative considered in detail including the proposed action so that reviewers may evaluate their comparative merits.

(c) Include reasonable alternatives not within the jurisdiction of the lead agency.

(d) Include the alternative of no action.

(e) Identify the agency's preferred alternative or alternatives, if one or more exists, in the draft statement and identify such alternative in the final statement unless another law prohibits the expression of such a preference.

(f) Include appropriate mitigation measures not already included in the proposed action or alternatives.

40 CFR § 1502.14.

As noted above, courts have held that an agency is not required to include every conceivable alternative in NEPA environmental documents. Instead, agencies are required to examine "reasonable" alternatives, and not those that are unlikely or are a "worst case scenario." Robertson v. Methow Valley Citizens Council, 490 U.S. 332, 354-55 (1989). An agency is not required to consider alternatives "whose effect cannot be reasonably ascertained, and whose implementation is deemed remote and speculative." Headwaters, Inc. v. Bureau of Land Management, Medford District, 914 F.2d 1174, 1180 (9th Cir. 1990) (quoting Life of the Land v. Brinegar, 485 F.2d 460 (9th Cir. 1973), cert. denied, 416 U.S. 961 (1974)). An agency is also not required to consider alternatives that are "infeasible, ineffective, or inconsistent with the basic policy objectives" of the proposal. Id. (citing California v. Block, 690 F.2d 753, 767 (9th Cir. 1982)).

Courts have upheld the appropriateness of an agency relying on statutory objectives as a guide for the purpose and need of a project. See Westlands Water Dist. v. U.S. Dep't of Interior, 376 F.3d 853, 866 (9th Cir. 2004) ("Where an action is taken pursuant to a specific statute, the statutory objectives of the project serve as a guide by which to determine the reasonableness of objectives outlined in an EIS."). See also City of New York v. U.S. Dep't of Transp., 715 F.2d 732, 743 (2d Cir. 1983) (statutory objectives provide a "sensible compromise" between unduly narrow objectives and "hopelessly broad societal objectives"); City of Alexandria v. Slater, 198 F.3d 862, 867-68 (D.C. Cir. 1999) (upholding agency's analysis of highway expansion project where purpose and need statement was focused upon factors required by the applicable, substantive statute).

CEQ guidance on this point is similar. "Reasonable alternatives include those that are practical or feasible from the technical and economic standpoint and using common sense, rather than simply desirable from the standpoint of the applicant." Forty Most Asked Questions Concerning CEQ's National Environmental Policy Act Regulations, 46 FR 18026, 18027 (March 23, 1981) (emphasis added).

The "rule of reason" also guides the choice of alternatives and the extent to which the EIS must discuss each alternative. See, e.g., City of Carmel-by-the-Sea v. U.S. Department of Transportation, 123 F.3d 1142, 1155 (9th Cir. 1997). See also American Rivers v. FERC, 201 F.3d 1186, 1200 (9th Cir. 2000) (same, quoting City of Carmel-by-the-Sea, 123 F.3d at 1155). Under the rule of reason, an agency "need not consider an infinite range of alternatives, only reasonable or feasible ones." Id. (citing 40 CFR § 1502.14(a)-(c), as set forth above). "[F]or alternatives which were eliminated from detailed study, [an EIS must] briefly discuss the reasons for their having been eliminated." American Rivers v. FERC, 201 F.3d 1186, 1200 (citing 40 CFR § 1502.14(a)) (emphasis in original).

With this understanding, and as explained in the NPRM and the DEIS, EPCA requires the Secretary of Transportation to establish average fuel economy standards for each model year at least 18 months before the beginning of that model year and to set them at "the maximum feasible average fuel economy level that the Secretary decides the manufacturers can achieve in that model year." When *setting "maximum feasible" fuel economy standards, the Secretary is required to "consider technological feasibility, economic practicability, the effect of other motor vehicle standards of the government on fuel economy, and the need of the United States to conserve energy." NHTSA construes EPCA's statutory factors as including environmental issues and permitting the consideration of other relevant societal issues, such as safety. "Congress did not prescribe a precise formula by which NHTSA should determine the maximally-feasible fuel economy standard, but instead gave it broad guidelines within which to exercise its discretion." Competitive Enterprise Institute v. NHTSA, 901 F.2d 107, 121 (D.C. Cir. 1990) (citing Public Citizen v. NHTSA, 848 F.2d 256, 265 (DC Cir. 1988)). See also Center for Auto Safety v. NHTSA, 793 F.2d 1322, 1340 (DC Cir. 1986) (same); Competitive Enterprise Institute v. NHTSA, 901 F.2d 107, 121 (D.C. Cir. 1990) (Wald, J.) (same). Thus, EPCA does not require the agency to establish fuel-economy standards at any chosen level, but instead confers on NHTSA broad discretion to balance these factors when setting an appropriate standard.*

Although NHTSA has used the Volpe model to inform its consideration of potential CAFE standards, the Volpe model does not determine the CAFE standards NHTSA will propose or promulgate as final regulations. NHTSA considers the results of analyses conducted by the Volpe model and analyses conducted outside the Volpe model, including analysis of the impacts of CO_2 and criteria pollutant emissions, analysis of technologies that might be available in the long term and whether NHTSA could expedite their entry into the market through these standards, and analysis of the extent to which changes in vehicle prices and fuel economy might affect vehicle production and sales. Considering all of this information—not solely that from the Volpe model—NHTSA considers the governing statutory factors, along with environmental issues and other relevant societal issues, such as safety, and promulgates the maximum feasible standards based on its best judgment on how to balance these factors.

This FEIS complies with NEPA and EPCA by informing decisionmakers and the public of the reasonable alternatives and the environmental impacts associated with each alternative. While mindful that EPCA's overall purpose is energy conservation, NHTSA sought to balance the EPCA statutory factors when proposing its Preferred Alternative in the DEIS. After careful consideration of all comments, NHTSA concludes that the Optimized Alternative remains the agency's Preferred Alternative. It is the point at which net benefits are maximized. Further, by limiting the standards to levels that can be achieved using technologies that provide benefits that at least equal their costs, the net benefit maximization approach provides a strong assurance of the marketability of the manufacturers' vehicles and thus economic practicability of the standards. This assurance assumes increased importance in view of current and anticipated conditions in the industry in particular and the economy in general.

With this understanding of the applicable standards for NEPA alternatives in the context of this rulemaking under EPCA, NHTSA turns now to the comments the agency received regarding alternatives. The comments fell into several subcategories, which are set forth below along with NHTSA's response.

10.2.3.2 Reasonable Range of Alternatives

Comments

Comment Number: 0564-2
Organization: Consumer Federation of America
Commenter: Mark Cooper

The analysis underlying the proposed rule is so fundamentally flawed that the agency has not considered an appropriate range of policy options, for which the environmental impact should be evaluated. Erroneous assumptions about market fundamentals have led NHTSA to center its analyses on a level of fuel economy that is so low that it sheds little light on what the environmental impact of a reasonable fuel economy standard would be. NHTSA has based the proposed rule on flawed assumptions and data on:

- Consumer behavior and attitudes toward fuel economy;
- Automaker capabilities to incorporate fuel savings technologies; and
- The price and value of energy.

Comment Number: 0572-10
Organization: Center for Biological Diversity
Commenter: Brian Nowicki, Mickey Moritz, Kassie Siegel

Even were the Volpe model not fundamentally rigged to provide an unreasonably low result, the inputs used by NHTSA ensured that the fuel economy levels that resulted were artificially low, again resulting in NHTSA failing to analyze a reasonable range of alternatives.

Comment Number: 0572-59
Organization: Center for Biological Diversity
Commenter: Brian Nowicki, Mickey Moritz, Kassie Siegel

The IPCC (2007) provides an extensive description of the different environmental impacts projected under different levels of greenhouse gas emission levels, as summarized in the Synthesis Report, Summary for Policymakers (Bernstein (2007). NHTSA refers to IPCC (2007) repeatedly, as on page 24357 of the NPRM, regarding the need to “take actions to reduce greenhouse gas emissions,” and starting on page 24413 of the NPRM, regarding the projection of “specific climate impacts.” The IPCC report Bernstein (2007) categorizes global greenhouse gas emission levels into quantitative emissions scenarios with impacts associated with particular levels of emissions. The proposed rule must analyze the impacts of the proposed CAFE standards in relation to the emissions scenarios and their associated impacts.

Comment Number: 0576-1
Organization: Public Citizen
Commenter: Joan Claybrook

To this aim, NHTSA has neither sharply defined the issues, nor has it provided a clear basis for choice among the options. Furthermore, NHTSA has not fulfilled the obligation to “rigorously explore and objectively evaluate all reasonable alternatives,” “[i]nclude reasonable alternatives not within the jurisdiction of the lead agency,” or “[i]nclude appropriate mitigation measures not already included in the proposed action or alternatives.” [Footnote: See original comment document.] NHTSA’s range of alternatives is unreasonably constrained by the Volpe model’s assumptions regarding the inputs, and NHTSA does not consider other reasonable alternatives out of its jurisdiction.

Comment Number: 0576-4
Organization: Public Citizen
Commenter: Joan Claybrook

The agency also does not include a technology-forcing alternative as required by Energy Policy and Conservation Act (EPCA). [Energy Policy and Conservation Act. Pub. L. 94-163 (Dec. 22, 1975).] While EPCA does not provide explicit guidance, NHTSA has been chided in its interpretation of the balance of the four factors in the statute. In *Center for Biological Diversity v. NHTSA*, the Ninth Circuit Court of Appeals found that NHTSA’s weighing the value of consumer choice over the “need of the nation to conserve energy” was arbitrary and capricious. The courts have affirmed the idea that technology-forcing statutes can impose standards that are at the technology horizon — levels which only the most advanced facilities in an industry may only achieve some of the time." [Footnote: See original comment document.]

Comment Number: 0576-5
Organization: Public Citizen
Commenter: Joan Claybrook

Consideration of alternatives not within the jurisdiction of the lead agency and mitigation measures not included in the proposed action or alternatives are particularly important in addressing the implications of fuel economy standards on reducing greenhouse gas emissions. NHTSA must therefore consider actions that fall outside the scope of the proposed action, and outside of the agency's jurisdiction — something it specifically failed to do when it stated in the draft EIS: "NHTSA emphasizes to the reader of this DEIS that the proposed action does not directly regulate the emissions from passenger cars and light trucks. NHTSA does not have that authority." [Footnote: See original comment document.]

Comment Number: TRANS-05-6
Organization: Consumer Federation of America
Commenter: Mark Cooper

The underlying analysis is so fundamentally flawed that the agency has not considered an appropriate range of policy options for which the environmental impact should be evaluated.

Erroneous assumptions about market fundamentals, about consumer behavior and attitudes towards fuel economy, auto making capabilities to incorporate fuel savings technologies, and the price and value of energy have led NHTSA to center its analysis on a level of fuel economy that is so low that it sheds little light on what the environmental impact of a reasonable fuel economy standard would be.

Comment Number: TRANS-06-1
Organization: Public Citizen
Commenter: Lena Pons

The first is the range of alternatives does not constitute the range of alternatives envisioned under the National Environmental Policy Act, and does not meet the requirements under the regulation.

Under the regulation set forth under the National Environmental Policy Act, agencies are required to consider a range of alternatives that include all reasonable regulatory alternatives. The regulatory alternatives that are considered in this proposal effectively are a confidence bound around the optimized scenario proposed in the regulation.

Response

Commenters state that NHTSA did not consider a reasonable range of alternatives. As noted in detail in the response at 10.2.3, under the applicable standards, NHTSA is not required to include every conceivable alternative in NEPA documents, nor necessarily the alternatives submitted by commenters. See *40 CFR § 1502.14(a). The content and scope of alternatives to the proposed action depends on the purpose and need for the action.*

Here, NHTSA considered the environmental impacts of alternatives ranging from taking no action to Technology Exhaustion. The environmental impacts stem from the mpg standard implemented by the decisionmaker. As such, the agency considered a broad spectrum of alternative actions and the *accompanying environmental impacts. Moreover, throughout the NEPA process, NHTSA has sought to give the decisionmaker and the public a thorough understanding of the range of environmental impacts of diverse CAFE standard setting, which is what is meant by a "reasonable range of alternatives" under NEPA. NHTSA has discussed and analyzed in the DEIS and this FEIS a broad spectrum of alternatives. NHTSA's range of alternatives, which analyze the setting of higher CAFE standards, is sufficiently broad to include the likely environmental impacts of potential greenhouse gas regulation approaches, including those proposed by the California Air Resources Board (CARB), other states, and other federal agencies. An analysis of such "other" potential alternatives would not present environmental impacts that fall outside the range of impacts resulting from the analysis of alternatives in this FEIS. Under NEPA's rule of reason, it would not serve a purpose to require NHTSA to evaluate in this FEIS other alternatives, the environmental impacts of which NHTSA has already considered and analyzed for the benefit of the decisionmaker and the public. NHTSA believes it has complied with the letter and the spirit of NEPA by considering a wide range of alternatives that informs the decisionmaker and the public of the potential environmental impacts associated with this rulemaking.*

10.2.3.3 Different Economic Inputs to the Volpe Model

Comments

Comment Number: 0572-11
Organization: Center for Biological Diversity
Commenter: Brian Nowicki, Mickey Moritz, Kassie Siegel

The NHTSA also abuses its discretion to balance the four EPCA factors by using inaccurate and unreasonably constrained values in the Volpe model. As discussed below, in each and every instance when NHTSA faced a choice of inputs, it chose the level that would minimize the resulting fuel economy level. Even if one or more of the NHTSA's choices were otherwise lawful under EPCA and the Administrative Procedures Act (APA), which they are not, the NHTSA's failure to disclose in the DEIS the impact of these input choices, and to provide an alternative based on choosing higher input numbers, violates NEPA as well.

Comment Number: 0572-21
Organization: Center for Biological Diversity
Commenter: Brian Nowicki, Mickey Moritz, Kassie Siegel

In summary, in each and every instance discussed above, NHTSA unreasonably chose an input level that would depress the fuel economy level that resulted from the modeling. Then, NHTSA disclosed in the DEIS only the results of the modeling runs using these unreasonable input figures. NHTSA's modeling is arbitrary and capricious and violates NEPA (as well as the EPCA, as described throughout and in our July 1, 2008 comments on the proposed rule). Even if NHTSA's use of the Volpe model were otherwise valid (which it is not, as described above), at a minimum, NHTSA was required to consider alternatives based on modeling with reasonable inputs. In other words, NHTSA should also have disclosed the level of its so called "optimization" and "technology exhaustion" alternatives had the model been run with inputs that would have led to higher fuel economy outputs. NHTSA failed to do so.

Response

Commenters suggested that NHTSA use different data inputs to the Volpe model when developing CAFE standards. While NHTSA continues to report the "Reference Case," the agency recognizes that the commenters' suggested inputs could reflect potential future conditions, depending on the economic situation in the future. Therefore, in response to those comments, and in the interest of informing the *decisionmaker and the public, this FEIS explores what CAFE standards could result when inputting different values into the Volpe model. This FEIS also evaluates the environmental impacts resulting from use of the different economic assumptions. See Section 10.2.2 of this FEIS for discussions of NHTSA's reasoning behind the use of the different economic assumptions. This FEIS now analyzes potential impacts of the alternatives resulting from the Volpe model's use of two separate sets of assumptions: the Reference Case Volpe model inputs and the "High Scenario" Volpe model inputs. NHTSA carefully selected the various economic assumptions used in the Reference Case, and described those values and the process for selecting each of them in detail in Section 7 of Chapter V of the NPRM, and in Chapter VIII of the PRIA. Section 3.4.4.2.2 of the DEIS and Section 10.2.2 of this FEIS also briefly discuss the values assigned to the Volpe model economic assumptions. Specifically, NHTSA calculated and analyzed mpg standards and environmental impacts associated with each alternative under both the Reference Case for key model inputs, which uses the EIA's Reference Case fuel price forecast, a domestic SCC, and a 7 percent discount rate; and under the High Scenario, which uses the EIA High Case for fuel price forecast, a global SCC, and a 3 percent discount rate. NHTSA also examined two additional input scenarios (Mid-1 and Mid-2) to show how various combinations of economic-assumption input values between those used in the Reference Case and High Scenario result in average mpg levels that fall between the required mpg standards associated with the Reference Case and High Scenario input values. See Table 2.3-6 (listing input assumptions for Mid-1, Mid-2 and High Scenarios). Sections 3.4 and 4.4 describe the environmental impacts of the Reference Case and High Scenario alternatives. Appendix B shows the analysis results for the Mid-1 and Mid-2 Scenarios. Because this FEIS analyzes the environmental impacts of the alternatives at different values for Volpe model input assumptions, the decisionmaker and the public are presented with the full range of environmental impacts resulting from the alternatives' range of stringencies, which is derived using varying sets of economic assumptions, some of which were suggested by commenters. Even varying these economic inputs into the Volpe model, the environmental impacts of the resulting CAFE standards still fall within the range of impacts between the No Action Alternative (Alternative 1) and the Technology Exhaustion Alternative (Alternative 7).*

The Center for Biological Diversity (CBD) suggested that NHTSA disclose the level of stringency associated with technology exhaustion "had the model been run with inputs that would have led to higher fuel economy outputs." CBD's comment indicates that CBD misunderstands the Technology Exhaustion Alternative. As set forth in the NPRM and the DEIS, the Technology Exhaustion Alternative represents the level at which vehicle manufactures apply all feasible technologies by progressively increasing the stringency of the standard in each model year until every manufacturer (among those without a history of paying civil penalties) exhausts technologies estimated to be available during MY 2011-2015. Except for phase-in constraints, this analysis was performed using the same technology-related estimates (e.g., incremental costs, incremental fuel savings, availability, applicability, and dependency on vehicle freshening and redesign) as used for other alternatives, such as those that maximize net benefits and those that produce total benefits approximately equal to total costs. For the Technology Exhaustion Alternative, NHTSA removed phase-in constraints in order to develop an estimate of the effects of fuel economy increases that might be achieved if manufacturers could apply as much technology as theoretically possible, while recognizing that some technology must still be installed as part of a vehicle freshening or redesign. Thus, the Technology Exhaustion Alternative is not (and could not be under any set of different model data inputs) affected by the economic assumptions used in the Volpe model.

