## INTRODUCTION

Eggs are manufactured into egg products, such as liquid, dried, powdered, frozen, or reduced cholesterol products. These products may be contaminated with Salmonella spp. if made from contaminated eggs. This annex describes the data and methods used to model the distribution of levels of Salmonella spp. contamination in egg products. This annex also serves as a draft report of the survey findings; a final, separate report will be issued when the serotype information has been analyzed.

## EGG PRODUCT BASELINE SURVEY

## Sample Design

All federally inspected plants that produced raw liquid egg products were eligible for sample selection. From this population of plants, separate frames were developed for each of three raw, liquid egg products: whole, whites, and yolks. A plant could be included in more than one frame if it produced more than one of these products. Sampling frames were updated on a quarterly basis throughout the study; however, during the course of the survey, there were no added plants. The resulting frames varied in number of plants by quarter and by product. The numbers of plants in the frames were 70 whole egg plants, 50 egg yolk plants, and 40 egg white plants. Each quarter, 117 ( 9 per week for 13 weeks) sample requests for each product were allocated to the plants. This was done by cycling through the list of plants of the appropriate sampling frame. That is, if there were 50 plants in the sampling frame, and 117 samples were to be requested, then each plant would be allocated two sample requests, and 17 plants would be allocated three requests. Sample allocation for the next quarter would then resume at the point in the frame where the previous quarter's allocation had been completed. Not all samples requested could be collected because the plant might not have been producing at the time of the request. For the first few months of the survey, it was noticed that the numbers of samples being analyzed were below expectations, so the number of samples allocated per week was increased. After the requests were allocated to the plants, specific weeks for sample collection were randomly assigned such that no plant received two requests for the same product in the same week. Over the duration of the study, for a given product, approximately the same number of sample requests would be allocated to each plant, achieving a nearly balanced allocation over the seasons of the year. Samples were assigned randomly to the laboratory in a manner that assured equal numbers of samples per lab each week. When the samples arrived at the laboratory, the temperature and the integrity of the containers were checked. If the temperature was too low or if there were signs of loss of integrity of containers, the sample was discarded.

The history of the eggs or of the liquid products derived from broken eggs. For example, whether or not the liquid product was produced within the plant, received from another plant, or returned from retail, produced and stored in the plant before pasteurizing - could affect the levels
of Salmonella in the liquid product before pasteurization. Consequently, FSIS classified samples of liquid product into one of 5 "risk" categories depending upon sampled liquid product history.

Samples were collected from Monday through Thursday of the designated week. The type of sample (whole, white, or yolk) to be collected was designated on the collection form but the risk category of the sample was to be determined by the Inspector in Charge, with priority to be given to products in order of the risk category (defined below). That is, products of the highest risk category (lowest number) were given the highest priority, products of the next highest risk category were given the next highest priority, and so forth. The sample was taken prior to any substance being added to the liquid egg product, as close in time to pasteurization as possible. For each sample request, using aseptic techniques, 100 ml of liquid egg product were placed in each of 2 cups (for a total of 200 ml ) and shipped by FedEx overnight service, on the same day of collection, to the designated FSIS laboratory (one of three). If the sample needed to be collected through a valve, then the valve was opened before collection to let sufficient liquid pass from the nozzle/spout so that the sample represented product that was in the tank, not the valve.

## Most probable number (MPN) analyses

Levels of Salmonella spp. in collected samples were measured using a 3-tube, 6-dilution most probable number (MPN) procedure. MPN is a method of inferring the level of viable cells in a sample from results of a series of qualitative tests of subsamples of different volumes (or sample dilutions). The tested materials are incubated in tubes, and typically, the numbers of tests for each dilution or volume are the same. Thus, for example, a 3-tube, 3-dilution MPN determination is based on three different volumes of samples (e. g., $10 \mathrm{ml}, 1 \mathrm{ml}, 0.1 \mathrm{ml}$ ) with 3 tubes per dilution. The MPN is the level (number of colony forming units (cfu's) of Salmonella per ml) that maximizes the likelihood of the pattern of results that were obtained from the tests, assuming that the distribution of the number of cfu's is uniform throughout the sample, the subsampled volume for each tube is a small portion of the total sample volume, and the likelihood of detecting a positive result in the presence of viable cells is $100 \%$ for all tests. In statistical terminology, this estimate is referred to as the maximum likelihood estimate (MLE). If the recovery were expected to be $66 \%$ instead of $100 \%$, a reasonable approximation of the MPN would be to multiply by 1.5 the MPN for an assumed $100 \%$ recovery.

For this survey, 6 dilutions were typically used to achieve sample volumes of $10 \mathrm{ml}, 1 \mathrm{ml}$, $0.1 \mathrm{ml}, 0.01 \mathrm{ml}, 0.001 \mathrm{ml}$, and 0.0001 ml , with 3 tubes per dilution. If the obtained pattern was anomalous, then the sample was discarded. For example, a sample result with pattern 030000 (MPN result of 0.094 ) was discarded ${ }^{\text {a }}$, while one with pattern 222000 (MPN $=0.348$ ) was not. If all 18 results were positive, then another set of analyses was performed, with higher dilutions (lower volumes, e. g., 0.00001 ml and 0.000001 ml ). For this survey, this event occurred only a few times, and once, mistakenly, the sample was not analyzed a second time at higher dilutions consequently, the MPN result of $>11,000$ was reported.

[^0]According to normal FSIS reporting procedure, the MPN value reported would be the one determined from the second set of analyses. However, FSIS realizes that using the results from the second set of analyses may create a bias, because the material used in the second set of analyses had been stored, refrigerated, for 3 or more days, which could result in a decrease or (less likely) increase in the number of viable Salmonella cells. Thus, for the risk assessment, the second result was not used. Since probabilities of outcomes for all possible levels are needed to estimate the distribution of Salmonella spp. levels, the reported MPN values themselves were not used, but rather the pattern of results - that is, the number of positive results for each dilution that were obtained were used, as described below.