As to CBD's larger point regarding alternate economic inputs, this has been addressed in the FEIS through use of the High, Mid-1 and Mid-2 scenarios, which use different economic inputs from the Reference Case.

10.2.3.4 Alternative 1 (No Action)

Comments

Comment Number: 0572-30
Organization: Center for Biological Diversity
Commenter: Brian Nowicki, Mickey Moritz, Kassie Siegel

The NHTSA compounds the other errors in its analysis by presenting the effect of its action only as an improvement over the "no action" alternative, which NHTSA defines as leaving fuel economy standards unchanged. The true "no action" alternative is the technologically achievable fuel economy level. NHTSA's "action" is to reduce this level, based on its consideration of the other statutory factors. Therefore, NHTSA was required to disclose in the DEIS the additional greenhouse gas emissions that will result from its decision to set fuel economy standards far lower than the technologically feasible level. The NHTSA failed to do so, instead continuing to portray its rulemaking merely as an improvement over the status quo, when in fact the opposite is true: it has proposed standards that are far lower than what is achievable with today's and future technology, and far lower than current levels in other countries. The true effects of this decision must be disclosed.

Comment Number: 0574-11
Organization: Alliance of Automobile Manufacturers
Commenter: Julie Becker

Under the case of *Department of Transportation v. Public Citizen*, 541 U.S. 752(2004), commonly referred to as the "Mexican Trucks" decision—a case in which NHTSA's parent Cabinet Department prevailed unanimously in the Supreme Court—the Court held that NEPA analysis must be framed based on directives from Congress, and must be performed only to the extent that a particular agency has discretion:

> We hold that where an agency has no ability to prevent a certain effect due to its limited statutory authority over the relevant actions, the agency cannot be considered a legally relevant "cause" of the effect. Hence, under NEPA and the implementing CEQ regulations, the agency need not consider these effects in its EA [Environmental Assessment] when determining whether its action is a "major Federal action." Because the President, not FMCSA [Federal Motor Carrier Safety Administration], could authorize (or not authorize) crossborder operations from Mexican motor carriers, and because FMCSA has no discretion to prevent the entry of Mexican trucks, its EA did not need to consider the environmental effects arising from the entry. (*Department of Transportation v. Public Citizen*, 541 U.S. 752 (2004) at 770.),

NHTSA never explains why the Mexican Trucks decision should not alter the no-action alternative the agency proposes, which imagines counterfactually that NHTSA can leave CAFE standards unchanged, contrary to Congress's directives in EISA. Instead, to justify continuing with its own view of how to define the no-action alternative, NHTSA states in a circular fashion that "NHTSA must analyze a scenario where NHTSA does not take this action [i.e., takes no action to increase fuel economy standards]." (DEIS, at 1-11) That assertion is non-responsive to the Alliance's NEPA scoping comments. NHTSA clearly cannot specify a "no action" alternative that incorrectly assumes that the agency has no duty to carry out EISA's directives. Instead, NHTSA must specify a "no action" alternative that is formulated with the congressionally ordered baseline of achieving at least 35 mpg by MY 2020 in mind. Given the time period over which NHTSA is proposing to establish standards (i.e., for half of the model years between MY 2011 and MY 2020), the simplest way for NHTSA to specify a proper baseline is to use the fuel economy level in MY 2015 that makes half of the progress necessary to achieve the 35 mpg target in MY 2020, and then judge all of its alternatives against that halfway mark. There may also be other defensible ways of defining a "no action" alternative, but pretending that EISA does not exist is not one of them.

Moreover, this debate over how to define the no-action alternative is no tan arid one lacking in practical significance. Properly specifying the baseline for analysis of regulatory alternatives that fall within NHTSA's discretion under EISA is vital. If NHTSA sets the baseline too high, then it will underestimate the benefits of a given set of fuel economy standards. If NHTSA sets the baseline too low, as it has done here by specifying a baseline that falls short of the congressional mandate in EISA, then it will *overestimate* benefits. For instance, using MY 2010 CAFE standards as the no-action alternative, NHTSA might conclude that the agency's preferred set of CAFE standards will reduce the global concentrations of CO_2 that might otherwise obtain by 1 ppm. By contrast, it might find that if the no-action alternative instead were defined to take as a given mandated increases in fuel economy by Congress in EISA, then the same agency-preferred set of CAFE standards might reduce global concentrations of CO_2 by only 0.1 ppm. These numbers are purely illustrative. The point is that by mis-specifying the no-action alternative, NHTSA improperly exaggerates the environmental benefits that its discretionary choices appear to achieve. Furthermore, if NHTSA corrects this error, it would provide further directional support for concluding the NEPA process with an EA/FONSI [Environmental Assessment/Finding of No Significant Impact] (primarily, or in the alternative), as opposed to concluding that process with a final EIS.

Comment Number: 0574-6
Organization: Alliance of Automobile Manufacturers
Commenter: Julie Becker

NHTSA continues to misidentify the so-called "no action" alternative. NHTSA's persistence in making comparisons against a "no action" alternative that uses MY 2010 CAFE standards as a baseline counter factually assumes that EISA was never passed and is based on circular reasoning.

Comment Number: 0576-7
Organization: Public Citizen
Commenter: Joan Claybrook

NHTSA has also influenced the context by choosing a baseline that is too low. The agency's baseline is the no action alternative; however, the agency assumes fuel economy levels of 27.5 mpg for passenger cars and 23.5 mpg for light trucks. [Footnote: See original comment document.] NHTSA's most recent report on the level of fuel economy performance of vehicles estimates that passenger cars are getting 31.2 mpg and light trucks are getting 23.4 mpg. [Footnote: See original comment document.] However, even this level of fuel economy is unlikely to capture a real baseline, considering the intense shift in consumer demand for fuel efficient vehicles and the auto industry's scrambling to produce and market more efficient vehicles. [Footnote: See original comment document.]

Comment Number: TRANS-01-1
Organization: Alliance of Automobile Manufacturers
Commenter: Julie Becker

The first issue relates to NHTSA's inclusion of a no action alternative in its array of options. In our scoping comments, the Alliance noted that the 2007 energy bill does not allow for a no action option. Instead the energy bill sets a clear trajectory for increasing fuel economy standards for the span of a decade, and requires at least steady progress toward a 35 mile per gallon goal in model year 2020. We do not think it is appropriate for NHTSA to continue to rely on no action as its starting point.

Comment Number: TRANS-06-3
Organization: Public Citizen
Commenter: Lena Pons

Additionally, the no action alternative should not be considered to be an extension of the situation as it stands, but should be a reflection of what would happen were there no regulatory intervention.

Response

NHTSA received several comments contending that we improperly selected our No Action Alternative. In response to these comments, NHTSA clarifies that its No Action Alternative does not assume that NHTSA would issue a rule directing manufacturers to continue to achieve the MY 2010 CAFE standard (the DEIS incorrectly stated this assumption but the analysis was unaffected). Rather, the No Action Alternative simply assumes that NHTSA would not issue a rule regarding CAFE standards. The No Action Alternative assumes that average fuel economy levels in the absence of CAFE standards beyond 2010 would equal the higher of a manufacturer's product plans or the manufacturer's required level of average fuel economy for MY 2010. The MY 2010 fuel economy level represents the standard NHTSA believes manufacturers would continue to achieve, assuming NHTSA does not issue a rule.

Some commenters asserted that the No Action Alternative is not legally available for selection. Other commenters stated that NHTSA did not use the proper fuel-economy standard for the No Action Alternative. NHTSA recognizes the commenters' concern that the current average fuel economy of automobiles and light trucks is rising due to high energy costs and a shifting market.

These commenters misunderstand the NEPA process. Although EISA's recent amendments to EPCA direct NHTSA to increase CAFE standards and do not permit the agency to take no action on fuel economy, CEQ regulations mandate analysis of a no action alternative. See 40 CFR § 1502.14(d). Indeed, CEQ has explained that:

> *[T]he regulations require the analysis of the no action alternative even if the agency is under a court order or legislative command to act. This analysis provides a benchmark, enabling decision makers to compare the magnitude of environmental effects of the action alternatives. It is also an example of a reasonable alternative outside the jurisdiction of the agency which must be analyzed. [See 40 CFR § 1502.14(c).] … Inclusion of such an analysis in the EIS is necessary to inform the Congress, the public, and the President as intended by NEPA. [See 40 CFR § 1500.1(a).] Forty Most Asked Questions Concerning CEQ's National Environmental Policy Act Regulations, 46 FR 18026 (1981) (emphasis added).*

Thus, "[i]n requiring consideration of a no-action alternative, the [CEQ] intended that agencies compare the potential impacts of the proposed major federal action to the known impacts of maintaining the status quo." Custer County Action Assoc. v. Garvey, 256 F.3d 1024, 1040 (10th Cir. 2001) (citing Association of Public Agency Customers v. Bonneville Power Administration, 126 F.3d 1158, 1188 (9th Cir. 1997), and 46 FR 18,026, 18,027 (1981)). Consistent with CEQ regulations, the baseline model year 2010 levels in NHTSA's No Action Alternative represent the level at which manufacturers are meeting the CAFE standards already in effect. Manufacturers are obligated under EPCA to either meet the current CAFE standards or pay a penalty for falling below those standards. Manufacturers are not, however, *mandated to reach a fleet-wide average fuel economy level above 27.5 mpg for passenger automobiles or 23.5 mpg for non-passenger automobiles. Therefore, NHTSA believes that it would be speculative to set the baseline No Action Alternative at a level of fuel economy stringency that not all manufacturers are currently mandated, or able, to meet. In NHTSA's view, a different or modified No Action Alternative is not reasonable and would not aid the decisionmaker or the public in understanding the environmental impacts of the alternatives, because the alternatives would simply be measured from a different reference point. Therefore, this FEIS has maintained the baseline No Action Alternative as set forth in the DEIS. It is consistent with CEQ regulations and applicable law, and provides a logical reference point that serves the purpose of displaying to the decisionmaker and the public the difference between no action (maintaining the status quo) and each of the six action alternatives.*

10.2.3.5 Alternative 3 (Optimized Scenario)

Comments

Comment Number: 0559-3
Organization: The Northeast States for Coordinated Air Use Management (NESCAUM)
Commenter: Arthur Marin

Despite these developments which call for bold policy steps to actively pursue significant improvements in fuel economy, NHTSA has chosen to pursue a very conservative course in setting near-term standards. We made this point in our comments submitted on the Proposed Rule, noting NHTSA's initial consideration of seven different fuel economy stringency scenarios (ranging from no-action to technology exhaustion alternatives), and ultimate choice of an "optimized" alternative that maximized net benefits from an economic standpoint. In settling on this alternative for which there is little to no impetus for forcing technology, NHTSA's actions will have a dampening effect on progress toward long term improvements to fuel economy and by extension to progress addressing the environmental impacts brought about by climate change.

Comment Number: 0572-12
Organization: Center for Biological Diversity
Commenter: Brian Nowicki, Mickey Moritz, Kassie Siegel

Moreover, even if NHTSA's choice of the "optimized" alternative were otherwise lawful, the use of incorrect inputs in the model results means that even by the NHTSA's own twisted definitions, this alternative does not actually represent the point at which marginal benefits equal marginal costs. The NHTSA's inaccurate claim that it does violates NEPA's requirement to provide accurate information to the public.

Comment Number: 0576-19
Organization: Public Citizen
Commenter: Joan Claybrook

NHTSA's sensitivity analysis shows that the level of fuel economy standards is highly sensitive to the price of gasoline. The agency's estimate for the high price scenario would set the car standard at 37.4 mpg in 2011, almost 20 percent higher than the agency's "optimized" scenario, and at almost exactly the same level as NHTSA's total costs balance total benefits (TC=TB) scenario. (PRIA A-2) The light truck standards are less responsive to changes in economic assumptions, which NHTSA attributes to a lack of "cost effective" technologies available to raise fuel economy above the level reached in the optimized scenario." (PRIA at IX-10-IX-13)

Response

As noted in the DEIS and in this FEIS, the Optimized Alternative is the agency's Preferred Alternative. This alternative reflects standards based on applying technologies until net benefits are maximized. For a more detailed discussion of the Optimized Alternative, see Section 2.3.4 of the FEIS; Section 2.3.3 of the DEIS; Section X of the NPRM; and Section III-1 of the PRIA.

Commenters suggested that the Optimized Alternative does not accurately reflect the point at which marginal costs equals marginal benefits because incorrect economic assumptions were input into the Volpe model. As noted above, in response to these comments, this FEIS explores what CAFE standards could result from inputting different values into the Volpe model. This FEIS also evaluates the environmental impacts resulting from the use of the different economic assumptions in these alternatives through the High, Mid-1 and Mid-2 Scenarios. See Chapters 3 and 4. Thus, the environmental analysis has been expanded to include the environmental impacts of the alternatives at different values for Volpe model input assumptions. NHTSA selected the various economic assumptions to be used in the Volpe model carefully, and described those values and the process for selecting each of them in detail in Section 10.2.2 of this chapter. Chapter 2 of this FEIS also provides a brief discussion of the values assigned to the Volpe model economic assumptions. Because this FEIS analyzes the environmental impacts of the alternatives at different values for Volpe model input assumptions, the decisionmaker and the public are presented with the full range of environmental impacts resulting from the alternatives' range of stringencies, which is derived using varying sets of economic assumptions, some of which were suggested by commenters.

10.2.3.6 Alternative 6 (Total Costs Equal Total Benefits)

Comments

Comment Number: 0564-13
Organization: Consumer Federation of America
Commenter: Mark Cooper

We believe that the TC=TB [total costs equal total benefits] approach is the proper way to recognize "the need of the nation to conserve energy."

At a minimum, an approach that would reasonably consider "the need to conserve energy" would balance the economic and conservation concerns and set the standard between the two extremes.

NHTSA did not do so. It simply chose to set the standard at the lower level with no consideration of the enormous energy conservation cost of that decision.

Comment Number: 0575-14
Organization: Union of Concerned Scientists
Commenter: Eli Hopson

An MC=MB [maximum costs equal maximum benefits] analysis produces noticeably more conservative findings for maximum cost-effective fuel economy levels. The MC=MB approach is also very sensitive to different valuations of the benefits, making it more error prone. It is therefore critical to accurately identify and account for the benefits associated with fuel-saving technologies. An MC=MB analysis that excludes or undervalues even some of the benefits—such as avoided carbon emissions, reduced oil dependence, or high gas prices—is fundamentally flawed.

Unfortunately, this NPRM contains numerous flaws including undervalued gasoline and carbon prices, among others (see Sections 1 and 2), which vastly underestimate consumers' economic and social savings from reduced fuel use. While NHTSA must fix these flaws, UCS suggests that NUTSA use a TC=TB analysis to determine maximum feasible U.S. fuel economy standards. Such an analysis would reduce the impact of any inaccurate monetizing of the benefits of reduced fuel consumption, such as improved energy security and reduced heat-trapping emissions, and ensure that the agency is doing the most possible to address these issues without negative consequences to U.S. consumers. As shown in Table 1 below, NHTSA's own analysis indicates that employing a TC=TB analysis would increase the economically practicable fleet average between 2.8 and 5.7 miles per gallon. This greater application of technology also produces higher lifetime societal benefits, as noted by NHTSA. Depending on discount rate selected (3% or 7%), opting for a TC=TB analysis over NHTSA's proposed standard would yield between $46.2 and $57.6 billion in additional lifetime benefits over the proposed standard. (Computed from PRIA Tables IX-2a and IX-2b, Passenger Cars and Light Trucks Combined (2006 dollars).]

Table 1: Required Fleet Average MPG Levels [See original comment document.]

NHTSA's decision to base deployment of fuel saving technology on the marginal, rather than total benefits, by definition, fails to reach the maximum feasible fuel economy level needed to address the Department of Transportation's legal requirements. The use of a TC=TB analysis, which would maximize the need to conserve energy while ensuring consumers are as well off as they are today, is a far more pragmatic economic assessment, and one that better meets the intent of Congress in raising fuel economy standards. UCS suggests that NHTSA use a TC=TB analysis to determine maximum feasible U.S. fuel economy standards.

Comment Number: 0575-6
Organization: Union of Concerned Scientists
Commenter: Eli Hopson

NHTSA based its rulemaking on costs and benefits on the margin rather than the total costs and benefits of improved standards.