## Information collected

Besides MPN data, FSIS collected information concerning the type of product - whole, white or yolk "risk" category, and other information concerning the production process used for the collected sample, including age of eggs; age of liquid product; temperature of bulk product at the time of sampling; volume of holding tanks; and location of sampling.

The five risk categories for egg products are defined based on how product arrived at the plant: (i) bulk shipments from another plant, not previously heat treated, without additives, and processed separately; (ii) liquid product from shell eggs received from another plant; (iii) liquid product from shell eggs returned from retail market for processing; (iv) liquid products stored in the plant; and (v) products from the plant's current production.

For dried egg products, the levels of Salmonella are assumed appropriate factors of the levels in the liquid product, reflecting the loss of moisture in the drying process. In the Egg Pasteurization Manual, ${ }^{1}$ the percentages of water in egg products are given as $87.6 \%$ for egg white, $73.7 \%$ for whole eggs, and 51.1-55.6\% for egg yolks. Further, the density of albumen and yolk is approximately $1.035 \mathrm{~g} / \mathrm{ml} .^{2 ; 3}$ These factors were used to convert between levels per ml of liquid product and levels per gram of dried product.

## Estimating Distribution of Salmonella Levels

While, from a statistical perspective, estimating a distribution from survey data has many of the same features as estimating a distribution from data collected from a controlled scientific study, the nature of the inference is quite different. In a scientific experiment, the conditions are controlled and the conclusions, or derived distributions, provide an estimate of the conditional possibilities, where the researcher determines the conditions. Because conditions can be varied in a controlled fashion, the conclusions are stated with "all things being equal" or similar modifier. The better control one achieves, the more specific and thus more confident one can be regarding those conclusions. In effect, the populations being studied are being controlled and thus defined by the experimenter to derive a general scientific relationship or law that can be related to a theory, either constructing, reinforcing, or challenging one. Thus, from such studies, the assumptions that the data, $x$, represent realizations from a distribution, $f$, that can be described with only a few parameters, $\theta$, is eminently reasonable, insofar as there is assumed some type of
regularity or commonality of the factors that influence the results that reflect the phenomena being studied.

The data collected from surveys, in comparison, of course, cannot be assumed realizations of processes that have a few common factors that influence results. Consequently, the assumption of a distribution function defined by a few parameters is, on the surface, problematic. Rather, the purpose of surveys is to collect samples that, in some well-defined fashion, represent the variety within the population, $P$, being studied, and to describe the distribution of some variable, and most often, related to some feature of $P$, as it is at the time of sampling. At different times, the features may change. It is important to note that as the actions of members of the population or the composition of entities within the population change, so (as expected) would the population distribution change. Thus, percentiles estimated from these types of data would not necessarily apply for the future.

MPN results reflect unknown processes and contingent events. In effect, each result, $X$, represents a process determined by actions (A) of perhaps, many people; stochastic events of certain natural processes ( $S$ ); and measurement errors ( $E$ ). Thus, $X$, symbolically, can be decomposed as a sum of terms reflecting the influence of the processes $A, S$, and $E$. In this vision, $A$ represents controllable factors of the total process that creates $X$; $S$, which depends upon $A$, represents that random, uncontrolled factors that influence the value of $X$; and $E$ is the measurement error, which for this discussion can be assumed to have an expected value of zero (ignoring in this discussion the bias inherent in the MPN estimation). In effect, each result $X$ represents can be written as,

$$
\begin{equation*}
X=X(A)+\eta(S(A))+E=Y(A)+E \tag{F1}
\end{equation*}
$$

where $\eta(S(A))$ represents the error associated with the variations of the uncontrolled factors associated with the actions, $A$.

Examples of actions might be the processing of eggs from free-range chickens or the temperature and time between collection of eggs after laying. $S$ are stochastic events of certain natural processes and $E$ are measurement errors. Of course, the distribution of $X$ over the population is not the desired one, since it is influenced by the error term, $E$. Because the error distribution is known, at least in theory, the likelihood of the realization $X$ can be written as

$$
\begin{equation*}
L_{A}(X)=\int \varepsilon(X \mid Y(A)) d G_{A}(Y(A)) \tag{F2}
\end{equation*}
$$

where $\varepsilon(X \mid Y)$ is the (known) likelihood of obtaining an MPN value of $X$ given a true level of $Y$, and $G_{A}(Y)$ is the (unknown) cumulative distribution function (cdf) of $Y(A)$, conditional on $A$. The error $\eta(S(A))$ is assumed to represent error that arises from random variation of contingent or stochastic processes. Thus, as with a controlled experiment, it may be reasonable to assume that $G_{A}(Y)$ can be described by a few parameters, so that, if repeated measurements under condition $A$ were made, then it would be possible, through Equation F2, to determine the distribution, $G_{A}(Y)$, through maximum likelihood or method of moments.

Thus, in studies such as this one, auxiliary information is collected, which might be used to define factors that influence the results, and thus, can serve as proxies for $A$. For example,
additional variables can be used to define post-stratification cells, such that, within each cell, the results can be assumed to arise from a common $A$. If the distributions within the post-strata are determined, then, since the probabilities of sample selection are known, the distribution over the surveyed population can, in theory, be estimated.

The small numbers of samples (less than 1,000 ) are unlikely to represent all the different types of handling or processing combinations that might affect the distribution. FSIS collected extra information on factors thought to affect the levels of Salmonella in liquid egg products. These factors certainly do not define very well all the possible actions that might influence the distribution. However, these variables are thought to be able to serve as post-stratification variables and thus help explain some of the variability among the results from the egg product survey.

Thus, there are two features involved with estimating the distribution of $Y(A)$ over the surveyed population: 1) identifying post-stratification variables which capture important factors that influence results and can serve as proxies for sets of actions, $A$, of the surveyed population; and 2) determining the portions of the population that sets of actions that exist within the studied population represent.

For the latter feature, the standard theory of survey estimation requires dividing each result, $X$, by its inverse probability of selection, $q(X)$. Since FSIS is interested in the distribution of Salmonella levels over the produced product, the amount of product produced under action $A$ is needed. In effect, this means identifying a volume of product, $V(X)$, associated with each sample result, $X$. The unbiased estimate for the population mean, $\mu$ is thus,

$$
\begin{equation*}
\mu=\frac{\sum_{k=1}^{n} \frac{V_{k}\left(X_{k}\right) X_{k}}{q_{k}\left(X_{k}\right)}}{\sum_{k=1}^{n} \frac{V_{k}\left(X_{k}\right)}{q_{k}\left(X_{k}\right)}} \tag{F3}
\end{equation*}
$$

where $n$ is the number of samples, and $k$ is an index for a sample. Let the coefficient of $X_{k}$ in the above estimator be $w_{k}$, it being understood that this is, or could be, a function of random variables. The coefficients can be thought of as an estimate of the proportion of the population represented by the $k^{\text {th }}$ sample. The estimate of the population mean, $\mu$, is thus the sum of the products $w_{k} X_{k}$, where $\Sigma w_{k}=1$.

Of primary interest, though, is the cdf, ), that can be estimated using the $w_{k}$ as follows. For a given $x$, let $\delta_{k}(x)=\delta\left(X_{k} \neq x\right)$, the Kronecker delta function, which equals unity if the argument is true, and otherwise zero. Then the MPN values are sorted from lowest to highest, so that $w_{n}$ represents the weight for the highest MPN value. Then

$$
\begin{equation*}
\mathfrak{J}(x)=\sum_{k=1}^{n} w_{k} \delta_{k}(x) \tag{F4}
\end{equation*}
$$

is the estimated distribution of $X$ over the population, $P$. However, the unconditional distribution over $Y(A), F$, is the desired one. Moreover, percentiles beyond the range of the data (for those greater than 1- $w_{n}$ ) cannot be estimated in a simple, direct procedure. Indirect procedures involving generalizing the shape of the estimated cdf, particularly at the higher percentile tail, are needed, which would permit making estimates of percentiles beyond the range of the data.

Alternatively, if the conditional (on $A$ ) cdf, $G_{A}$, were known, and the proportion of the population associated with each $A$, $w_{A}$, were known (estimated from

$$
\begin{equation*}
w_{A}=\sum_{k \in A} w_{k} \tag{F5}
\end{equation*}
$$

where the sum extends over all those observations that are associated with action set $A$ ) then $F$ is determined as,

$$
\begin{equation*}
F(x)=\sum_{A \in P} w_{A} G_{A}(x) \tag{F6}
\end{equation*}
$$

where the sum is over action sets $A$ that exist within the population, $P$. To estimate the weights, $w_{A}$, usual survey procedures would be used. This would involve adjustments for non-response and possible benchmarking or ratio adjustments using known information of the population being studied. Biases, thus, could be kept at a minimum. Therefore, an advantage of using Equation F6 is that it permits straightforward estimates of the higher percentiles, beyond the range of the data.

## ANALYSIS OF DATA

A total of 1,034 egg product samples were analyzed. Based on MPN results from these 1,034 samples, $74 \%$ were positive; $26 \%$ were greater than 24 MPN; $15 \%$ were greater than 100 MPN, and $2 \%$ were greater than $1,000 \mathrm{MPN}$. Of the 21 MPN results greater than 1,000, 3 were from egg white, 6 from egg yolk, and 12 from whole egg. The 8 highest results are given in Table F1, along with other information collected for the samples, including a randomly assigned plant number identifier.

Table F1 Highest reported mpN values. For results obtained when two sets of analyses were performed, the MPN from the first set is given in parentheses (column 1).

| Highest MPN <br> values (MPN/mI) | Product | Risk <br> Class | Max. age of <br> eggs (d) | Max. age of <br> liquid (h) | Plab \# <br> ld \# | Date <br> (m/yr) |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| $(>11,000)$ | 24,000 | Yolk | 2 |  | 4 | 1302 | 35 |
| $(>11,000)$ | 24,000 | Yolk | 2 | 15 | 24 | 1302 | 67 |
| $(>11,000)$ | 24,000 | White | 2 | 10 | 8 | 1302 | 67 |
| $>11,000$ | Whole | 5 | 14 | 2 | 1302 | 67 | $10 / 02$ |
| 9,330 | Whole | 2 | 15 | 5 | 1302 | 67 | $04 / 02$ |
| 9,330 | Yolk | 2 | 20 | 4 | 602 | 67 | $07 / 02$ |
| 4620 | Whole | 5 | 6 | 1.5 | 2902 | 13 | $08 / 02$ |
| 4270 | Yolk | 2 | 10 | 6 | 1302 | 67 | $12 / 02$ |

If the true level of Salmonella in a sample were $155,000 \mathrm{cfu} / \mathrm{ml}$, there would be about a $1 \%$ chance of observing an MPN result equal to or less than $24,000 \mathrm{MPN} / \mathrm{ml}$, using a 3 -tube, 3 dilution MPN table with appropriate dilutions. It is possible, then, that the true level of Salmonella, in at least one of these samples with a reported MPN of 24,000 , was greater than $10^{5}$ cells $/ \mathrm{ml}$. In addition, because of the absence of $100 \%$ recovery and possible clustering effects, the actual number of Salmonella cells per ml could be higher than this value. FSIS is identifying serotypes in positive sample; thus, while not conclusive, the results of these analyses might provide an indication of possible sources of contamination. If SE serotypes are found more often associated with samples with high MPN results, then this might indicate that the high levels are due to internal contamination of eggs.