Response

Another alternative NHTSA evaluated in the DEIS is the Total Costs Equals Total Benefits Alternative (Alternative 6). As an initial matter, the Union of Concerned Scientists and other commenters suggested the Total Costs Equals Total Benefits Alternative during NHTSA's CAFE rulemaking for MY 2008-2011 for light trucks. This alternative reflects standards based on manufacturers applying technologies until total costs equal total benefits, yielding zero net benefits. The Total Costs Equal Total Benefits Alternative is the second most stringent set of mpg standards examined in this FEIS, after the Technology Exhaustion Alternative (which yields negative net benefits). For a more detailed discussion of the Total Costs Equal Total Benefits Alternative, <u>see</u> *Section 2.3.7 of the FEIS, Section X of the NPRM, and Section III-1 of the PRIA.*

Commenters suggested that NHTSA select the Total Costs Equals Total Benefits Alternative as its Preferred Alternative, arguing that it properly recognizes the need of the nation to conserve energy and is a far more pragmatic economic assessment that better meets the intent of Congress in raising fuel economy standards. Upon a considered analysis of all information available, including all information raised to NHTSA in comments, NHTSA concludes that the Optimized Alternative remains the agency's Preferred Alternative. It is the point at which net benefits are maximized. Further, by limiting the standards to levels that can be achieved using technologies that provide benefits that at least equal their costs, the net benefit maximization approach provides a strong assurance of the marketability of the *manufacturers' vehicles and thus economic practicability of the standards. This assurance assumes increased importance in view of current and anticipated conditions in the industry in particular and the economy in general.*

10.2.3.7 Alternative 7 (Technology Exhaustion)

Comments

Comment Number: 0572-6
Organization: Center for Biological Diversity
Commenter: Brian Nowicki, Mickey Moritz, Kassie Siegel

NHTSA's "technology exhaustion" would result in average fuel economy of 31.1 mpg in 2011 to 41.4 mpg in 2015. It is clear that this cannot, by any stretch of the imagination, be equated with what is "technologically feasible." First, cars on the road in the U.S. today already achieve approximately the same or better gas mileage than what NHTSA has defined as the combined fleet "technology exhaustion" for model year 2015. These include the Toyota Prius (48/45; city/highway) and the Honda Civic Hybrid (40/45; city/highway). [Footnote: See original comment document.] Even more vehicles cars already achieve the "technology exhaustion" standard for the combined fleet in MY 2011: smartcar (33/41; city/highway); Mini Cooper(28/31); Toyota Yaris (29/36); Toyota Corolla (28/37); Nissan Altima Hybrid (35/33); Toyota Camry Hybrid (33/34); Hyundai Accent (27/32); Kia Rio (27/32); Mazda Tribute Hybrid 2WD (34/30); and Honda Fit (28/34). [Footnote: See original comment document.]

Second, NHTSA's "technology exhaustion" alternative results in fuel economy standards, even in 2015, which are below current standards in many other countries, and far below Japanese standards for 2015. In contrast, Europe and Japan had average fuel economy standards of approximately 40 mpg in 2006—over 15 mpg higher than U.S. standards (ICCT 2007). Both Europe and Japan are predicted to continue increasing their fuel standards; even their high standards are not the technology maximum. That other countries have achieved higher fuel standards indicates that there are eminently feasible technology options available today that have not been included in the DEIS. (We note the substantial overlap in manufacturers of the European fleet and U.S. fleet (ICCT 2007:13), and that at least one manufacturer, Ford, has already declared its intention to "make big changes to the vehicles it sells domestically" and bring "six small cars made in Europe to the North American market (Smith 2008).")

Figure 1. [See original comment document.]

By contrast, NHTSA's definition of "technology exhaustion" is the level that would "require every manufacturer to apply every feasible fuel saving technology to their MY 2011-2015 fleet." (DEIS at 2-2) By what sleight of hand does NHTSA transform what is "technologically feasible" into something called "technology exhaustion" that is so much lower? The answer lies in the unlawful constraints of the Volpe model itself.

Comment Number: 0574-2
Organization: Alliance of Automobile Manufacturers
Commenter: Julie Becker

The Alliance agrees with much of the analysis presented in the DEIS. For instance, NHTSA's analysis of the fuel economy impacts associated with mandating higher levels of fuel economy under the alternatives studied leads to the conclusion that even if NHTSA were to adopt the so-called "technology exhaustion" alternative, NHTSA would be able to reduce global mean surface temperatures in 2100 by only an additional 0.006°C as compared to the temperature reductions associated with the "optimized" alternative

NHTSA favors in its notice of proposed rulemaking ("NPRM"). [Footnote: See original comment document.]. See DEIS 2-16 (Table 2.5-4 (comparing "Reduction from No Action" for the "Optimized" and "Technology Exhaustion" scenarios). This is obviously a very small change, and is less than both the natural variability in temperature on an annual basis and the error in measuring temperatures from year to year. [Footnote : See original comment document.]

Comment Number: 0588-9
Organization: New York State Department of Transportation
Commenter: Stanley Gee

Tables 3.2-2 and 3.2-3 indicate that the technology exhaustion alternative will yield more incremental benefits for light trucks than it yields for passenger vehicles. Figure 4.2-2 also indicates that the technology exhaustion alternative will yield a significant incremental benefit for light trucks. Certain sections of the DEIS suggest that if the CAFE standards are set too stringent, manufacturers may opt to pay noncompliance penalties rather than meet or exceed the standard. If this is the case, wouldn't the more aggressive alternatives (3-7) yield less benefit than the preferred alternative? The FEIS should explain this in more detail and clearly describe how the Volpe model and other models treat this issue for alternatives 3-7.

Response

NHTSA disagrees with the Center for Biological Diversity's (CBD) comment suggesting that the Technology Exhaustion Alternative is not truly "exhaustive" because some cars sold in the United States achieve higher fuel economy than the fleetwide average NHTSA estimated would be achieved under the technology exhaustion alternative NHTSA performed for MY 2011 and MY 2015. Other commenters contend that NHTSA did not fully explore what is technologically feasible.

As an initial matter, NHTSA developed the Technology Exhaustion Alternative by progressively increasing the stringency of the standard in each model year until every manufacturer (among those without a history of paying civil penalties) exhausted technologies estimated to be available during MY 2011-2015. Except for phase-in constraints, this analysis was performed using the same technology-related estimates (e.g., incremental costs, incremental fuel savings, availability, applicability, and dependency on vehicle freshening and redesign) as used for other alternatives, such as those that maximize net benefits and those that produce total benefits approximately equal to total costs. For the Technology Exhaustion Alternative, NHTSA removed phase-in constraints in order to develop an estimate of the effects of fuel economy increases that might be achieved if manufacturers could apply as much technology as theoretically possible, while recognizing that some technology must still be installed as part of a vehicle freshening or redesign.

In each year, NHTSA increased the stringency until the first manufacturer exhausted available technologies; beyond this stringency, NHTSA estimated that the manufacturer would be unable to comply (NHTSA is precluded from considering manufacturers' ability to use CAFE credits) and would be forced to pay civil penalties. NHTSA then increased the stringency until the next manufacturer would be unable to comply, and continued to increase the stringency of the standard until every manufacturer was unable to apply enough technology to comply.

NHTSA did not, as CBD appears to suggest, estimate the stringency that would force every manufacturer to apply to every single vehicle every theoretically applicable technology. This approach would completely ignore product planning cycles and real constraints on the pace at which technologies can even conceivably be added to manufacturers' fleets. Rather, as mentioned above, NHTSA applies constraints related both to vehicle engineering and to vehicle freshening and redesign schedules.

The Center for Biological Diversity further argues that NHTSA's Technology Exhaustion Alternative is not truly "exhaustive" because other countries achieve higher fuel economy levels. This argument ignores the fact that the United States does not, even setting aside technological differences, have the same fleet profile as other countries, and that average fuel economy is strongly dependent on fleet profile. EPCA requires NHTSA to set maximum feasible CAFE standards for passenger cars and light trucks produced for sale in the United States, not to set standards that force manufacturers to make the U.S. vehicle market have a profile like that of any other country.

In response to the comment suggesting that this FEIS explain how the Volpe model considers manufacturers' election to pay noncompliance civil penalties rather than meet the prescribed CAFE standard, Sections 3.1.4, 3.4.3.1, 3.4.4.2.2, and 4.4.3.1 of this FEIS illustrate how the estimated penalty rate is accounted for in the Volpe model. For additional discussion of how noncompliance civil penalties are accounted for in the Volpe model, see page III-13, V-55-56 of the PRIA.

10.2.3.8 New Alternatives

Comments

Comment Number: 0572-23
Organization: Center for Biological Diversity
Commenter: Brian Nowicki, Mickey Moritz, Kassie Siegel

The EPCA is a "technology-forcing" statute, whereby a challenging standard encourages technological innovation. The EIS must consider alternatives in light of EPCA's technology-forcing character. As the court in *Center for Auto Safety v. Thomas* noted, "[t]he experience of a decade leaves little doubt that the congressional scheme in fact induced manufacturers to achieve major technological breakthroughs as they advanced towards the mandated goal." (847 F.2d 843, 870 (D.C. Cir. 1988) (overruled on other grounds); *see also Green Mt. Chrysler Plymouth Dodge Jeep v. Crombie*, 508 F. Supp. 2d 295, 358-359 (D. Vt. 2007) (discussing technology-forcing character of EPCA and the use of increased fuel efficiency to augment performance rather than mileage). As explained by the court in *Kennecott Greens Creek Min. Co. v. Mine Safety and Health Admin*., "when a statute is technology forcing, "when a statute is technology forcing, the agency can impose a standard which only the most technologically advanced plants in an industry have been able to achieve-even if only in some of their operations some of the time." (476 F.3d946, 957 (D.C. Cir. 2007) (quoting *United Steel Workers of America, AFL-CIO-CLC v. Marshall*, 647F.2d 1189, 1246 (D.C. Cir. 1980)). With regard to a similarly technology-forcing statute, the Clean Air Act, legislative history indicates that the primary purpose of the Act was not "to be limited by what is or appears to be technologically or economically feasible," which may mean that "industries will be asked to do what seems impossible at the present time." (116 Cong. Rec. 32901-32902 (1970), 1 Legislative History of the Clean Air Amendments of 1970 (Committee Print compiled for the Senate Committee on Public Works by the Library of Congress), Ser. No. 93-18, p. 227 (1974); *see also Whitman v. American Trucking Associations*, 531 U.S. 457, 491 (2001)).

Due to the technology-forcing nature of the statutory scheme, the NHTSA was required to include one or more technology-forcing alternatives in the DEIS. Such an alternative would include standards that may appear impossible today, but that would force innovation as industry strives to meet a challenging standard. NHTSA's "technology exhaustion" alternative, defined by the criteria "whether a particular method of improving fuel economy can be available for commercial application in the MY for which the standard is being established" (DEIS at 1-2) clearly cannot substitute for consideration of a technology-forcing alternative.

While NHTSA will likely argue that it was not required to consider a technology-forcing alternative because it has pre-determined that it would not select such an alternative, it is clear that all reasonable alternatives, even those falling outside the lead agency's jurisdiction, must be considered. *Natural Resources Defense Council. v. Morton*, 458 F.2d 827, 834 (D.C. Cir. 1972). Because EPCA is a technology-forcing statute, the failure to include a technology-forcing alternative was unreasonable and unlawful.

Having failed to include such an alternative, the NHTSA then failed to analyze the environmental impacts of a technology-forcing standard. This omission is particularly significant because such a technology forcing standard would have environmental benefits that not only amplify the ability of automakers to meet higher standards in later years, but that also ripple through the economy. NHTSA's failure to consider this important aspect of the analysis renders the DEIS inadequate.

Comment Number: TRANS-06-2
Organization: Public Citizen
Commenter: Lena Pons

Additionally, under the regulations, agencies may consider regulatory alternatives that are not in the jurisdiction of the lead agency, which would include more protective types of regulations such as greenhouse gas regulations for motor vehicles, such as those envisioned by the State of California and other states, and also part of the EPA's proposed greenhouse case, economy-wide greenhouse gas regulations.

Response

While NHTSA recognizes that under Section 1502.14 of the CEQ NEPA implementing regulations, an agency may consider alternatives not within its jurisdiction, we disagree with commenters who suggested that NHTSA consider the regulation of GHGs as potential alternatives under CAFE. NHTSA can issue CAFE standards, which necessarily have the effect of regulating CO_2*, just as EPA can issue* CO_2 *standards, which necessarily have the effect of regulating CAFE. Indeed, in the Advance Notice of Proposed Rulemaking, EPA published in response to the* Massachusetts v. EPA *ruling on the regulation of* CO_2*, vehicle efficiency ranges are comparable to the ranges in NHTSA's proposed rulemaking because both were based on product plans available to both agencies at the time of the analyses.*[22] *Because regulating CAFE is tantamount to regulating* CO_2*, it would add nothing to the alternatives to include* CO_2 *regulations.*

Section 1502.14 of the CEQ regulations authorizes an agency to "include reasonable alternatives not within the jurisdiction of the lead agency." An agency, however, need not consider alternatives that are outside its power to implement. See Sierra Club v. Babbitt, 65 F.3d 1502, 1513 (9th Cir. 1995); see also Citizens Against Rails-To-Trails v. Surface Transportation Board, 267 F.3d 1144, 1151 (D.C. Cir. 2001). An agency is also not obligated to consider an alternative that would "override and redefine" the stated purpose of the project. See Crutchfield v. County of Hanover, 325 F.3d 211, 221-223 (4th Cir. 2003). NEPA does not require discussion of an alternative that is not reasonably related to a project's purpose(s). Native Ecosystems Council, 428 F.3d at 1245-1247 (EA case); City of Richfield v. FAA, 152 F.3d 905, 907 (8th Cir. 1998); Citizens Against Burlington, Inc. v. Busey, 938 F.2d 190, 195-196 (D.C. Cir. 1991); Northern Alaska Environmental Center v. Kempthorne, 457 F.3d 969, 978 (9th Cir. 2006) (agency need not discuss alternatives that are infeasible, ineffective, or inconsistent with the objectives of the project).

[22] *73 FR 44354, 44442-43 (July 30, 2008).*

The CBD relies on Natural Resources Defense Council. v. Morton, 458 F.2d 827, 834 (D.C. Cir. 1972) for the proposition that "all reasonable alternatives, even those falling outside the lead agency's jurisdiction, must be considered." This case from the early 1970's must be read in light of more recent Supreme Court and federal case law. In light of Vermont Yankee Nuclear Power Corp. v. Natural Resources Defense Council, Inc., 435 U.S. 519 (1978), and subsequent case law, the District of Columbia Circuit itself has stated that Morton stands only for the proposition that a reasonable alternative is defined by reference to a project's objectives. City of Alexandria v. Slater, 198 F.3d 862, 869 (D.C. Cir. 1999), cert. denied sub nom., Alexandria Historical Restoration and Preservation Com'n v. Federal Highway Admin., 531 U.S. 820 (2000).

Indeed, the District of Columbia Circuit has noted that "[w]e doubt the continuing vitality of the rather expansive view of NEPA we expressed in Morton, since subsequent Supreme Court cases have directly criticized us for overreading that statute's mandate." City of Alexandria, 198 F.3d at 869 n. 4 (citing, among other authorities, Baltimore Gas and Elec. Co. v. Natural Resources Defense Council, Inc., 462 U.S. 87, 97 (1983) and Vermont Yankee, 435 U.S. at 554).

Where, as here, "an action is taken pursuant to a specific statute, the statutory objectives of the project serve as a guide by which to determine the reasonableness of objectives outlined in an EIS." Westlands Water Dist. v. U.S. Dep't of Interior, 376 F.3d 853, 866 (9th Cir. 2004). The purpose and need of this rulemaking is to set maximum feasible average fuel economy levels under EPCA. NHTSA does not have the statutory authority to reduce the total amount of GHGs emitted by all vehicles driven, because NHTSA, under its statutory authority conferred by EPCA, cannot control how many miles citizens elect to drive. Nevertheless, NHTSA appreciates the fact that, despite the complex global nature of the problem, we still have an obligation to take a "hard look" under NEPA and analyze the effects of this rulemaking on global warming within the context of the other actions that affect global warming. Thus, NHTSA believes that the range of alternatives – including that of the Technology Exhaustion Alternative at the highest level of stringency – fully informs the decisionmaker and the public about the environmental impacts of any other reasonable CAFE standard, including climate-change issues.

Moreover, as noted above, NHTSA has discussed and analyzed in the DEIS and in this FEIS a broad spectrum of alternatives. NHTSA's range of alternatives, which analyze the setting of higher CAFE standards, is sufficiently broad to include the likely environmental impacts of potential GHG regulation approaches, including those proposed by the California Air Resources Board (CARB), other states, and other federal agencies. An analysis of such "other" potential alternatives would not present environmental impacts that fall outside of the range of impacts resulting from the existing analysis of the alternatives.

Finally, in response to the CBD's comment that NHTSA did not include a technology-forcing alternative, NHTSA states that other than the No Action Alternative, all of the analyzed alternatives induce manufacturers to implement new technologies to increase the fuel efficiency of their vehicles and are, therefore, technology-forcing. For a discussion of the alternatives, see Section 2.3 of the DEIS and this FEIS, Section X of the NPRM, and Section III-1 of the PRIA. For example, the Technology Exhaustion Alternative represents the level at which vehicle manufactures apply all feasible technologies without regard to costs. NHTSA removed phase-in constraints, in order to develop estimates of fuel economy increases that might be achieved if manufacturers could apply as much technology as theoretically possible, while recognizing that some technologies must still be installed as part of a vehicle freshening or redesign.