## Some factors correlated with MPN levels

Analyses of variances were performed using PC-SAS ${ }^{\circledR}$, release 8.0, PROC GLM procedure.

## Seasonality

Table F2 presents the fractions of the MPN results that were positive, greater than $24 \mathrm{MPN} / \mathrm{ml}$, and greater than $100 \mathrm{MPN} / \mathrm{ml}$, by month of survey and product type. It can be seen that the MPN levels for the whole and yolk egg products are generally higher than those for the white egg products. The fractions of samples greater than 24 and $100 \mathrm{MPN} / \mathrm{ml}$ are lowest for the egg white product; however, the fraction of positive samples is lowest for the yolk product. Note also that the numbers of samples for the first few months of the survey are lower than those of later months.

Table F2 FRaction of MPN Results >0, >25 AND >100 MPN/ML BY SAMPLING DATE.

|  | 1 | 21 | 0.810 | 0.190 | 0.095 | 23 | 0.739 | 0.304 | 0.087 | 18 | 0.667 | 0.167 | 0.000 |
| 2003 | 2 | 23 | 0.739 | 0.217 | 0.130 | 19 | 0.737 | 0.316 | 0.158 | 23 | 0.609 | 0.261 | 0.217 |
|  | 3 | 21 | 0.810 | 0.190 | 0.095 | 23 | 0.652 | 0.261 | 0.174 | 20 | 0.300 | 0.100 | 0.050 |
| All |  | 341 | 0.736 | 0.188 | 0.100 | 375 | 0.800 | 0.293 | 0.179 | 319 | 0.674 | 0.282 | 0.157 |

The fractions are, in general, lower for the first 5 or so months of the survey for the white and yolk egg products, whereas for the whole egg product, there does not appear to be a significant pattern. For the egg white product, there is clear demarcation of fractions between the first 7 months of the survey (October 2002 - April 2003) and the remaining 8 months; for the yolk product, there is a clear difference for the fractions of positive samples between the first 4 months and the remaining months and for the fractions of results greater than 24 and greater than $100 \mathrm{MPN} / \mathrm{ml}$ between the first 6 months and the remaining months.

## Laboratory effect

In Table F1, 6 of the highest 8 MPN values were from samples from a single plant, and 6 were from a single laboratory. The question that needs to be answered is whether there was a significant laboratory effect on the results of the survey. Many factors might contribute to laboratory effects, including differences in reagents, environments, equipment, or analysts. These effects should not be large at any given time, and should, over the period of the survey, average out, so to speak. The three FSIS laboratories were randomly assigned samples in an attempt to assure an equal number of samples per laboratory per week, but with no particular attention being paid to the numbers of samples being assigned to any one plant from one laboratory.

Figures F1a and b present the fractions of samples with MPN $>24$ and 100 by month of survey, for the 3 laboratories. The smoothed curves for the three laboratories are similar, with only a deviation for laboratory 1302 for September to November 2002 for MPN > 24 (lesser so for MPN >100). For these months, 199 samples were analyzed: 60 by laboratory 602, 67 by laboratory 1302, and 72 by laboratory 2902. Analysis of variance and logistic regression for the
fraction of MPN greater than 24, with laboratory as a fixed factor indicated a lab effect with $P$ value $=0.07$, but when comparing laboratory 1302 versus the other two labs, the significance level was approximately 0.025 . However, the significance level using Scheffe's test (for the ANOVA), accounting for the multiplicity of comparisons being considered, was about 0.09 (based on F-statistic with 2 and 196 degrees of freedom).

FIGURE F1A-B FRACTION SAMPLES MPN >24 AND >100 BY MONTH AND LABORATORY (KEY). Smooth line based on normal kernel with band of 3 MONTHS .

Table F4 provides summaries of the fractions of positive samples and the means of $\log _{10}$ (MPN) by laboratory, time of sampling, and type of product. The mean of the $\log _{10}$ (MPN) over all samples for laboratory 1302 is 0.83 , which is between the means for the other two laboratories. The least square means for the percentage of positive MPN results, estimated from the ANOVA model (adjusted means when assuming a balanced distribution of samples over the factors plant, type of product, and time of sampling), for the three laboratories are $70 \%$ (laboratory 602), 71\% (laboratory 1302), and 74\% (laboratory 2902). The least square means of the $\log _{10}(\mathrm{MPN})$ for MPN positive results are 0.87 (laboratory 602), 0.66 (laboratory 1302), and 0.70 (laboratory 2902); and the least square means for the percentage of MPN results greater than 24 are $22 \%$ (laboratory 602), $21 \%$ (laboratory 1302), and $23 \%$ (laboratory 2902). These results suggests the possibility of systematic laboratory differences for samples with low MPN levels, where laboratory 602 is less likely to obtain positive MPN results for low level samples, and laboratory 2902 is more likely to do so. However, the differences appear small; there were no significant laboratory effects in the ANOVA. Selected percentiles of the sample distribution $\log _{10}(\mathrm{MPN})$ results, by laboratory, are given in Table 5.