10.2.3.9 Alternatives Relationship to Maximum Feasible Fuel Economy Standard

Comments

Comment Number: 0557-6
Organization: The Natural Resources Defense Council
Commenter: Luke Tonachel, Brian Siu

The Draft Environmental Impact Statement is inaccurate because [it] evaluates an unlawful NHTSA CAFE proposal. As explained in NRDC's comments to the proposed rule, NHTSA failed to meet its statutory directive to set the maximum feasible fuel economy levels. [Footnote: See original comment document.] In calculating the required fuel economy level, NHTSA used erroneous assumptions for key input parameters and NHTSA set arbitrary limits on the availability of key vehicle technologies that could significantly improve fuel economy. These assumptions inaccurately characterized technologically feasible and economically practicable fuel economy in NHTSA's NPRM for both the proposed rule and the alternatives and therefore similarly skew the findings in the DEIS.

Comment Number: 0564-14
Organization: Consumer Federation of America
Commenter: Mark Cooper

NHTSA chose to define "feasibility" and "practicability" in a manner that lets the least fuel-efficient automakers drive down the standard. It protects the least capable automakers rather than requiring them to rise up to the level that the industry as a whole could achieve. Ironically, by setting a lower standard, in the face of dramatically rising consumer expectations, the Administration is creating an environment of failure for those companies who are driving down the standard. NHTSA allows the laggards in the industry, who have been trailing farthest behind the shift in consumer behavior, to pull the standard down.

Comment Number: 0564-4
Organization: Consumer Federation of America
Commenter: Mark Cooper

The crucial role of a higher fuel economy standard is to push the automakers to deliver what the public wants and deliver the maximum feasible fuel economy, but NHTSA has failed to do so.

Comment Number: 0572-1
Organization: Center for Biological Diversity
Commenter: Brian Nowicki, Mickey Moritz, Kassie Siegel

The NEPA analysis must be conducted in a way that is both meaningful and appropriate given the underlying statutory scheme. The EPCA requires that NHTSA set fuel economy standards for each model year at the "maximum feasible" level, taking into account four factors: technological feasibility, economic practicability, the effect of other motor vehicle standards of the Government on fuel economy, and the need of the United States to conserve energy. (49 U.S.C. § 32902(f)). The EPCA is a "technology-forcing" statute, whereby a challenging standard encourages technological innovation. [Footnote: See original comment document.] As part of the statutory balancing, NHTSA must necessarily determine what is "technologically feasible." The NHTSA has discretion to set standards somewhere below that level based on its consideration of the three other statutory factors, <u>if it is reasonable to do so.</u>

In December 2007, Congress passed the Energy Independence and Security Act of 2007 (Pub. L.11-140, 121 Sat. 1492 (Dec. 18, 2007) (EISA)). The EISA eliminates the previous 27.5 mpg standard for passenger cars with a mandate that NHTSA set separate passenger car and light truck standards annually at the "maximum feasible level," with a minimum fleet wide fuel economy of 35 mpg by 2020.

Comment Number: 0572-20
Organization: Center for Biological Diversity
Commenter: Brian Nowicki, Mickey Moritz, Kassie Siegel

Manufacturers not only manipulate market demand as discussed above, but also respond to it. When economics demand, a manufacturer would certainly implement a change outside a normal development cycle. Similarly, if regulations required, automakers could make changes outside a normal development cycle. Development cycles are a product of commercial convenience, not practicability. As a result, they have no bearing on the considerations of technology implementation within the cost benefit analysis.

Comment Number: 0572-45
Organization: Center for Biological Diversity
Commenter: Brian Nowicki, Mickey Moritz, Kassie Siegel

The proposed CAFE standards fail to comply with the EPCA's mandate to set the CAFE standards at the "maximum feasible" level that the automakers can achieve for each model year. While the EPCA does authorize the agency to consider technological feasibility and economic practicability when deciding maximum feasible average fuel economy standards, it does not authorize NHTSA to set standards that maximize net economic benefits at the expense of fuel savings that are feasible, practicable, and necessary to meet the nation's acute conservation needs. In fact, the EPCA mandates that NHTSA must maximize feasible fuel savings, even if these fuel savings are not "optimal" by an incremental parsing of costs and benefits. 49 U.S.C. § 32902(a),(f). See also, *Center for Biological Diversity v. National Highway Traffic Safety Administration*, 508 F.3d 508 (9th Cir. 2007).]

Overall, the proposed rule systematically manipulates the analysis, assumptions and modeling inputs such that NHTSA selects proposed CAFE levels far below the statute's technology forcing mandate. The methodologies used by NHTSA in the development of these CAFE standards do not consider the maximum feasible level of fuel efficiency. The Volpe model and economic cost-benefit analyses defer overwhelmingly to the automakers and prioritize the economic benefit of the automakers. In doing so, NHTSA artificially and inappropriately constrained the analysis to exclude available and feasible efficiency technologies, assign low priorities and delayed implementation schedules for individual technologies, and ultimately limit the range of potential efficiency increase analyzed and adopted.

NHTSA defers overwhelmingly to auto manufacturer's preferences and convenience in violation of EPCA's technology forcing mandate. For example, the Volpe model generally does not apply a new technology until a given vehicle is due for a "redesign or refresh." (73 *Fed. Reg.* 24386) The assumption that the manufacturers need apply new technologies only when it is most convenient to do so is completely at odds with the statutory mandate to set fuel economy at the maximum feasible level. NHTSA's use of this and other such assumptions to systematically reduce the maximum feasible fuel economy level violates the statute.

Comment Number: 0572-47
Organization: Center for Biological Diversity
Commenter: Brian Nowicki, Mickey Moritz, Kassie Siegel

NHTSA has manipulated the definition of "technological feasibility" to such an extent that it bears no relation to the plain meaning of those words. This manipulation and artificial constraint of the analysis leads to the perverse result that the "maximum technology" alternative considered by NHTSA of 37.5 mpg in 2011 is far below the fuel economy of many cars on the road today. (73 *Fed. Reg.* 24466) NHTSA's limitation of the regulatory universe to scenarios in which manufacturers' fleet mix remains the same is arbitrary and capricious in light of the nation's urgent need to conserve energy and slow global warming.

Comment Number: 0572-5
Organization: Center for Biological Diversity
Commenter: Brian Nowicki, Mickey Moritz, Kassie Siegel

As part of the statutory balancing, NHTSA must necessarily determine what is "technologically feasible." While NHTSA has discretion to set standards somewhere below that level based on its consideration of the three other statutory factors, if it is reasonable to do so, NHTSA violates both EPCA and NEPA by failing to even consider or disclose what is truly "technologically feasible." An essential component of the DEIS must be disclosure of the "technologically feasible" fuel economy level, along with the environmental impact of choosing this level of fuel economy as compared to the NHTSA's preferred alternative and a reasonable range of additional alternatives. The DEIS fails to provide both the basic starting point for this analysis and the proper analysis that must follow.

"Technologically" is defined by Merriam-Webster's Dictionary as "of or relating to a capability given by the practical application of knowledge." Merriam-Webster Online Dictionary (2008) (definition 1b for technology). "Feasible" is defined as capable of being done or carried out." *Id.* (definition 1). Therefore, NHTSA must disclose what practical application of the knowledge [in the area of engineering] is capable of being done or carried out. NHTSA has failed to do so.

Comment Number: 0575-7
Organization: Union of Concerned Scientists
Commenter: Eli Hopson

NHTSA's own analysis confirms that simply using more realistic gas prices or switching to an analysis based on total benefits would have led them to propose a fleet wide average of at least 35 mpg by 2015—five years earlier than the required minimum. (PRIA Pages III-6, IX-12 and IX-13) Given the urgency of global warming, and the fact that removing CO_2 early on is essential to reducing the risks of dangerous climate change, NHTSA is significantly underestimating the potential environmental impact of increased fuel economy simply because they are failing to exercise their legal obligation to set standards at maximum feasible levels.

Comment Number: 0575-8
Organization: Union of Concerned Scientists
Commenter: Eli Hopson

NHTSA's own analysis proves that technologically feasible and economically practicable fuel economy levels can go well beyond 35 mpg by 2020. In fact, NHTSA's analysis indicates that by employing more sound assumptions, fleet average fuel economy can exceed 35 mpg by even 2015, the final year covered by this rule, setting the stage for even further improvements in fuel economy between 2016 and 2020.

Comment Number: 0576-15
Organization: Public Citizen
Commenter: Joan Claybrook

The agency's mission under EPCA and EISA is to deliver the "maximum feasible" level of fuel economy in a given model year. (See 49 U.S.C. 32902(a).) It is not the agency's responsibility to take into account how the industry could most easily comply. Instead, NHTSA is required to set standards based on "technological feasibility, economic practicability, the effect of other motor vehicle standards of the Government on fuel economy, and the need of the United States to conserve energy." (49 U.S.C. at 32902(f))

Comment Number: 0576-25
Organization: Public Citizen
Commenter: Joan Claybrook

The logic behind the restructured CAFE standards is to add the minimum amount of fuel saving technology to bring a manufacturer into compliance with the standard for a given year, with significant latitude given to individual manufacturers for compliance based on the specific fleet mix of a given manufacturer. This approach necessarily undercuts the maximum feasible level of fuel economy. In its November 2007 decision in *Center for Biological Diversity v. NHTSA* the Court of Appeals for the Ninth Circuit said: "the agency's cost-benefit analysis does not set the CAFE standard at the 'maximum feasible' level and fails to give due consideration to the need of the nation to conserve energy." (*Center for Biological Diversity et al., v. NHTSA*. 508 F. 3d 508. (November 15, 2007).)

NHTSA states in this notice on fuel economy standards: "In striking [a] balance [between costs and benefits], the agency was mindful of the growing need of the nation to conserve energy for reasons that include increasing energy independence and security and protecting the environment." (73 *FR* 24457) However, analysis of the Volpe Model suggests that the assumptions NHTSA uses to set the standards are not sufficiently mindful of the need to conserve energy or environmental protection.

Public Citizen recognizes that since the Ninth Circuit decision there have been changes to the Volpe Model since the 2006 light truck rule: "the set of technologies represented was updated, the logical sequence for progressing through these technologies was changed, methods to account for 'synergies' (*i.e.*, interactions) between technologies and technology cost reductions associated with a manufacturer's 'learning' were added, the effective cost calculation used in the technology application algorithm was modified, and the procedure for calibrating a reformed standard was changed, as was the procedure for estimating the optimal stringency of a reformed standard." (73 *FR* at 24396) But these changes have not corrected the problems with the model that prevent it from setting standards at the maximum feasible level. Although Congress authorized NHTSA to restructure the CAFE scheme for passenger cars, but it did not mandate the NHTSA use Volpe Model. There are other ways the agency could model fuel economy that would set targets at the maximum feasible level and would improve public participation in the process.

Comment Number: 0576-8
Organization: Public Citizen
Commenter: Joan Claybrook

The Volpe model for fuel economy is structured in such a way that it undercuts the maximum feasible level of fuel economy statutorily mandated by EPCA. This is because the model is designed to minimize the estimate of what is technologically feasible and economically practicable. The fuel economy targets set by the Volpe model are a direct product of the economic assumptions made in the inputs to the model. The model also constrains the level of fuel economy by excluding technologies judged not to be cost efficient, and applying phase-in caps on certain technologies, which skews the impacts across the entire range of alternatives.

Comment Number: 0585-1
Organization: Attorneys General of the States of California, Massachusetts, New Jersey, New Mexico, New York, and Oregon, Secretary Of The Commonwealth of Pennsylvania Department of Environmental Protection, and New York City Corporation Counsel
Commenter: Edmund Brown Jr., Joseph Powers, Martha Coakley, Michael Cardozo, Anne Milgram, Gary King, Andrew Cuomo, Hardy Myers

Ultimately, therefore, the DEIS must disclose whether NHTSA has adequately considered the environmental impacts of its new CAFE rule, and determined whether the need to reduce GHG emissions is of such critical importance that it requires the Agency to place more emphasis on energy conservation and to set the CAFE standard at a significantly higher level than proposed. In this case, the higher level would be represented either by the 25% above optimized, 50% above optimized, total cost equal total benefits, or technology exhaustion level alternatives. [Footnote: See original comment document.] The DEIS does not answer this question.

Comment Number: 0596-7
Organization: Environmental Defense Fund
Commenter: Martha Roberts

The statutory mandate in the Energy Policy Conservation Act (EPCA) requires NHTSA to set the "the maximum feasible average fuel economy level" while considering "technological feasibility, economic practicability, the effect of other motor vehicle standards of the Government on fuel economy, and the need of the United States to conserve energy." (49 U.S.C. 32902(a), 32902(f)) NHTSA's statutory task is to first determine the "maximum feasible" limits of achievable fuel economy. Then NHTSA has some discretion to require less than the maximum feasible standard if such standard is not "economically practicable," but the agency is not given discretion to balance these statutory factors in a manner that defeats the primary purpose of EPCA. Congress has not given NHTSA discretion to "undermine the fundamental purpose of the EPCA: energy conservation." (p. 14865 *Center for Biological Diversity*)

The EIS fails to properly weigh the statutory factors because it impermissibly relies upon the assumption that economic considerations may be used to reject the "maximum feasible" alternative without a showing that the economic costs associated with an alternative make that alternative not "economically practicable." Merely showing that the estimated mix of economic costs and benefits are optimized at one alternative level of the standard does not establish a basis for concluding that more stringent standards may be rejected as not "economically practicable."

Congress did not establish the optimization of costs and benefits as the controlling factor for setting the standard. The controlling statutory factor is the "maximum feasible" level, but in this rulemaking NHTSA has impermissibly substituted the level at which costs and benefits are optimized as the controlling factor for setting the standard. The statute only gives weight to economic factors to the extent that the maximum feasible standard is not economically practicable. Here, the EIS does not identify economic factors that make the maximum feasible standard not practicable, and fails to explain why alternatives more stringent than the economically optimized level of the standard are not "economically practicable." The failure of the EIS to explore the limits of what is economically practicable is fundamentally arbitrary and capricious because it fails to consider the factors made relevant by the statute.

Comment Number: 0596-9
Organization: Environmental Defense Fund
Commenter: Martha Roberts

The limited findings of the EIS suggest alternatives preferential to the "optimized" alternative. Any of the alternatives with higher fuel efficiency than that of the "optimized" alternative better minimize environmental impacts and foster energy conservation. For example, the "costs = benefits" alternative saves 5.5 billion gallons of fuel annually in 2020 compared to the "optimized" alternative. Furthermore, as described in section II, greater fuel efficiency will prevent thousands of premature deaths a year.

In summary, the EIS supports adoption of the most stringent CAFE standard rather than NHTSA' s preferred "optimized" standard. NHTSA must adopt the feasible standard that achieves the greatest reduction in fuel use because that standard is mandated by the primary objective of EPCA—energy conservation—, unless the agency can show that such standard is not economically practicable. NHTSA must accordingly revise its preferred CAFE alternative to one of greater fuel efficiency.

Comment Number: 0598-2
Organization: Sierra Club
Commenter: Caroline Keicher

NHTSA' s own analysis shows that between 2011 and 2015, significantly higher standards are technologically feasible and economically practicable when higher gas prices are used ($3.14 per gallon in 2016). NHTSA's final rule should be, at a minimum, consistent with the analysis provided in the PRIA. NHTSA's use of below-cost energy estimates is arbitrary and capricious and violates the agency's statutory charter to impose mandatory maximum feasible fuel economy standards based upon a review of economic and technological feasibility.

Comment Number: 0599-1
Organization: Center for Biological Diversity
Commenter: Multiple Signatories

You are required by law to set U.S. fuel-economy standards at the "maximum feasible level." Doing so requires an honest assessment of the real costs and benefits of these standards, but your agency has failed to do so.

Comment Number: 0599-3
Organization: Center for Biological Diversity
Commenter: Multiple Signatories

Your decision to set the "maximum feasible" fuel-economy standard for U.S. automobiles in 2015 at 31.6 mpg, far below what vehicles must achieve today in Europe, Japan, China, Australia, and elsewhere is not only illegal, but also an affront to American ingenuity and resourcefulness.

Comment Number: TRANS-05-8
Organization: Consumer Federation of America
Commenter: Mark Cooper

The crucial rule of higher fuel economy standards is to push the automakers to deliver vehicles that consumers want, and to push the auto industry to the maximum technologically feasible and economically practicable level. NHTSA has failed to do so.

Comment Number: TRANS-12-4
Organization: Individual
Commenter: Sam Blodgett

Failure to utilize the higher cost projection violates NHTSA's statutory charter to impose mandatory feasible fuel economy standards based on economic and technological feasibility.

Comment Number: TRANS-19-8

Commenter: Eli Hopson

The second problem is with the announcements that the rule is based on. Recent UCS report indicates that auto makers can cut cost effectively their fleet wide average fuel economy of cars and trucks and improve it to 42 miles per gallon by 2020, and up to 50 and more than 50 by 2030, with a modest 25 percent penetration of hybrids by 2020.

Comment Number: TRANS-24-10
Organization: Individual
Commenter: Heather Moyer

NHTSA's own analysis shows that between 2011 and 2015 significantly higher standards are feasible and economically practical when higher gas prices are used. NHTSA's final rule should be, at a minimum, consistent with the analysis provided in the preliminary impact analysis that accompanied this proposed, this notice of proposed rulemaking.

Comment Number: TRANS-24-9
Organization: Individual
Commenter: Heather Moyer

It is time to put existing fuel saving technology to work by increasing fuel economy standards to the levels that reflect the maximum achievable standards for vehicles produced in 2011 and 2015.