TABLE F5 SELECTED PERCENTILES OF THE SAMPLE DISTRIBUTION LOG ${ }_{10}(M P N)$ RESULTS, BY LABORATORY.

| Laboratory | No. Samples | Fraction Positive MPN | $\begin{gathered} \text { Median } \\ \text { Log }_{10}(\mathrm{MPN}) \end{gathered}$ | $75^{\text {th }}$ Percentile $\log _{10}(\mathrm{MPN})$ | $90^{\text {th }}$ Percentile $\log _{10}(\mathrm{MPN})$ | $95^{\text {th }}$ Percentile $\log _{10}(\mathrm{MPN})$ |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| 602 | 336 | 0.71 | 0.36 | 1.63 | 2.36 | 2.63 |
| 1302 | 321 | 0.75 | -0.03 | 1.63 | 2.38 | 2.97 |
| 2902 | 378 | 0.75 | 0.02 | 1.36 | 2.36 | 2.63 |

The $90^{\text {th }}$ percentiles are nearly the same for all laboratories, and the highest percentile shown above is largest for laboratory 1302, due in part to the large number of samples analyzed by this laboratory from the "worst" plant ( $67^{\mathrm{b}}$ ). Of the 28 samples from this plant, 15 were analyzed by laboratory 1302, 7 by laboratory 602, and 6 by laboratory 2902. On the other hand, of the 31 samples from the "best" plant (where 2 of 31 samples were MPN positive), 7 were analyzed by laboratory 1302, 10 by laboratory 2902, and 14 by laboratory 2902 (which had the 2 positive samples with MPN values reported to be 0.43 and 2.31). During the 3 -month period September to November 2002, 5 samples from Plant 67 were analyzed, 4 by laboratory 1302. The MPN value from the one sample not analyzed by lab 1302 was 427 . The 4 MPN values obtained by lab 1302 from this plant were (by date of collection) 7.4, >11,000 (the highest egg white MPN value in the survey), 2,400 , and 2,400 (the last two samples being collected on the same day). The laboratory also analyzed a third sample (egg white) collected on the same data as the last two samples and obtained a value of 0.036 . This allowed us to eliminate entertaining the possibility of a systematic lab effect for samples collected on that day.

One peculiar set of results was obtained from laboratory 1302 for a three-month period in which the results were on the average higher than those of other laboratories. However, this event was likely happenstance, a sort of pattern that can readily occur during a long survey. We were unable to attribute it to any sort of systematic error. We conclude that there were not systematic laboratory effects in the survey.

## Plant effects

There are analytical results from 70 plants where the numbers of samples per plant range from 2 to 33 , and, with the exception of the highest 3 numbers (30, 31, and 33), are approximately uniformly distributed over the plants. That there might be plant effects can be seen by examining the highest MPN results in Table 1, where 6 of the 8 were from one plant (plant 67). Summary data for all plants are given in Table 6. About $50 \%$ of the plants had $80 \%$ or more samples with positive MPN results. For plant 67, all but one of 28 results were positive; $60 \%$ of the results were greater than $100 \mathrm{MPN} / \mathrm{ml}$, and $36 \%$ of the results were greater than $1,000 \mathrm{MPN} / \mathrm{ml}$. For comparison, plant 4 had two positive results ( 0.43 and $2.31 \mathrm{MPN} / \mathrm{ml}$ ) out of 31 samples. The sampled products from both plants were predominantly risk category 2 , and both plants had

[^1]samples of the three product types. One clear difference among the samples for the two plants was the age of the liquid product sampled; for the "best" plant, the ages were recorded as 2 hours for all the samples, whereas for the "worst" plant, the ages generally were higher, between 0.5 hours and 24 hours (one of the two highest MPN results ( $24,000 \mathrm{MPN} / \mathrm{ml}$ ) was for the 24 -houraged sample). However, even the MPN results for liquid samples that were recorded at 0.5 and 2 hours-old in this plant were high: $42.7 \mathrm{MPN} / \mathrm{ml}$ and $>11,000 \mathrm{MPN} / \mathrm{ml}$, respectively. Therefore, age of liquid product itself does not explain the high results for this plant.

Analyses of variances yielded highly significant plant effects ( $P$-value $<0.0001$ ) in all analyses, with the following independent variables: plant; type and risk category of product; time of sampling; laboratory; and with interaction of these, and dependent variables: $\log _{10}(\mathrm{MPN})$; and indicator variables of whether the MPN exceeded 0,24 , or 100 . The consequence of the plant effect is that volume of production may be an important factor for estimating the distribution of the Salmonella levels in the product before pasteurization.

## Risk Category

Besides type of product, samples were categorized with respect to processing history. There were 5 "risk" categories of product, as explained above. Table F7 provides the fraction of MPN positive results and MPN results $>100$, by risk category, type of product, and time of sample (where early = 2001 and the first four months of 2002 and later = the remainder). It is seen that the higher fractions of MPN $>100$ belong to risk categories 1 and 2 . Because product from these risk categories was shipped from one plant to another, there may have been some additional growth of Salmonella. For samples from risk category 1, the fractions of positive samples are the highest. Ignoring samples for risk category 3 (due to the small number of them), samples of risk
category 2 showed the smallest number of positives. The relatively low fraction of positive MPN and relatively high fraction of large MPN results for samples in risk category 2 can be explained in part from the above discussion for plants: the "best" and "worst" plants had samples identified as risk 2 product; and for plant 69, 6 of 17 risk category 2 samples were positive; and for plant 53, only 1 of 8 risk category 2 samples were positive.