Comment Number: TRANS-32-3
Organization: Environmental Defense Fund
Commenter: James Keck

We are also concerned that even though EDFCA requires NHTSA to select the maximum technically feasible fuel economy that is economically practicable, the administration has deviated from this mandate and instead selected the standard that supposedly maximizes economic benefits. This so called optimized standard falls below alternative standards that convey less net economic benefits, but are still economically practicable and better meet the other recognized statutory considerations of energy conservation, environmental, and human health protection.

Comment Number: TRANS-35-6
Organization: Individual
Commenter: Alina Fortson

If we are to take advantage of our best, and most feasible technology, we would be in a position to reduce our oil use, in addition to lessening the impact that the price of gasoline has on families like mine. NHTSA's current proposal hinders this potential.

Comment Number: TRANS-37-6
Organization: Individual
Commenter: Jaafar Rizvi

I am here because I am concerned for several reasons that the fuel economy standards that you all have proposed are not strong enough.

According to the DEIS, fuel economy standards should be set at the maximum feasible average that the Secretary of Transportation decides the manufacturers can achieve in that model year, while simultaneously considering technological feasibility, economic practicability, the effect of other motor vehicle standards of the government on fuel economy, and the need for the U.S. to conserve energy.

And I agree with those guidelines. I think they're good. But I fear that NHTSA didn't properly analyze each of those specifically. For example, when considering economic practicability, the report doesn't really go into all of the economic benefits of lowering emissions, as well as the moral issues, which I won't talk about right now.

Comment Number: TRANS-37-8
Organization: Individual
Commenter: Jaafar Rizvi

And I've heard environmental scientists talk about why they disagree with this report. And I haven't heard any argument about why they are wrong. So basically, I'm left with the position where I feel like something isn't right with the research that's been done here.

And that makes me skeptical about analysis on two of the other categories that were mentioned before, the need for the U.S. to conserve energy and technological feasibility.

Comment Number: TRANS-39-4
Organization: American Jewish Committee
Commenter: Ami Greener

The use of the low cost energy estimates violates the agency's charter to impose mandatory maximum feasible standards based upon a review of economic and technological feasibility. NHTSA must reconsider the proposed standards and use its authority to meet the urgent need of the U.S. to conserve oil and meet the growing demand of American consumers for vehicles that go farther on a gallon of gas.

Response

NHTSA notes that under EPCA, the role of fuel economy standards is to set maximum feasible fuel economy standards. EPCA requires NHTSA to consider "economic practicability," which, as set forth in the NPRM, we have interpreted as not permitting the CAFE standards to cause substantial economic hardship and job loss for automakers. See 49 U.S.C. § 32902(f). Additionally, NHTSA does not have the statutory authority to dictate vehicle fleets. The legislative history of EPCA also demonstrates that Congress was concerned that CAFE standards should not unduly limit consumer choice. See H.R. Rep. No. 94-340, at 87 (1975), reprinted in 1975 U.S.C.C.A.N. 1762, 1849 ("any regulatory program must be carefully drafted so as to require of the industry what is attainable without either imposing impossible burdens or unduly limiting consumer choice as to the capacity and performance of motor vehicles").

Some commenters stated that because specific vehicles currently in production can achieve a fuel economy equal to or greater than EISA's statutory goal of combined fleet fuel economy of 35 mpg by 2020, NHTSA should effectively raise the fuel economy standards to a level that creates innovation among these high-fuel-economy vehicles. These commenters misunderstand how NHTSA measures and calculates CAFE levels under EPCA. CAFE standards are not measured by the performance of a single vehicle in a manufacturer's fleet. Rather, as set forth in the NPRM, they are measured as the average of the manufacturer's fleet-wide fuel economy. As explained in detail in the NPRM, the actual CAFE standards for each manufacturer are a function of their product mix. Vehicles with a larger footprint have a lower fuel economy goal than vehicles with a smaller footprint. NHTSA has, and continues to, set CAFE standards while keeping in mind the preservation of consumer choice, by assuming that manufacturers' product plans reflect this variable. NHTSA uses the manufacturers' product plans to inform what manufacturers' capabilities and capacities will be for any given model year. As stated earlier, NHTSA updated its technology assumptions based on comments received and used these updated assumptions in the Volpe model. NHTSA continues to believe that more stringent standards result in a substantial number of manufacturers falling out of compliance with the standards. This goes to the issue of economic practicability – technological feasibility cannot be viewed independently of this and other EPCA factors. If, for example, a manufacturer chooses to pay civil penalties, NHTSA would not reach the necessary fuel savings goal of achieving a combined fuel economy average for MY 2020 of at least 35 mpg.

Some commenters are concerned with NHTSA's use of purportedly "low" energy costs. As noted above, this FEIS explores CAFE standards resulting when inputting a different fuel price into the Volpe model. This FEIS also evaluates the environmental impacts resulting from the use of other different economic assumptions. <u>See</u> FEIS Sections 3.4.4.2 and 10.2.2. ***.*** *Regarding NHTSA's selection of fuel price in the DEIS, we relied on the most recent fuel price projections from the U.S. Energy Information Administration's (EIA) Annual Energy Outlook (AEO) for this analysis. Specifically, we used the AEO 2008 Early Release forecasts of inflation-adjusted (constant-dollar) retail gasoline and diesel fuel prices, which represent the most up-to-date estimate of the most likely course of future prices for petroleum products. Federal Government agencies generally use EIA's projections in their assessments of future energy-related policies. <u>See</u> 73 <u>FR</u> 24405, May 2, 2008. For a more detailed discussion, <u>see</u> Section 7 of Chapter V of the NPRM, and Chapter VIII of the PRIA. Section 3.4.4.2.2 of the DEIS and Section 3.4.5 of this FEIS also provide a brief discussion of the values assigned to the Volpe model economic assumptions.*

Regarding the comments that NHTSA must adopt the "environmentally preferable" alternative as its preferred alternative, neither EPCA nor NEPA require this. As noted above, "Congress in enacting NEPA . . . did not require agencies to elevate environmental concerns over other appropriate considerations." <u>Baltimore Gas and Elec. Co. v. Natural Resources Defense Council, Inc.</u>, 462 U.S. 87, 97 (1983). Instead, NEPA requires an agency to develop "alternatives to the proposed action" in preparing an EIS. 42 U.S.C. § 4332(2)(C)(iii).

Other commenters stated that NHTSA must take into account the looming threat of global warming on the environment and give further emphasis to energy conservation by setting the CAFE standards at a higher level. NHTSA's range of alternatives considers the effect of global warming on the environment. Moreover, the purpose of an EIS is to present the reasonably foreseeable environmental impacts of the agency's proposed action to the decisionmaker and to the public, not to force policymakers' decisions. The Supreme Court in <u>Public Citizen v. Department of Transportation</u> found that "NEPA itself does not mandate particular results" but rather, "NEPA imposes only procedural requirements on federal agencies with a particular focus on requiring agencies to undertake analyses of the environmental impact of their proposals and actions." 541 U.S. 752, 756-57 (2004) (citing <u>Robertson</u>

v. Methow Valley Citizens Council, 490 U.S. 332, 349-50 (1989). Accordingly, a normative determination that GHG emissions reduction are of critical importance is not the purpose of an EIS.

10.2.3.10 The Need of the United States to Conserve Energy

Comments

Comment Number: 0564-12
Organization: Consumer Federation of America
Commenter: Mark Cooper

NHTSA failed to give the "need to conserve energy" proper consideration in light of the clear, obvious, and painful national energy crisis currently facing all Americans. In speaking for the American public, Congress was very clear in its requirement that NHTSA set the fuel economy standard at the "maximum feasible level." In doing so, NHTSA was to take into consideration "the four statutory factors underlying maximum feasibility (technological feasibility, economic practicability, the effect of other standards on fuel economy, and the need of the nation to conserve energy)." NHTSA completely failed to give proper consideration to this last and most fundamental reason for the Act: "the need of the nation to conserve energy."

Comment Number: 0585-11
Organization: Attorneys General of the States of California, Massachusetts, New Jersey, New Mexico, New York, and Oregon, Secretary Of The Commonwealth of Pennsylvania Department of Environmental Protection, and New York City Corporation Counsel
Commenter: Edmund Brown Jr., Joseph Powers, Martha Coakley, Michael Cardozo, Anne Milgram, Gary King, Andrew Cuomo, Hardy Myers

Ultimately, however NHTSA chooses to present the data, there must be some analysis that enables the Agency and the public to determine whether the proposed CAFE rule, when combined with other anticipated actions, is sufficiently stringent to reduce, over time, GHG emissions and stabilize CO_2 concentrations at levels that will prevent us from reaching the area of dangerous anthropogenic interference. If the proposed CAFE rule is not sufficiently stringent to reach those goals, then NHTSA has not properly considered whether our need to conserve energy and lower GHG emissions outweighs the remaining factors under EPCA, and requires a stricter CAFE standard and higher fuel economy.

Comment Number: TRANS-14-5
Organization: U.S. Public Interest Research Group
Commenter: Annie Chau

We fully support the comments of the Consumer Federation of American and we agree that NHTSA has failed to prioritize the need to conserve energy, has undervalued the benefits of increased vehicle fuel economy, and has kept standards too low for too long.

Response

Some commenters claimed that NHTSA did not prioritize the need to conserve energy. Throughout this rulemaking and the development of the DEIS and this FEIS, NHTSA did, and continues to, appropriately prioritize the need to conserve energy when balancing the EPCA factors, along with environmental issues and relevant societal issues, in an effort to set maximum feasible fuel economy standards. The extent of such prioritization is within NHTSA's discretion. Notably, "Congress did not prescribe a precise formula by which NHTSA should determine the maximally-feasible fuel economy *standard, but instead gave it broad guidelines within which to exercise its discretion." Competitive Enterprise Institute v. NHTSA, 901 F.2d 107, 121 (D.C. Cir. 1990) (citing Public Citizen v. NHTSA, 848 F.2d 256, 265 (D.C. Cir. 1988)). See also Center for Auto Safety v. NHTSA, 793 F.2d 1322, 1340 (D.C. Cir. 1986) (same); Competitive Enterprise Institute v. NHTSA, 901 F.2d 107, 121 (D.C. Cir. 1990) (Wald, J.) (same). Thus, EPCA does not require NHTSA to establish fuel-economy standards at any particular level, but instead confers on NHTSA broad discretion to balance these factors when setting an appropriate standard. However, in response to comments, NHTSA is presenting the CAFE stringencies and the resulting environmental impacts that would result from using the higher AEO forecast, which increases the value of fuel-saving technology. Thus, higher fuel prices produce model results that imply an increased emphasis on the need for the nation to conserve energy. In this way, NHTSA has acknowledged the commenters' concerns and addressed the scenario of increased need for the nation to conserve energy. For a more detailed discussion of NHTSA's balancing of EPCA's four factors, including the need to conserve energy, along with the environmental issues and relevant societal issues, such as safety, see Section 2.2 of this FEIS.*

10.2.3.11 More Aggressive Alternative

Comments

Comment Number: 0533-1
Organization: Individual
Commenter: Robert Burchard

Even the President now recognizes the reality of anthropogenic global warming. This threat to the biosphere combined with increasing acidity of the earth's oceans caused by increasing atmospheric CO_2 necessitates the need for early implementation of rigorous fuel economy standards independent of "paying-for-itself considerations. America's auto industry needs to have its feet held to the fire and quickly. If Japanese manufacturers can do it, why can't "Detroit"?

Comment Number: 0534-1

We need to raise cafe standards not erode them. It is insane to drill in environmentally sensitive areas when we can directly reduce demand for oil by mandating that all passenger cars get at least 40 mpg by 2012. It is so clear, double the mpg and you double the fuel supply.

Comment Number: 0548-1
Organization: Individual
Commenter: Carl Henne

The CAFE requirement should be at least 50 mpg for all cars and light trucks by 2018 and an equal proportional improvement for all trucks and busses.

Comment Number: 0550-5
Organization: Individual
Commenter: Sarah Larsen

Although there is no magic antidote to get us to an 80% reduction in CO_2 emissions by 2050, one of the single biggest step we can take in this country to reduce our global warming emissions is to make our cars and trucks go further on a gallon of gasoline. The technology exists today to safely and cost-effectively make all passenger cars and light trucks reach a fleet wide fuel economy average of at least 35 miles per gallon by 2015. Taking this step will achieve the goals of the new fuel economy law and as is most pertinent to this hearing will greatly reduce the global warming emissions from the transportation sector.

Comment Number: 0555-1
Organization: National Counsel of Churches and Christ
Commenter: Elizabeth McGurk

On behalf of the religious organizations we represent, we urge you to increase the Corporate Fuel Economy (CAFE) standards of America's vehicles

Comment Number: 0557-12
Organization: The Natural Resources Defense Council
Commenter: Luke Tonachel, Brian Siu

If NHTSA had used reasonable assumptions for their analysis, the fuel economy levels in the proposed rule and all cost-dependent alternatives would be higher. For example, based on NHTSA's *own* sensitivity analysis presented in the Preliminary Regulatory Impact Assessment, the MY2015 fuel economy standards should be set at least at the level that would result in a combined fleet average of 35 mpg by MY2015 if the fuel savings are more properly valued.

The potential additional public and private benefits of raising the standards to 35 mpg by MY2015 are enormous. Consumer pocketbooks, the nation's energy security, and the environment would all stand to benefit tremendously from a 35 mpg standard. We estimate by 2020, the U.S. would conserve 3 billion barrels of oil, 1.5 times more, if the MY2015 standard was set at a level that resulted in a combined 35 mpg instead of 31.6 mpg. The 35 mpg level in MY2015 also avoids 510 million metric tons of global warming pollution (see Figure 5). [See original comment document for Figure 5.]

The emissions reduction estimates are conservative, however. Beyond 2015, the fuel economy standards could continue to increase to over 40 mpg in 2020, which would result in even greater pollution reductions.

Comment Number: 0557-15
Organization: The Natural Resources Defense Council
Commenter: Luke Tonachel

In the DEIS, NHTSA characterizes the differences in the environmental impacts between the proposed standard and the other evaluated alternatives as small and difficult to distinguish. The fuel economy level proposed by NHTSA in the CAFE rule, referred to as the "Optimized" alternative in the DEIS, reaches a fleetwide fuel economy level of 31.6 mpg in for model year (MY) 2015. Other alternatives reach higher levels; for example the Total Cost Equals Total Benefits (TC=TB) alternative reaches 37.5 mpg for MY 2015. The DEIS concludes that there is almost no difference between the proposed standard and the TC=TB alternative, noting that the two alternatives differ by only 0.2 percent in terms of global warming emissions reductions in 2100. Our analysis of similar alternatives shows that NHTSA's characterization is misleading. In reality, more aggressive alternatives to the proposed rule can have very significant environmental benefits over the proposal. For example, a standard that reaches 35 mpg with MY 2015 instead of MY 2020 could save more than a billion barrels of oil and cut greenhouse gas (GHG) emissions by more than 510 million metric tons of CO_2-equivalent (MMT CO_2e) by 2020. A 35 mpg standard for MY 2015 would also pave the way for future fuel economy increases beyond 2015; these increases would put the U.S. on a path to achieve at least 40 mpg by 2020 and provide further oil and GHG savings not envisioned by the current DEIS.

Comment Number: 0559-6
Organization: The Northeast States for Coordinated Air Use Management (NESCAUM)
Commenter: Arthur Marin

As a general observation, we note that NHTSA has taken a rather conservative approach towards setting fuel economy standards. The proposal emphasizes "available technologies" for achieving fuel economy improvements and reflects a rather strong preoccupation with the ability of individual auto manufacturers to meet more stringent standards, compared to what is proposed. Further, NHTSA's optimized standards are couched almost exclusively in economic terms; emphasizing a perceived need for "maximizing net societal benefits... where the estimated benefits to society exceed the estimated cost of the rule by the highest amount." NHTSA appears very reluctant to propose more ambitious standards if the effect would be to reduce the consumer payback by any amount.

Comment Number: 0572-52
Organization: Center for Biological Diversity
Commenter: Brian Nowicki, Mickey Moritz, Kassie Siegel

These findings are merely the most recent in a growing body of literature that is refining the scientific understanding of the need to quickly and drastically reduce our greenhouse gas emissions to minimize the impacts of global climate change. This represents a significant advance in the scientific understanding of global climate change, which previously has included the assumption that global atmospheric concentrations of CO_2 must be contained below 450 to 550 parts per million (ppm) in order to avoid the worst impacts of climate change. NHTSA fails to refer to or consider this essential information in the proposed rule. The urgency of the climate crisis and the need to immediately and rapidly reduce greenhouse gas emissions in order to avoid catastrophic climate changes, clearly tops the list of reasons that our nation needs to conserve energy. NHTSA's complete failure to address this information violates the law.

Comment Number: 0575-1
Organization: Union of Concerned Scientists
Commenter: Eli Hopson

Instead of doing the bare minimum to satisfy the law, NHTSA should put cars and trucks on a path to 42 mpg by 2020 and at least 50 mpg by 2030. This would cut global warming pollution from new cars and trucks in half by 2030 and would save about 50 billion barrels of oil through 2050.

A recent UCS report indicates that automakers can cost-effectively boost the fleet wide average fuel economy of cars and trucks to 42 mpg by 2020 and to more than 50 mpg by 2030, with a modest 25% penetration of hybrids by 2020. [Footnote: See original comment document] Yet the recent notice of proposed rulemaking just barely gets cars and trucks on the road to the 35 mpg minimum by 2020, and assumes that hybrids don't enter the market until 2014. [Footnote: See original comment document.] Let me just reiterate that – despite the fact that there are more than one million hybrids on the road today, in 2008, and that the Toyota Prius is the 9th best-selling car in America, the analysis NHTSA used assumes hybrids won't reach the market until 2014.