Another point of interest is that the differences between the early and late periods of the survey are evident for the risk category 2 , egg white and yolk product, for both fractions given in Table 7, and for risk category 1 product for the fraction of MPN $>100$. The KS test for a nonuniform pattern was significant at the 0.01 level for the egg white product for positive MPN and MPN $>24$. However, in analysis of variances, combining the risk 1 through 3 category samples into one super risk class (srisk = 1), and the other samples into another super risk class (srisk $=$ 2), the srisk variable was not significant (at better than the 0.10 level) for any model attempted that included plant and type of product factors. That is, when the indicators of positive MPN, MPN $>24$, MPN $>100$, and the $\log _{10}($ MPN ) were the dependent variables, and plant, type of product, time of sampling, srisk, and interactions of these, were the independent variables, the srisk variable by itself or interacting with other terms were not significant (type III significance). Plant, type of product, and the interaction of type of product were significant in all models, and in some models, the time of sampling was significant. The "significance" of the risk category is seen when ignoring all effects except srisk and type, in which case both variables are significant, but with the type of product effect more so. Table F8 gives the least square means for the dependent variables from the model, ignoring the plant effect, with type of product and srisk as main effects (the interaction terms were not significant).

Table F7 Fractions of MPN positive and >100 by type, risk category and period of SAMPLE COLLECTION. EARLY $=2001$ AND 2002 UP TO APRIL 30. LATE $=$ MAY 2002 THROUGH MARCH 2003.

Fraction of Samples with:

|  | MPN + | MPN $\mathbf{~} \mathbf{2 4}$ | MPN >100 | $\mathbf{L o g}_{10}(\mathbf{M P N})$ |
| :--- | :---: | :---: | :---: | :---: |
| Product Type |  |  |  |  |
| White | 0.737 | 0.187 | 0.099 | 0.588 |
| Whole | 0.802 | 0.292 | 0.177 | 0.985 |
| Yolk | 0.678 | 0.280 | 0.153 | 0.993 |
| Risk Category |  |  |  |  |
| 1, 2, and 3 | 0.713 | 0.265 | 0.165 | 0.952 |
| 4 and 5 | 0.765 | 0.242 | 0.121 | 0.759 |

The fraction of positive samples, MPN >24, and MPN >100 are not as different between the 2 super risk categories as they are among the 3 product types. The primary difference for the type of products is between the egg white product and the others for the measured levels for positive samples. For example, the average $\log _{10}(\mathrm{MPN})$ for the eggwhite positive samples is approximately $0.4 \log _{10}$ lower than the averages for the samples of other two types of products.

## Age of egg and liquid product effects

One difference between the "best" and the "worst" plants identified above was the age of liquid product before pasteurization. It would be expected that egg age and liquid product would have an effect on Salmonella levels. One aspect of the data that confounds the analysis is that recorded ages represent maxima; many plants use eggs from different sources in unknown amounts. In addition, the true effect of these variables cannot be determined from survey data because of the possible confounding of other factors associated with actions by the plants and farms, as well as other unknown random or contingent factors. Nevertheless, over many observations, differences associated with the ages of the eggs and liquid product might be seen.

There were 266 samples for which the ages of the eggs were not recorded and 146 samples for which the age of the liquid product was not recorded. One missing value for the liquid egg product came from plant 4, in which the other 30 samples were reported as being 2 hours old for liquid product; thus, for the missing value, a value of 2 hours was assigned. Tables Fa and F9b provide the fractions of MPN values $>24$, and the means of the $\log _{10}($ MPN $)$ for samples by the maximum age of the eggs used and by the maximum age of the liquid product used, for the 2 super risk categories of product. The results show that younger eggs and liquid product have a greater likelihood of lower MPN levels before pasteurization. Specifically, samples from eggs $\leq$ 1 day old and liquid product $\leq 3$ hours old had lower than average MPN values. Samples were
classified as whether the ages of the eggs were $\leq 1$ day, or whether the age of the liquid was $\leq 3$ hours. If $<30 \%$ of the plants data regarding age of eggs or liquid product were missing and the age classifications were the same for the non-missing data, then the common age classification was imputed for the missing data.

Tables F10a and F10b provide fractions of MPN >24, for whole and yolk egg product, and whether ages of eggs and liquid product satisfy the above conditions. The results show a greater difference associated with the age of the liquid product being $>3$ hours old than is associated with the age of the egg being $>1$ day old. This, of course, is not a surprising finding since Salmonella grows more rapidly in yolk product than in albumen. Differences observed for whole and yolk product samples were not observed for egg white product samples.

Table F9a Fractions of MPN values >24, and the means of the $\operatorname{LOG}_{10}(\mathrm{MPN})$ For positive MPN SAMPLES, BY MAXIMUM AGE OF EGG.

|  | Risk Category |  |  |  |  |  |  |  |  |

TABLE F10A ANd F10b FRACTIONS OF MPN >24 AND 100, FOR WHOLE AND YOLK EGG PRODUCT, AND WHETHER AGES OF EGGS AND LIQUID PRODUCT SATISFY THE SPECIFIED CONDITIONS.

The above analyses indicate age of liquid product is correlated with MPN levels, particularly for yolk and whole egg product. Figure F2 is a plot of the $\log _{10}(\mathrm{MPN})$ versus $\ln (1+$ age of liquid product) by product type. For the purposes of the plot, when MPN was non-detect, a value of -2 was assigned.

FIgure F2 Plot of THE LOG 10 (MPN) VERSUS LN(1 + AGE OF LIQUID PRODUCT) BY PRODUCT TYPE. MPN NON-DETECT IS SHOWN AS A VALUE OF -2. THE VERTICAL LINE IS AT 3 HOURS AND THE OTHER SOLID LINE IS A SMOOTHED LINE USING A NORMAL KERNEL WITH BANDWIDTH 1, OF THE LOG ${ }_{10}(\mathrm{MPN})$ VERSUS LN(1 + AGE), PRODUCED BY THE S-PLOT PROCEDURE.