Comment Number: 0576-2
Organization: Public Citizen
Commenter: Joan Claybrook

NHTSA has obfuscated the relative benefits of the alternatives it considered by not putting the impacts in context.

NHTSA has unreasonably constrained its range of alternatives, omitting a number of reasonable options. For example, NHTSA considered but did not analyze in detail more aggressive or accelerated standards. Instead, the agency asserts that it requires standards be raised by 4.5 percent per year, a rate fast enough that extended to 2020 would exceed the 35 by 2020 mandate of Congress. The agency explains, "other alternatives that would establish higher CAFE standards would result in larger fuel savings and emission reductions than those resulting from the preferred alternative. However, they would also result in lower net benefits than the preferred alternative due to higher costs to society. As such, NHTSA is already considering accelerated fuel economy standards." [Footnote: See original comment document.]

Comment Number: 0588-1
Organization: New York State Department of Transportation
Commenter: Stanley Gee

The transportation sector currently contributes nearly a third of the national carbon dioxide (CO_2) and other greenhouse gas (GHG) emissions, both byproducts of petroleum fuel combustion. There is a need to reduce these emissions to slow the rate of anthropogenic-induced climate change, which is having serious impacts on the global, and regional environment, Due to the global urgency associated with reducing the nation's reliance on imported petroleum and to reduce GHG emissions, the preferred alternative should increase the fuel economy standards beyond 35.7 mpg and 28.6 mpg for MY 2015 passenger cars and light trucks, respectively.

NYSDOT recommends that NHTSA establish a more aggressive standard and achievement timetable for the new CAFE standards. At a minimum, NHTSA should consider a hybrid alternative that is equivalent to the "Technology Exhaustion" alternative for light-duty trucks and "Total Costs Equal Total Benefits" alternative for passenger cars. NYSDOT believes that this approach would provide significantly greater GHG emissions reductions than the proposed preferred alternative, yet would consider the diminishing returns of technology exhaustion for passenger cars as indicated in Tables 3.2-2 and 3.2-3. It is important for environmental, energy and economic reasons to increase the national fuel economy from the proposed rate of increase to a much more rapid yet technologically achievable rate.

NHTSA must set the right "optimized" standard and then recalibrate the other bounds. The 35 mpg target for 2020 is a floor, not a ceiling — the law directs that the standards should be the maximum that are technologically feasible.

Comment Number: 0598-3
Organization: Sierra Club
Commenter: Caroline Keicher

Because NHTSA' s proposed standards are based upon flawed assumptions, the range of options considered in the DEIS is incorrect. In the DEIS, NHTSA's basic approach to setting new fuel economy standards is to strictly adhere to hitting, but not exceeding, 35 mpg in 2020. At several points in the DEIS, NHTSA recognizes the two critical words "at least," which precede 35 mpg in the 2007 Energy Independence and Security Act. At other points, NHTSA says the standards must be set to merely hit 35 mpg in 2020. NHTSA should recognize that 35 mpg is the floor that Congress provided and set standards that are not improperly bound to meeting a minimum fleetwide average of 35 mpg in 2020. Because NHTSA's proposed standards are too low, the range of options NHTSA considers in the DEIS are also too low.

Comment Number: 0598-9
Organization: Sierra Club
Commenter: Caroline Keicher

If we implement the weak proposed standards that NHTSA has published, which put us on a path to 35 mpg by 2020, we will save around 1.4 million barrels of oil per day in 2020. This is equivalent to keeping almost 220 million metric tons of CO_2 out of the atmosphere. While this is significant, it isn't enough to get us to 423 MMT CO_2e. However, if NHTSA speeds up fuel economy standards to 35 mpg by 2015, using a more accurate price of gasoline and fully incorporating all of the current available technology advances, and puts us on a path to 42 mpg by 2020, we will save an additional 880,000 barrels of oil a day in 2020. This brings us to a grand total of 2.28 million barrels of oil saved every single day in 2020 – a number that will increase as the fleet turns over – and will keep at least 360 million metric tons of CO_2 out of the atmosphere. While still short of the target cuts from cars and light trucks, 35 mpg by 2015 gets us significantly closer to these goals.

To simplify this even further, to be on track for necessary carbon reductions, we need to reduce the emissions from cars and light trucks by 25%. NHTSA's proposed 35 mpg by 2020 standards only gets us halfway there. Not nearly enough in a global warming context.

I call upon you to raise the proposed fuel—economy standards for model years 2011—2015 to at least 50 mpg, in order to challenge automakers to respond to the urgent need to conserve energy and reduce greenhouse pollution.

Comment Number: TRANS-06-4
Organization: Public Citizen
Commenter: Lena Pons

Other reasonable alternatives would include a situation wherein there was additional increases in fuel economy standards beyond the period of the Energy Independence and Security Act, which would require only that vehicles reach a standard of 35 miles per gallon for the combined fleet, cars and light trucks by 2020.

However, given the fact that there are significant market incentive and also environmental incentive to extend the standards beyond that level, then there is a likely, there's likely a reasonable alternative to consider what would happen if you had standards that extended beyond that level.

Comment Number: TRANS-07-2
Organization: Individual
Commenter: Eliza Berry

NHTSA is currently making a decision that will profoundly influence our emissions during the next 10 years and beyond. NHTSA should therefore contribute to the effort to peak emissions sooner rather than later. This means adopting the highest fuel economic standards economically and technologically possible.

In summary, I would like to ask NHTSA to reevaluate the conclusions drawn from their draft environmental impact statement, and encourage NHTSA to require a 35 mile per gallon fuel economy standard by 2015.

Comment Number: TRANS-08-1
Organization: Sierra Club
Commenter: Ann Mesnikoff

Raising fuel economy standards to at least 35 miles per gallon in 2015 is a key step to curing our oil addition and reducing global warming pollution.

Comment Number: TRANS-08-11
Organization: Sierra Club
Commenter: Ann Mesnikoff

The 35 mpg target in 2020 is a floor not a ceiling. The law directs that the standards be what is maximally feasible. How can the public have confidence in NHTSA, that NHTSA is setting the right standards when some of the key inputs in its analysis are flawed.

Second, can the public have confidence in the range of options considered in the DEIS. NHTSA strictly adheres to a 35 by 2020 standard. At several points NHTSA recognizes the two critical words which proceed 35 in the 2007 energy bill, the words at least.

Comment Number: TRANS-10-1
Organization: Individual
Commenter: Matt Dernoga

I find it perplexing that NHTSA would aspire to only a mere 35 miles per gallon by 2020, the bare minimum of what is required by the Energy Independence and Security Act.

Comment Number: TRANS-11-1
Organization: Individual
Commenter: Jazzlin Allen

NHTSA's current proposed standards for cars and light trucks put us on a path to increasing fuel economy to only the bare minimum, 35 miles per gallon by 2020 required by the Energy [Independence] and Security Act of 2007. NHTSA fails to take full advantage of available fuel saving technologies, and must reconsider the proposed standards and use its statutory authority to meet the urgent need of the United States to reduce carbon emissions, conserve oil, and meet the growing demand of American consumers for vehicles that go farther on a gallon of gas.

Comment Number: TRANS-12-1
Organization: Individual
Commenter: Sam Blodgett

I strongly believe that NHTSA must raise CAFE standards to 35 miles per gallon by the year 2015. Failure to do so would be a failure of the American people who are in desperate need of relief from rising gas prices.

Comment Number: TRANS-14-2

Commenter: Marissa Knodel

Increasing CAFE standards to 35 miles per gallon by 2015, instead of waiting for 2020 as currently required save 300,000 gallons of oil per day by 2020, which is equivalent to keeping 280 million metric tons of carbon dioxide out of the atmosphere.

Comment Number: TRANS-19-7
Organization: Union of Concerned Scientists
Commenter: Eli Hopson

The other list has been mentioned, but I just want to summarize and say your own analysis showed that if you use a more realistic gas price, or switch to an analysis based on total benefits, each of those would allow us to reach Congressionally mandated minimum five years earlier, so 35 miles per gallon by 2015, and would help us get a head start on solving our global warming problem.

Comment Number: TRANS-20-3
Organization: Sierra Club
Commenter: Caroline Keicher

In addition, the proportion of emissions saved is much less important than the total cumulative carbon savings. The front end reductions are more important and have more cumulative impact than later emission reductions.

Taking this into account, it seems even more obvious that NHTSA should set new fuel economy standards to reach 35 miles per gallon by 2015. Not only is this standard economically and technologically feasible when a more accurate gas price is used, but it gets our cars and light trucks traveling an average of 35 miles per gallon five years sooner, the cumulative carbon savings of which is anything but insignificant.

Comment Number: TRANS-21-3
Organization: Individual
Commenter: Christina Marie Yagjian

In order to ensure that we take the strongest measures available, NHTSA must do its part. They must begin now by evaluating fuel economy standards in the correct context and setting fuel economy standards at the maximum feasible level, at least 35 miles per gallon by 2015.

Comment Number: TRANS-21-5

Commenter: Emily Spear

The transportation sector has the ability to add their contribution by increasing fuel economy standards, if we know that currently America has the capacity to increase standards to 35 miles per gallon by 2015, what's stopping us?

Response

NHTSA received comments on the DEIS and the NPRM urging more "aggressive" fuel-economy standards. One commenter requested that NHTSA describe how more aggressive alternatives would contribute to reducing global warming. For a discussion of the environmental impacts associated with all of NHTSA's alternatives, including its most aggressive alternatives, <u>see</u> Sections 3.2.3, 3.3.2, 3.4.4, 4.2.2, 4.3.2, and 4.4.4 of this FEIS.

Most commenters emphasized that EISA's goal of at least 35 mpg by 2020 is a floor, or a minimum CAFE requirement by 2020, and argued that 35 mpg in the combined fleet can be reached as the maximum feasible fuel-economy level by 2015. NHTSA has considered the increasing need of the United States to become more energy independent, consistent with EPCA's overarching goal of energy conservation, and the threat of global climate change. NHTSA recognizes that this rulemaking is in a unique position to address both of these concerns. NHTSA takes this opportunity and responsibility very seriously. However, Congress has stated that when setting maximum feasible CAFE standards, NHTSA must consider and balance the four EPCA statutory factors. NHTSA notes that electing to impose more aggressive standards would impose substantial additional costs on the industry at a time when the industry and economy are both facing difficult conditions or induce more manufacturers to pay penalties rather than achieve higher levels of fuel economy. Overly aggressive standards would not achieve the result intended by EPCA, i.e., meeting EPCA's overarching goal of energy conservation while ensuring economic practicability and technological feasibility.

10.3 AFFECTED ENVIRONMENT AND ENVIRONMENTAL CONSEQUENCES

10.3.1 Introduction

Comments

Comment Number: 0595-11
Organization: Environmental Protection Agency
Commenter: Susan Bromm

In several places throughout the DEIS, the text implies that in addition to evaluating several alternatives for model year 2011-2015 CAFE standards, the DEIS also includes analysis of future model year 2016-2020 CAFE standards (for example, in the third paragraph of the June 24, 2008 DEIS cover letter from Deputy Administrator James F. Ports, Jr., and in the titles to Table 2.5-8 and 2.5-9, and the titles to Figures 2.5-3, and 2.5-4). The Environmental Protection Agency (EPA) was unable to determine from reading the DEIS if, in fact, new standards were analyzed for model years 2016-2020. NHTSA should clarify this issue in the final EIS, and to the extent potential CAFE standards were modeled for 2016-2020, such standard scenarios should be described in detail in the final EIS.

Response

NHTSA notes the need for clarification. Because EISA directs NHTSA to increase CAFE standards to reach a combined fleet average CAFE level of at least 35 mpg by model year 2020, MY 2016-2020 CAFE standards are reasonably foreseeable and must be accounted for when analyzing the cumulative impacts of the proposed action. For each alternative, NHTSA assumed that passenger-car and light-truck CAFE standards would continue to increase over model year 2016-2020 at their average annual rate of increase over MY 2011-2015. This assumption results in passenger-car and light-truck CAFE standards under each action alternative that meet or exceed the EISA requirement of a combined fleet average of 35 mpg by model year 2020. NHTSA assumed further that the fuel economy standards for model year 2020 would remain in effect through the end of the analysis period. Because the CAFE standards apply to new vehicles, this assumption results in emissions reductions and fuel savings that continue to grow as new vehicles meeting the CAFE standards for MY 2020 and beyond are added to the fleet in each subsequent year, reaching their maximum values when all passenger cars and light trucks in the U.S. fleet meet these standards. NHTSA included this effect in the analysis. NHTSA has expanded our explanation of these assumptions in the beginning of the FEIS cumulative impacts discussions. See FEIS Sections 4.3.2.1, 4.4 (introduction), 4.4.4.1, and 4.4.4.2.

10.3.1.1 Approach to Scientific Uncertainty and Incomplete Information

Comments

Comment Number: 0572-25
Organization: Center for Biological Diversity
Commenter: Brian Nowicki, Mickey Moritz, Kassie Siegel

The statement of "uncertainty" is overused and abused throughout the DEIS. To avoid further analysis and consideration of environmental impact, the DEIS frequently presents background on climate change, but qualifies the information as "uncertain." In most instances this is uncalled for. The argument could be made that every piece of information in any EIS is uncertain, yet an agency is expected to make a good faith effort to consider impacts that are reasonably certain. While the IPCC may label the intensity of some effects as "likely" as opposed to "very likely," the effects are still just as certain as effects such as smog due to criteria pollutant emissions. For instance, the IPCC states that "Warming of the climate system is unequivocal, as is now evident from observations of increases in global average air and ocean temperatures, widespread melting of snow and ice, and rising global average sea level." (Alley et al. 2007) By overusing the uncertainty qualification, the DEIS fails to consider important impacts of climate change and obfuscates the issue so that the decisionmakers and public will not be able to adequately evaluate the balance of harms that may occur as a result of different alternatives.

Comment Number: 0572-3
Organization: Center for Biological Diversity
Commenter: Brian Nowicki, Mickey Moritz, Kassie Siegel

Recent court decisions have shaped the context in which the NEPA analysis must be conducted with regard to global warming. The United States Supreme Court held in *Massachusetts v. EPA* that carbon dioxide and other greenhouse gases are "unquestionably 'agents' of air pollution" and unambiguously fall within the Clean Air Act's definition of an air pollutant. 127. S.Ct. 1438, 1460 n. 26(2007). Furthermore, the Court held that the EPA could not avoid its statutory obligation to regulate greenhouse gases merely due to "some residual uncertainty" about the "various features of climate change." 127. S.Ct. 1438, 1463 n. 26 (2007). This holding underscores that priority must be given to addressing climate change despite the lack of some details. The excessive use of "uncertainty" in the DEIS violates this mandate to act on what is already known.

Response

NHTSA appropriately refers to the "Incomplete or Unavailable Information" provision in the CEQ regulations (40 CFR § 1502.22) in its climate modeling discussion. NEPA requires federal agencies to assess the environmental impacts of proposed federal actions. See 42 U.S.C. § 4332(C). CEQ regulations provide a process for evaluating reasonably foreseeable significant adverse impacts when the necessary information is incomplete or unavailable. Under conditions of uncertainty, 40 CFR § 1502.22 requires evaluation of "existing credible scientific evidence" relevant to assessing significant adverse impacts, including catastrophic consequences that have a low probability of occurrence. See 40 CFR § 1502.22(b)(3)-(4). If the agency cannot obtain adequate information to evaluate the impacts, the EIS must explain the relevance of this information to evaluating reasonably foreseeable significant adverse impacts, and evaluate the impacts based on theoretical approaches or research methods generally accepted in the scientific community. See Mid States Coalition for Progress v. Surface Transportation Board, 345 F.3d 520, 549-50 (8th Cir. 2003) (quoting 40 CFR § 1502.22(b)). Where an agency reasonably determines that a risk is too remote or unquantifiable, a qualitative discussion of that risk and potential accompanying environmental impacts is appropriate. See 42 U.S.C. § 4332 (requiring federal agencies to "identify and develop methods and procedures … which will insure that presently unquantified environmental amenities and values may be given appropriate consideration"); 40 CFR § 1502.23 (requiring an EIS to discuss the relationship between a cost-benefit analysis and any analyses of unquantified environmental impacts, values, and amenities); CEQ, Considering Cumulative Effects Under the National Environmental Policy Act (1984), available at http://ceq.hss.doe.gov/nepa/ccenepa/ccenepa.htm (recognizing that agencies are sometimes "limited to qualitative evaluations of effects because cause-and-effect relationships are poorly understood" or cannot be quantified).

NHTSA's determination that distinctions between the alternatives in various areas of the impacts discussion cannot be quantifiably evaluated is also appropriate because the means to obtain the relevant information to accurately quantify these effects are not known. For example, climate modeling is not yet sensitive enough to model temperature, sea-level, or precipitation changes on regional levels or to such a precise order of magnitude as to allow the analysis to distinguish among the alternatives. CBD appears to be saying that NHTSA is labeling as uncertain changes or impacts that are clearly certain (i.e., *"increases in global average air and ocean temperatures"). NHTSA agrees that these are reasonably foreseeable future impacts. What are uncertain are their timing, degree, and ramifications within regional and global ecosystems. This uncertainty results because the current state of science does not provide a means to obtain this information to accurately quantify these aspects of the impacts. Accordingly, these foreseeable impacts of NHTSA's CAFE rulemaking fall within the meaning of "Incomplete or Unavailable Information," and NHTSA has included the appropriate qualitative analysis required by Section 1502.22 of the CEQ regulations. See Mayo Foundation v. Surface Transportation Board, 472 F.3d 545, 555-56 (8th Cir. 2006) (upholding the Surface Transportation Board's use of 40 CFR. § 1502.22(b) procedures after admitting that their model could not be used to model impacts at a local level, and the Board extensively discussed the potential impacts on air quality that could result from the implementation of the project in the EIS); Lee v. U.S. Air Force, 354 F.3d 1229, 1241-45 (10th Cir. 2004) (upholding EIS as adequately addressing, under NEPA, noise effects of increased overflights, impacts of increased low-level overflights on livestock, and environmental and economic impacts of aircraft accidents, against claims that the Air Force used flawed methodology to analyze noise impacts, used outdated studies to assess livestock impacts, and failed to consider the impact of aerial refueling or the potential secondary effects of aircraft accidents; deferring to Air Force's methodology where it was explained thoroughly in the EIS); Mid States Coalition for Progress v. Surface Transportation Board, 345 F.3d 520 (8th Cir. 2003) (holding that degradation of air quality was a "reasonably foreseeable" indirect effect of proposed rail lines, even if its extent was not; encouraging use of Section 1502.22 for evaluating reasonably foreseeable impacts of CO_2 emissions when necessary information is incomplete or unavailable – the EIS must explain the relevance of this information to evaluating reasonably foreseeable significant adverse impacts, and evaluate the impacts based on theoretical approaches or research methods generally accepted in the scientific community); Sierra Club v. Marita, 46 F.3d 606, 621 (7th Cir. 1995) (upholding U.S. Forest Service's EIS, including its refusal to apply conservation biology science suggested by petitioner, after considering the implications and "determin[ing] that science to be uncertain in application," holding that an agency is entitled to use its own methodology, unless it is irrational); Salmon River Concerned Citizens v. Robertson, 32 F.3d 1346, 1359 (9th Cir. 1994) (upholding U.S. Forest Service's EIS under NEPA, finding agency's accounting of "chemically sensitive persons by including a safety factor" resulted in a reasoned analysis and adequate disclosure of the evidence before it, where agency experts found that the scientific community cannot determine what causes a reaction in a chemically sensitive person, or define discreetly that reaction); cf San Luis Obispo Mothers for Peace v. Nuclear Regulatory Commission, 449 F.3d 1016 (9th Cir. 2006) (holding that the Nuclear Regulatory Commission's categorical refusal under NEPA to consider environmental effects of terrorist attack on proposed interim spent fuel storage installation, or the nuclear facility in general, was not reasonable).*

10.3.1.2 Modeling After 2020

Comments

Comment Number: 0550-4
Organization: Individual
Commenter: Sarah Larsen

NHTSA takes a presumed 35-mpg fleet in 2020, assumes that fuel economy stops increasing, and then measures the cumulative CO_2 savings through the year 2100. I believe NHTSA should only be measuring reductions at the 35-mpg fleet level for the life of these vehicles. Fuel economy should not be presumed to stop at 2020 levels. If NHTSA wants to evaluate carbon savings through the year 2100, then they should do so by assuming fuel economy standards continue to increase to the year 2100 at the same rate of increase as between 2011-2015. Furthermore, considering that relevant science is talking about reductions needed by 2050, it again seems out of context for NHTSA to have randomly picked the year

2100 as timeline for measuring success of today's carbon reductions from vehicles. I believe success and progress should be measured by how close these fuel economy improvements get us to reducing the transportation sector's carbon emissions by 80% in time for the 2050 deadline. To do otherwise fails to realistically evaluate vehicle emission reductions as a key part of the strategy to curb global climate change.

Comment Number: 0559-2
Organization: The Northeast States for Coordinated Air Use Management (NESCAUM)
Commenter: Arthur Marin

The DEIS, inconsistent with the regulations and policy guidance on cumulative effects, evaluates the effects of new CAFE standards without consideration of other important factors. For example, while NHTSA asserts the DEIS fully addresses foreseeable impacts through the year 2100, it errs by incorporating an assumption that technological improvements in fuel economy cease after model year 2020. [Footnote: NHTSA's apparent rationale is that the Energy Information and Security Act (EISA) mandates a fuel economy target that extends only through model year 2020.] In reality and in contrast with this approach, technology-forcing requirements historically have spurred technological innovation to meet and even exceed environmental benchmarks. This interrelationship between policy initiatives and technology advancement has been well documented by numerous researchers [Footnote: See original comment document.] for more than thirty years and has even been given a name: *induced technological change*. There is little question that policies and legislative initiatives aimed at reducing carbon emissions are in our future, and these programs will create economic disincentives to continued business as usual, relative to consumption of fossil fuels in the transportation sector. Consequently and according to the principles of induced technological change, business and government will respond by engaging in more extensive research and development, including in the fuel economy arena, with a goal of reducing reliance on conventional fuels. As these research and development efforts bear fruit, technological progress will follow.

Given this principle of induced technological change, coupled with the underlying legislative requirement (i.e., the Energy Policy and Conservation Act – EPCA) for NHTSA to take a technology-forcing approach to future fuel economy requirements, further improvements beyond model year 2020 are, in fact, *reasonably foreseeable*. Thus, the approach taken in the DEIS disregards both precedent and the law. It is also important to note that economics by itself will play a future role, inducing technological change to improve fuel economy. The U.S. Energy Information Administration in its *2008 Annual Energy Outlook* projects in its "high economic growth–high fuel price" scenario that between 2008 and 2030, energy use in the light duty vehicle sector will grow by 13 percent while at the same time, the price of gasoline will grow by 18 percent. As this scenario unfolds, there will be further incentives for investment into research and development for improving fuel economy. Therefore, NHTSA would do well to incorporate such economic factors into its cumulative effects analysis.

Comment Number: 0559-4
Organization: The Northeast States for Coordinated Air Use Management (NESCAUM)
Commenter: Arthur Marin

The DEIS, in its assessment of global benefits, also disregards the principle of technology transfer. If U.S. industries develop technology that markedly improves fuel economy, it's very unlikely that the technology will remain confined to the U.S. fleet. Ultimately, fleets worldwide will incorporate the same technologies. According to the World Resources Institute, energy consumption accounts for 61 percent of total GHG emissions and transport accounts for 22 percent of all energy consumption-related GHG emissions. U.S. transportation, according to the Energy Information Administration, accounts for 18 percent of global GHG emissions from petroleum consumption. Clearly, an aggressive program in the

U.S. to markedly improve fuel economy, coupled with technology transfer, can be a key strategy for reducing GHG emissions globally.

Comment Number: 0572-29
Organization: Center for Biological Diversity
Commenter: Brian Nowicki, Mickey Moritz, Kassie Siegel

One of the ways NHTSA minimizes the apparent impact of its rulemaking is to limit its analysis to a world in which fuel economy levels become fixed beyond the last year of the current rulemaking. To limit the analysis to this assumption is inconsistent with the statutory scheme, which of course requires that (1) fuel standards for the combined fleet reach *a minimum* of 35 mpg by 2020 and (2) the NHTSA set fuel standards must be set at the "maximum feasible level" each year. 49 U.S.C. §32902(a); (b)(2)(C). This regulatory regime requires NHTSA to continue to raise standards each and every year through 2100. While the NHTSA may have been free to calculate and discuss the resulting environmental impact that would result from fixing the standard beyond the current rulemaking, disclosing only this piece of information was clearly not sufficient, especially given the statutory scheme that requires the NHTSA to continue increasing fuel economy to the maximum feasible level each year.

While the DEIS states that the standards for 2011-2015 will impact the 2016-2020 standards, the DEIS improperly limits its analysis to the environmental impacts from the emissions of just those vehicles in MY 2011-2015. Limiting the analysis in this manner allowed NHTSA to minimize the apparent impact of its action, because despite the fact that the lifetime emissions of these five model years of U.S. vehicles will be massive, even this large chunk of emissions can be made to incorrectly appear insignificant if it is compared to a large enough number. In order to give a complete picture of this aspect of the problem, NHTSA should have compared its alternatives for model years 2011-2015 not just to the emissions that would result if fuel economy standards thereafter remained fixed, but also to the emissions that would result if fuel economy standards continued to improve along the trajectories established by each of a reasonable range of alternatives. Had NHTSA done so, the impact of its action would have appeared in a very different light. This is particularly true since technology innovation today will both amplify the gains that can be made in the auto industry in the future, and will also have spillover effects into other sectors of the economy. The NHTSA was required to address these issues in the DEIS, but failed utterly to do so.

Because of the application of technologies developed in response to a valid, technology-forcing CAFE standard to other sectors of the economy and in other countries, there should be a non-linear increase in projected reductions with increased stringency of fuel standards. The DEIS should have included an analysis of continual increases in fuel economy through year 2100. EPCA requires that *each year* the maximal fuel economy standard be established. It is certain that technology will continue to improve and thus that the maximum feasible fuel standards will continue to increase through 2100. As shown in the figure below [See original comment document for figure.], one way to estimate the emissions savings due to a continual increase in fuel economy would be to iteratively sum the projected reduction in CO_2 from the MY 2011-2015 standards (obtained from the difference between the "no action" and "technology exhaustion" alternative emissions in Table 3.4-2 of the DEIS) out to year 2100.

Employing this strategy results in a substantially greater effect than the artificial assumption in the DEIS that fuel economy will not improve after MY 2015. The cumulative carbon savings would be 39 Gigatons of carbon by year 2100, and a 15 ppm difference between "no action" and "technology exhaustion" in CO_2 concentration in 2100.

Comment Number: 0576-3
Organization: Public Citizen
Commenter: Joan Claybrook

NHTSA does not consider impacts of extending fuel economy standards beyond the mandated 35 mpg by 2020, although there is clear need and a Congressional mandate to continue to improve efficiency to make the reductions that are needed, which serves to minimize the value of action when NHTSA extrapolates the benefits to 2100. However, EISA requires that NHTSA set fuel economy standards that are the maximum feasible for each model year from 2021-2030. Standards that exceed the 2020 level should be considered to increase at least until 2030, when the statutory mandate ends. It is also reasonably foreseeable that fuel economy standards or some combination of policies will be employed to continue to reduce oil consumption beyond 2020. [Footnote: See original comment document.]

Comment Number: 0585-5
Organization: Attorneys General of the States of California, Massachusetts, New Jersey, New Mexico, New York, and Oregon, Secretary of the Commonwealth of Pennsylvania Department of Environmental Protection, and New York City Corporation Counsel
Commenter: Edmund Brown Jr., Joseph Powers, Martha Coakley, Michael Cardozo, Anne Milgram, Gary King, Andrew Cuomo, Hardy Myers

NHTSA's cumulative impacts analysis fails to comply with this mandate and is flawed in several respects. On the one hand, in projecting the impact of the CAFE rule through 2100, NHTSA considers only the CAFE rules for 2011-2015 and 2016-2020, and assumes that miles per gallon will remain the same from 2020 through 2100. DEIS at 4-19, 4-27. On the other hand, it appears that NHTSA assumes that VMT will continue to increase through 2100. DEIS at 3-57. The combination of these assumptions understates NHTSA's ability to contribute cumulatively to GHG reduction efforts through more stringent CAFE standards. In the same way that it can be anticipated that VMT will continue to increase after 2020, it can also be anticipated that future CAFE rulemakings after 2020 will continue to increase the miles per gallon required for cars and light trucks, and that improved technology will enable car manufacturers to meet those increases. Thus, NHTSA must recalculate its cumulative projections to take into account the impact of future CAFE rulemakings after 2020 on the anticipated emissions through 2100.

Comment Number: 0596-2
Organization: Environmental Defense Fund
Commenter: Martha Roberts

The EIS fails to account for additional global ramifications of U.S. fuel efficiency standard setting; namely the influence of U.S. CAFE regulations on the global automobile market. Vehicle manufacturers tend to produce cars that comply with one of three dominant regulatory programs, the U.S., the European Union, or Japan, regardless of whether the vehicle is to be sold in that region. Thus U.S. CAFE standards impact the fuel efficiency of vehicles driven in other countries, and subsequently their greenhouse gas emissions. Although we do not have precise figures relating to the influence of the U.S. fuel economy standards on the global automobile market, figures for an analogous impact, that of U.S. vehicle emissions standards, are available. In addition to the approximately 17 million cars and light trucks sold in the U.S. in 2005, another 5.2 million vehicles were sold that year in other countries that met U.S. emissions regulatory standards. [Footnote: See original comment document.] The number of cars sold globally that follow U.S. fuel economy standards could be greater or less than those following emissions standards. The cumulative impacts assessment in this EIS must account for the additional non-U.S. vehicles that follow U.S. CAFE standards and the resulting cumulative effect that more stringent standards will exert on global greenhouse gas (GHG) emissions.

Comment Number: 0598-4
Organization: Sierra Club
Commenter: Caroline Keicher

NHTSA notes that only the 2016-2020 standards are foreseeable in the DEIS and therefore does not consider increases to the standards after 2020. The law clearly provides for maximum feasible standards in the years that follow. Increases beyond 2020 are foreseeable, perhaps just as foreseeable as the vehicle miles traveled (VMT) increases NHTSA presumes through 2100.

Comment Number: TRANS-08-12
Organization: Sierra Club
Commenter: Ann Mesnikoff

NHTSA says the standards must be set to 35 by 2020. NHTSA notes that the 2016 to 2020 standards are foreseeable in the draft environmental impact statement, but the law provides them for the maximum feasible thereafter. Increases beyond 2020 are foreseeable, perhaps just as foreseeable as the VMT increases NHTSA presumes through 2100.

Comment Number: TRANS-21-2
Organization: Individual
Commenter: Christina Marie Yagjian

An issue I would like to highlight is in this draft environmental impact statement is that NHTSA has arbitrarily picked 2100 as a time line for measuring the success of today's carbon reductions. A nearer term goal would help to ensure that the transportation sector does its part to achieve the goal set by the scientific community of 80 percent reductions by 2050.

In the EIS NHTSA presumes that fuel economy standards stop increasing after 35 miles per gallon in 2020. In order to properly evaluate carbon savings through 2100, NHTSA should extrapolate a curve of increasing fuel economy standards that continues to increase to 2100 at the same rate of increase as between 2011 and 2015.

Comment Number: TRANS-36-5
Organization: Individual
Commenter: Matt Kirby

And [NHTSA is] setting the 35 miles per gallon by 2020, but actually to extrapolate this through 2100, to not say that 35 miles per gallon is the be all, end all fuel efficient standard, because it shouldn't be.

Comment Number: TRANS-39-8
Organization: American Jewish Committee
Commenter: Ami Greener

NHTSA should not conclude in its analyses that fuel economy gains are presumed to stop at 2020 levels, but further grow by means of using existing technologies. We see the use of alternative and renewable fuels, new lightweight materials, and electric vehicles taking up a bigger percentage of miles driven in the U.S. in the near future.

Response

Because EISA directs NHTSA to increase CAFE standards to reach a combined fleet average CAFE level of at least 35 mpg by model year 2020, MY 2016-2020 CAFE standards are reasonably foreseeable and must be accounted for when analyzing the cumulative impacts of the proposed action. For each alternative, NHTSA assumed that passenger-car and light-truck CAFE standards would continue to increase over model year 2016-2020 at their average annual rate of increase over MY 2011-2015. This assumption results in passenger-car and light-truck CAFE standards under each action alternative that meet or exceed the EISA requirement of a combined fleet average of at least 35 mpg by model year 2020. NHTSA assumed further that the fuel economy standards for model year 2020 would remain in effect through the end of the analysis period. Because the CAFE standards apply to new vehicles, this assumption results in emissions reductions and fuel savings that continue to grow as new vehicles meeting the CAFE standards MY 2020 and beyond are added to the fleet in each subsequent year, reaching their maximum values when all passenger cars and light trucks in the U.S. fleet meet these standards. NHTSA included this effect in the analysis.

While NHTSA recognizes the possibility that technological advancement could continue absent future regulation, little empirical evidence supports this argument. In fact, from 1985 to 2005, when Congress prohibited NHTSA from promulgating new CAFE standards, in-use fuel economy decreased, despite gains in automobile fuel economy. See John German, Light Duty Vehicle Technologies: Opportunities and Challenges, available at http://www.its.ucdavis.edu/events/outreachevents/ asilomar2007/presentations%20list.php. Although vehicle engines became more efficient, manufacturers used this improved technology to make the vehicles more powerful and for other passenger amenities, rather than for additional gains in fuel economy.

Although it might be true that higher fuel prices will promote greater technical innovation and greater fuel savings, whether the current trend in higher fuel prices will persist remains to be seen. Most forecasts, including the EIA's, indicate only moderately high fuel prices in the future, which might not be sufficient to promote greater fuel efficiency without regulation. Recent literature suggests that a large increase in the real price of gasoline is necessary to substantially influence vehicle purchase decisions over the long term. See Small and Van Dender (2005).

Regarding increases in CAFE standards beyond 2020 as reasonably foreseeable, as previously explained, when setting "maximum feasible" average fuel economy levels under EPCA, NHTSA is required to consider economic practicability, technological feasibility, the effect of other motor vehicle standards of the government on fuel economy, and the need of the United States to conserve energy. See 49 U.S.C. § 32902(f). In the 1980s, NHTSA found it necessary to roll back fuel economy standards to lower levels because manufacturers could not meet them. Maximum feasible standards must be economically practicable under EPCA. The requirement to set economically practicable standards is especially important in times of economic uncertainty.