The relationship of MPN with liquid product age beyond three hours is not as pronounced as within the first few hours. The lack of an observed relationship beyond a certain number of hours does not imply that age is not important for relatively large ages, but rather that there may be other factors that need to be taken into account for explaining the data.

## Sample location - valve effect

In an effort to ensure that egg product samples represented product at the time immediately before pasteurization, if samples had to be collected from valves or spigots, collectors were instructed to "let sufficient liquid pass from the nozzle to ensure that the sample represents product that is in the tank, not in the valve." We were concerned that samples taken from valves or spigots would be contaminated by a build up of bacteria within them.

Among the 1,035 samples, 30 did not include information about the location of sample collection; 160 did not include the words valve or spigot in their sample location descriptions; and the remaining 845 had at least one of these words in their sample location descriptions. Most of the samples that were not collected from a valve came from risk category 1 product. Many of the missing values were from plants for which almost all other samples had information. Thus, imputed values for missing data were made if all samples with known information from a plant, either from risk category 1 or from the other risk categories, as appropriate, had the same classification. After the imputations, there were 13 samples for which information was missing, 161 that were designated not to have been collected from a valve, and 861 samples that were designated to have been collected from a valve.

Because of the plant effect, for determining the significance of a "valve" effect, the plant variable needs to be accounted for in the analysis. The summaries in Table 11 are results for risk category 1 product from plants that had samples collected from (i) valves and (ii) not valves. Differences of the fractions of positive MPN, MPN $>100$, and MPN $>1,000$, and means of the $\log _{10}$ (MPN) between valve and non-valve sample results (valve - nonvalve) are small or are negative, and are not statistically significant (through analyses of variance with plant as a fixed effect). The most notable differences are for the: (i) 'MPN $>1,000$ ' samples, where for the risk categories 2-5, whole egg products, only samples collected from valves had MPN results $>1,000$; however, of the 83 'risk categories $2-5$, whole products' samples collected from valves, 4 ( $4.8 \%$ ) had MPN values $>1,000$. With only 31 samples within this group that were not collected from a valve, it is not possible to infer a significant effect; and (ii) MPN >100 samples, where for the risk categories $2-5$, yolk egg products, only samples collected from valves had MPN results $>100$; however, of the 95 'risk categories 2-5, yolk products' samples collected from valves, 9 ( $9.47 \%$ ) had MPN values greater than 1,000 . With only 14 samples within this group that were not collected from a valve, it is not possible to infer a conclusion of a significant effect. Even combining the two combinations, the significance of the valve effect, based on $9+4=13$ 'positive' results from 178 samples collected from valves, versus no 'positive' results from 44 samples not collected from valves, results in Fisher's exact test significance at the 0.05 level, which is not definitive evidence of a valve effect.

To explore the relationship of MPN levels and valves, two additional analyses were performed: (i) an analysis of the relationship of the maximum MPN within a plant and the incidence variable, "Valve," defined as equal to 1 when the sample was from a valve, and zero otherwise "Valve"; and (ii) an analysis of the within-plant correlations of the MPN and the variable "Valve." Both analyses did not produce significant evidence suggesting a systematic valve effect. The details of these analyses are presented in Attachment 1 to this annex.

The lack of a detectable systematic valve effect does not preclude valve effects occurring sporadically for some plants. Attachment 1 presents a summary of the high MPN values by plant, regarding whether they were from samples collected through valves. Three plants that had samples both collected from valves and non-valves, with ID numbers 5, 12, and 60, in particular, can be seen to have had high MPN values associated with valves. For plant 5, with 23 samples of which 15 were from valves, the 6 samples with the highest MPN results, ranging from 147 to 2.4 MPN/ml, were collected from valves (which, by the hypergeometric distribution has a 0.05 probability, thus reflecting the probability that there would be at least a run of 6 of the highest MPN results being from samples collected from valves), while there were also 4 samples from valves that had a non-detect MPN. For plant 12, with 28 samples of which 9 were from valves, the 2 samples with the highest MPN results, 427 and $24 \mathrm{MPN} / \mathrm{ml}$, were collected from valves, and 3 of the top 4 MPN values were from samples collected from valves. And for plant 60, with 7 samples of which 3 were from valves, the 2 samples with the highest MPN results, 2,400 and 14.9 MPN/ml, were collected from valves, while 1 sample collected from a valve had a nondetect MPN.

In conclusion, only a small percentage of samples were not collected through valves, and thus it is difficult to conclude that samples collected from valves, given everything else being equal, would typically have higher Salmonella levels than those that were not. Some exceptions might exist. Since there does not appear to be a clear systematic valve-effect (Table F11), all data were used in the following analysis.

Table F11 Fraction (Frac) of MPN results >0, 100, and 1,000, and the average of the LOG $_{10}$ (MPN) FOR POSITIVE MPN VALUES. FOR EACH ROW, RESULTS ARE FROM SAMPLES THAT WERE COLLECTED IN PLANTS FOR WHICH BOTH VALVE AND NON-VALVE SAMPLES WERE OBTAINED.

## Estimation Procedures

## Construction of sample weights

The above analyses suggest plant and type of product are the "most" significant factors. Time of sampling, age of eggs and liquid product, and risk category also affect the results, but clearly, the most important variable is the plant, as seen by examining results for plants 4 and 67. Ideally, Asets could be defined for each plant; however, the numbers of samples for each plant are too small to expect reliable estimates of the distribution of Salmonella levels. For equation F6, it is not practical to determine distributions for each plant separately. Thus, Equation F6 is used, combining all the data over the plants. If a good fit is achieved using a simple distribution, reasonable estimates of percentiles within the range of the data would be provided. Equation F6 will be considered for each of the product types by super risk categories, designated by the variable, srisk, where srisk = 1 for samples from risk categories 1,2 , and 3, and srisk $=2$ for the other samples. Observations are weighted taking into consideration the production volume of the plants for the type of product, and the time of sampling.