One commenter suggested that if VMT increases are reasonably foreseeable, then fuel economy increases also should be. According to the Federal Highway Administration, which tracks and reports VMT in its "Highway Statistics," the long-term trend of increasing VMT began in the 1950s when the Eisenhower Interstate System was established. Since then, VMT has shown a decline in only a few years. The trend is very clear. Fuel economy, on the other hand, exhibits no such long-term trend, and thus, is much more difficult to forecast.

Due to these complex and sometimes conflicting concerns, NHTSA had to ask: At what point would improving fuel economy no longer be technologically feasible, or should NHTSA assume that no *technological limits would be discovered? NHTSA selected the middle ground – maintaining fuel economy standards that would be constant at the 2020 level.*

Other commenters questioned the extension of the analysis through 2100 and expressed concern that extrapolating the impacts that far out minimized the impact of the proposed action. In this FEIS, NHTSA reports substantial reductions in GHGs under the action alternatives; demonstrates that such reductions compare favorably to other emissions-reduction initiatives; and has added a new analysis showing the effect of the alternatives on U.S. passenger vehicle emissions. See Section 3.4.4. NHTSA understands that the small climate effects exhibited for temperature, precipitation, and sea-level rise are functions of the magnitude of a problem that is global in nature. While NHTSA shows these impacts through 2100, we also present analyses for various periods between the present and 2100. While NHTSA might have chosen a shorter final time frame than 2100, we note that shortening the time frame would only serve to demonstrate even smaller climate effects.

Several commenters stated that NHTSA should compare these anticipated emissions reductions with a target reduction of 60 to 80 percent by 2050. See our response to these comments in Section 10.2.1.

10.3.2 Air Quality

Comment

Comment Number: 0595-12
Organization: Environmental Protection Agency
Commenter: Susan Bromm

Chapter 1, pg. 1-6, Lines 26-29:

In order to address the limitations of the air quality modeling in the EIS, EPA recommends that these lines be revised as follows:

"EPA indicated that many of the factors that affect air quality, such as meteorology and atmospheric processes, will not be taken into account when evaluating human health and environmental impacts without a full-scale photochemical air quality modeling analysis. This limitation needs to be acknowledged. NHTSA agrees with EPA's suggestion, and this limitation is acknowledged in Chapters 3 and 4."

There is also no mention of this limitation in Chapter 4. Please repeat the limitation text in that chapter.

Response

NHTSA has revised Section 1.3.2.1 and Section 4.3.2.1 in response to this comment.

10.3.2.1 Affected Environment

Comment

Comment Number: 0588-11
Organization: New York State Department of Transportation
Commenter: Stanley Gee

NHTSA confuses the discussion of emissions impacts (particularly Figure 3.3-1) by including the effects of increased vehicle emission regulation stringency. NHTSA should revise its presentation to ensure that the effects of proposed CAFE standards are clearly differentiated from the effects of vehicle emissions standards and general VMT growth.

Response

NHTSA has revised the text of Section 3.3.1.4 to clarify the differences among effects of the CAFE standards, vehicle emissions standards, and VMT growth.

Comment

Comment Number: 0595-15
Organization: Environmental Protection Agency
Commenter: Susan Bromm

Chapter 3, pg. 3-13, lines 36-40 and pg. 3-14, lines 1-3:

In order to accurately characterize ozone-related health impacts, EPA recommends adding the following sentence to the end of the ozone health effects description:

"There is also highly suggestive evidence that short-term ozone exposure directly or indirectly contributes to non-accidental and cardiopulmonary-related mortality."

Response

NTHSA has added this text to Section 3.3.1.2.

Comment

Comment Number: 0595-9
Organization: Environmental Protection Agency
Commenter: Susan Bromm

In several locations in Section 3.3.1, the description of hazardous air pollutants emitted by mobile sources (mobile source air toxics, or "MSATs") analyzed in the DEIS is mischaracterized and incorrectly cited. EPA recommends the following revisions and clarifications:

Page 3-1 1: As Section 112(b) of the Clean Air Act is not relevant to mobile sources and the analysis in the DEIS does not include all of the hazardous air pollutants, EPA recommends the following edit:

"The air quality analysis assesses the impacts of the alternatives with respect to criteria pollutants and some hazardous air pollutants from mobile sources (also known as mobile source air toxics.) ~~Hazardous~~

~~Air Pollutants (HAPs, also known as toxic air pollutants or air toxics) as defined under Section 112(b) of the CAA.”~~ [Strikethrough provided by commenter.]

Page 3-13: As EPA has not identified a specific list of priority MSATs, including in the MSAT final rule, we recommend the following edit to the fourth paragraph:

“~~The relevant air toxics for this analysis are referred to by EPA and Federal Highway Administration (FHWA) as the priority Mobile Source Air Toxics (MSAT). The priority MSATs~~ [Strikethrough provided by commenter.] The MSATs included in this analysis are acetaldehyde, acrolein, benzene, 1,3-butadiene, diesel particulate matter (DPM), and formaldehyde (~~EPA, 2008~~). [Strikethrough provided by commenter.] DPM is a component of exhaust from diesel-fueled vehicles and falls almost entirely within the $PM_{2.5}$ particle size class.”

In addition, page 3-13 states that the description of the health effects of the six Federal criteria pollutants is adapted from EPA 2008b. This does not appear to be properly referenced. There is no EPA 2008b listed in the references, and neither of the EPA 2008 references appear to be relevant here.

Page 3-15: Similarly, as EPA has not identified a list of priority MSATs, we request deletion of the word “priority” to describe the MSATS referenced. Furthermore, we believe that Claggett and Houk, 2006 is an inappropriate source for the information presented. A summary of health effects should be referenced to a more primary source (such as EPA’s Integrated Risk Information System), or EPA’s own synthesis of health effects (such as the 2007 MSAT rule preamble and/or RIA[Regulatory Impact Analysis]).

Page 3-16 cites EPA, 2008 as the reference for EPA’s MSAT rule. This is an incorrect reference. The MSAT rule was published in 2007, and the full details of that reference are in footnote 16. [See original comment document for footnote.]

Response

NTSHA has revised and clarified the text in Section 3.3.1 and has revised the references in response to this comment.

10.3.2.2 Methodology

Comment

Comment Number: 0572-39
Organization: Center for Biological Diversity
Commenter: Brian Nowicki, Mickey Moritz, Kassie Siegel

Black carbon is also detrimental to human health. It has been linked to a variety of circulatory diseases. One study found an increased mortality rate was correlated with exposure to black carbon (Maynard 2007). The same is true for heart attacks (Tonne 2007). Another study found that residential black carbon exposure was associated with increased rates of infant mortality due to pneumonia, increased chronic bronchitis, and increased blood pressure (Schwartz 2007).

In developed countries, diesel burning is the main source of black carbon. Diesel emissions include a number of compounds such as sulfur oxides, nitrogen oxides, hydrocarbons, carbon monoxide, and particulate matter. Diesel particulate matter is approximately 75% elemental carbon. (EPA Diesel Health Assessment 2002.) Furthermore, global inventories of emissions rates from a variety of sources exist to facilitate quantitative estimates. (See, e.g., Bond et al. 2004.) Thus, it is crucial that black carbon be addressed in the DEIS.

Analyzing particulate matter is insufficient to address black carbon.

Particulate matter (PM) refers to the particles that make up atmospheric aerosols. The primary constituents of PM are sulfates, nitrates, and carbon compounds. Sulfates and nitrates form in the atmosphere from the chemical reaction of sulfur and nitrogen dioxides. These may often be present as ammonium sulfate or nitrate salts. Carbon compounds may be directly emitted, e.g., black carbon emitted from combustion, or may form in the atmosphere from other organic vapors, e.g., oxidation of volatile organic compounds.

Because PM can be reduced through mitigation of other constituents of PM than black carbon, it is essential that black carbon emission reduction strategies be considered independently from PM reductions. The proportions of the constituents of PM vary over time and by location (see EPA Particle Pollution Report 2004). According to a recent series of surveys conducted at various U.S. cities under the EPA's "Supersite" program, black carbon was often only about 10% of total measured $PM_{2.5}$. [Footnote: See original comment document.]

In contrast to total $PM_{2.5}$, diesel PM is composed largely of black carbon. Nonetheless, some diesel PM reduction strategies do not affect black carbon. For instance, diesel oxidation catalysts can reduce diesel PM emissions as a whole by approximately 20 to 40%, yet they do not decrease black carbon emissions (Walker 2004). In addition, while low-sulfur fuel will reduce sulfate emissions, in and of itself low-sulfur fuel will not reduce black carbon. Low-sulfur fuel is important because it *allows* for better technology to reduce black carbon. See, e.g., 69 Fed. Reg. 38957, 38995 (June 29, 2004). Yet those reductions can only occur once the technology has been implemented.

Response

EPA is charged under the Clean Air Act with protecting human health from air pollution. EPA has established National Ambient Air Quality Standards (NAAQS) for particulate matter (PM) for the PM_{10} and $PM_{2.5}$ size classes. EPA has identified diesel particulate matter (DPM) as a Mobile Source Air Toxic (MSAT) of concern that should be considered in air quality analyses (EPA 2001). EPA has not established NAAQS for DPM. DPM is composed of an elemental carbon core and adsorbed organic compounds (organic carbon), sulfates, nitrate, metals, and other trace elements (EPA 2004c). EPA provides no special status for elemental carbon, also called carbon black or black carbon. Rather, EPA considers elemental carbon to be a component of $PM_{2.5}$, produced from both gasoline- and diesel-powered vehicles.

The FEIS addresses PM in terms of $PM_{2.5}$ emissions, which are calculated using emissions factors from the EPA MOBILE6.2 model, EPA's required procedure for deriving highway vehicle emissions factors for an EIS. MOBILE6.2 estimates primary $PM_{2.5}$ (i.e., $PM_{2.5}$ that is emitted directly) from three sources: the vehicle tailpipe (the largest source); brake and tire wear; and reentrainment of road dust into the atmosphere. MOBILE6.2 calculates $PM_{2.5}$ and PM_{10} by vehicle type, and NHTSA uses the portion of PM_{10} emitted by light-duty diesel vehicles (cars and trucks) in the FEIS to represent DPM. EPA concluded in the 2002 Health Assessment for Diesel Exhaust Emissions (EPA 2002a) that DPM is "no more likely to be toxicologically potent than any other fine particle constituents that typically make up ambient $PM_{2.5}$" and that based on this "the annual $PM_{2.5}$ standard would also be expected to provide a measure of protection for DPM" (EPA 2002a, p. 6-30).

The FEIS addresses PM_{10} using $PM_{2.5}$ as a surrogate because almost all PM_{10} from light-duty vehicles consists of $PM_{2.5}$. Thus, PM_{10} emissions are very close to the reported $PM_{2.5}$ emissions. The $PM_{2.5}$ emissions analysis and the relationships noted above between $PM_{2.5}$ and black carbon suggest, first, that black carbon emissions associated with the alternatives should be less than $PM_{2.5}$ emissions. Second, black carbon emissions should vary among the alternatives in the same pattern as $PM_{2.5}$.

The elemental carbon component of DPM is only one factor in the human toxicological response, and the human health effects of elemental carbon cannot be considered independent of their PM constituents in relation to PM generated by motor vehicles. The EPA Air Quality Criteria Document for Particulate Matter described research findings about the health effects of elemental carbon independent of particulate matter, and ongoing research further assesses the health effects (EPA 2004c).

In research comparing elemental carbon and DPM, the organic components of DPM have been linked to the generation of reactive oxidative species; elemental carbon alone and diesel particles without organics did not induce apoptosis (cell death) (Hiura et al., as cited in EPA 2002). In addition, DPM has been shown to impair pulmonary defense, while elemental carbon particles alone did not have the same effect (Mundandhara et al. 2006). Elemental carbon particles have been shown to induce an inflammatory response, but this response is similar to the one induced by DPM (EPA 2002a). Elemental carbon particles are also important in the observed carcinogenic response in rats, but DPM containing the elemental carbon particles produced a similar carcinogenic response (EPA 2002a).

In air quality studies, black carbon (elemental carbon) is typically used as a surrogate for PM or DPM when better information is not available (Lewtas 2007). In epidemiological studies such as Maynard et al. (2007), elemental carbon is used as an identifier or an index for PM generated from motor vehicles. In toxicology research similar to that described in Mundandhara et al. (2006), elemental carbon is used as an experimental control to demonstrate the effects of other PM constituents.

Based on the above, NHTSA believes that considering the health effects of inhaled elemental carbon independently of PM or DPM is unnecessary because elemental carbon will not be emitted without the other accompanying components of PM. NHTSA has revised the FEIS to clarify the distinctions among PM as a criteria pollutant, DPM as an air toxic pollutant, and black carbon. See Section 3.3.1.2.

Comment

Comment Number: 0595-16
Organization: Environmental Protection Agency
Commenter: Susan Bromm

Chapter 3, pg. 3-17, lines 40-43 & pg. 3-18, lines 1-2:

In order to better describe the limitations of the air quality analysis performed by NHTSA, EPA recommends the paragraph be revised as follows:

"Full-scale photochemical air quality modeling was not conducted for this analysis; therefore, the EIS is unable to characterize the ambient air quality impacts associated with each alternative. Instead, the action alternatives were analyzed by calculating the emissions from passenger car and light trucks that would occur under each alternative, and assessing the changes in emissions relative to the No Action Alternative. Lower emissions should result in lower ambient concentrations of pollutants on an overall average basis, which should lead to decreased health effects of those pollutants.

"Full-scale photochemical air quality modeling is necessary to accurately project levels of $PM_{2.5}$, ozone and air toxics. A national-scale air quality modeling analysis would analyze the combined impacts of each alternative on $PM_{2.5}$, ozone, and air toxics (i.e., benzene, formaldehyde, acetaldehyde, ethanol, acrolein and 1 ,3-butadiene). The atmospheric chemistry related to ambient concentrations of $PM_{2.5}$, ozone, and air toxics is very complex, and making predictions based solely on emissions changes is extremely difficult."

Response

NHTSA has made the suggested revision to the text in Section 3.3.2.3.

Comment

Comment Number: 0595-17
Organization: Environmental Protection Agency
Commenter: Susan Bromm

Chapter 3, page 3-20, lines 7-16:

EPA recommends the paragraph be revised as follows in order to more clearly indicate that incomplete/unavailable information limitations affect the air quality and health impacts analysis done:

"As noted above, the estimates of emissions rely on models and forecasts that contain numerous assumptions and data that are uncertain. Examples of areas in which information is incomplete or unavailable include future emission rates, vehicle manufacturers' decisions on vehicle technology and design, the mix of vehicle types and model years, emissions from fuel refining and distribution, and economic factors. Furthermore, a full-scale photochemical air quality modeling analysis to estimate the ambient concentrations of PM, ozone, and air toxics was not conducted The lack of air quality modeling data limited the conclusions that could be made about health and environmental impacts associated with each alternative. Instead, a screening-level estimate of monetized health benefits, in the form of dollar-per-ton of criteria pollutant emissions reduced, was used to approximate the health benefits associated with each alternative. The use of such dollar-per-ton numbers, however, does not account for all potential health and environmental benefits, which leads to an underestimate of total criteria pollutant benefits. Where information in the analysis included in the DEIS is incomplete or unavailable, the agency has relied on CEQ's regulations regarding incomplete or unavailable information. See 40 CFR § 1502.22(b). NHTSA has used the best available models and supporting data. The models used for the DEIS were subjected to scientific review and have received the approval of the agencies that sponsored their development. NHTSA believes that the assumptions that the DEIS makes regarding uncertain conditions reflect the best available information and are valid and sufficient for this analysis"

Response

NHTSA has made the suggested revision to the text of Section 3.3.2.3.

Comment

Comment Number: 0595-18
Organization: Environmental Protection Agency
Commenter: Susan Bromm

Chapter 3, pages 3-26 and 3-28:

NHTSA's estimates of criteria pollutant reductions (e.g., 54,000 - 232,000 tons of NO_x in 2020) connected with the proposed CAFE standards appear to be larger than EPA would expect. EPA has not been able to replicate NHTSA's estimate, so we do not know for certain if there is an issue. The magnitude of the resulting inventory reductions suggests that NHTSA may be taking credit for criteria (and possibly toxic) emission benefits that occur internationally during crude oil transport to the U.S., rather than just counting the domestic benefits of reduced refinery and fuel distribution emissions. The lack of details in the DEIS does not allow EPA to comment for certain on how the NHTSA DEIS estimates were calculated, but the text in the Federal Register notice, page 24412, seems to support this suggestion:

"Reductions in domestic fuel refining using imported crude oil as a feedstock are tentatively assumed to reduce emissions during crude oil transportation and storage, as well as during gasoline refining, distribution, and storage, because less of each of these activities would be occurring."

An additional possible cause for the large emission reductions estimated by NHTSA is the use of the GREET model to generate those estimates. EPA has noticed that the heavy-duty truck, rail, and barge emission factors in GREET [Greenhouse Gases, Regulated Emissions, and Energy Use in Transportation] do not reflect the latest round of EPA emission standards that substantially reduce VOC, NO_x, and PM emissions in future years (the heavy-duty highway 2007/2010 standards). Use of these more controlled emission factors would decrease the "No Action" emissions as well as emissions from the various CAFE alternatives, with the net result being smaller benefits from the program than estimated using an unmodified version of GREET. We suggest NHTSA verify what standards are assumed in the version of GREET used for the DEIS, and modify as appropriate for the final EIS.

Response