FSIS collected production volume information from each plant, for every month over the life of the survey. The collected information included production volume for white, whole, and yolk products, by whether the product was received by the plant, or whether it was processed originally within the plant. However, there was a difficulty in interpreting the production volume numbers. Often times the production volume for incoming product was not reported or reported as zero while samples from risk categories 1 , 2 or 3 were collected from plants; and, much fewer times, the production volume for in-plant product was not reported or reported as zero while samples from risk categories 4 or 5 were collected from plants. Weighted estimates of the distributions, consequently, are made only when combining all results within a product type. These estimated distributions are used in the risk assessment.

Recall (Table F2) that the numbers of monthly samples were slightly less than average for the first few months of the survey, and the percentages of positive samples for white and yolk product categories tended to be lower than their respective category averages for the first few months of the survey. To help mitigate possible biases that might arise because of these trends, sample results were weighted differentially by time of period for the white and yolk egg product categories. Weights for each sample result for these two categories were computed for the first 5 months or the last 13 months of the survey, as appropriate for the sample. The weight for a result from a sample collected from an establishment $(k)$, within the first 5 months of the survey $(j=1)$ or the last 13 months of the survey $(j=2)$ is proportional to: $V_{k j} / n_{k j}$, where $V_{k j}$ is the total production volume and $n_{k j}$ is the number of samples for the $k^{\text {th }}$ establishment within the $j^{\text {th }}$ period, for the white or yolk product category, as appropriate. If, for a given plant, there were no samples for a period, and for all samples of whole egg product, the weight for that plant's samples was determined by using the total plant's production divided by the total number of samples.

For sample results for whole product, no weight adjustment for the different periods of the survey was needed since there does not appear to be a trend to the degree that trends occurred for the other product categories; thus, the weights for results within the whole product category are
proportional to the production divided by the number of samples for the particular establishment. To estimate the distribution $\mathfrak{I}$ using Equation F6, the error distribution from Equation F2 of the MPN measurements need be specified.

## More detailed account of the use of the results obtained from the MPN procedure

To compute an MLE of parameter values defined in Equation F6, for each reported MPN value, the pattern of the 18 results associated with the 6-dilution, 3-tube MPN procedure needs to be determined. For the analysis presented in this report, the following procedure was used for assigning a pattern to the reported MPN result. The reported MPN value corresponds to a pattern of positive results for a 3-tube, 3-dilution MPN, $a b c$, where $a$ represents the number of positives in the lowest dilution (largest volume of sample); $b$ represents the next lowest dilution; and $c$ represents the highest. For dilutions higher than that of the $c$ result, a value of 0 was assigned; for dilutions lower than that of the $a$ result, a value of 3 was assigned. For example, an assumed pattern could be $33 a b c 0$, or $a b c 000$, or $333 a b c$, and so forth. If all tubes were negative, then a non-detect was reported, corresponding to a pattern of 000000 . The highest reported result was $24,000 \mathrm{MPN} / \mathrm{ml}$ (twice) and there was one reported value of $23,100 \mathrm{MPN} / \mathrm{ml}$. These results from second sets of analyses and the one reported as $\gg 11,000 \mathrm{MPN} / \mathrm{ml}$, however, were assigned a pattern 333 333. Thus, an MPN value corresponds to a unique 6 -tuple vector.

Let $P_{0}(V, r)=e^{-r V}$ be the probability of a negative result in a tube containing a volume $V$ of sample material, assuming a "true" level of $r$ uniformly distributed throughout the sample; $V_{j}, j=$ $1,2, \ldots, 6$, be the volumes of the sample material in the 6 dilutions used for determining the MPN value; and $x_{j}, \mathrm{j}=1,2, \ldots, 6$ be the number of positive tubes from among the $n_{j}$ tubes of volume $V_{j}$. The assumption for $P_{0}$ is reasonable, since the highest volume in a given tube of sample tested was 10 ml and the total sample consisted of 200 ml . Assume $x$ corresponds to the vector $x=$ $\left(x_{1}, \ldots, x_{6}\right)$ and that $\gamma(x \mid r)$ is the probability of obtaining a vector $x$, corresponding to a $\operatorname{MPN}(x)$ value. Using the binomial distribution, the probability of the obtaining a result $x, \gamma(x \mid r)$, is given as:

$$
\begin{equation*}
\gamma(\mathrm{x} \mid \mathrm{r})=\prod_{\mathrm{j}=1}^{6}\binom{\mathrm{n}_{\mathrm{j}}}{\mathrm{x} j}\left(1-\mathrm{P}_{0}\left(\mathrm{~V}_{\mathrm{j}}, \mathrm{r}\right)^{\mathrm{X}_{\mathrm{j}} \mathrm{P}_{0}\left(\mathrm{~V}_{\mathrm{j}}, \mathrm{r}\right)^{\mathrm{n}_{\mathrm{j}}-\mathrm{x}_{\mathrm{j}} .} . . . . .}\right. \tag{F7}
\end{equation*}
$$

The MPN is the MLE estimate using Equation F7. That is, the MLE estimate, A, satisfies the following equation:

$$
\begin{equation*}
\sum_{j=1}^{6} \frac{v_{j}\left(x_{j}-n_{j}\left(1-e^{-v_{j} \tilde{\tilde{r}}}\right)\right)}{1-e^{-v_{j} \tilde{i}}}=0 . \tag{F8}
\end{equation*}
$$

A rough approximation of the variance of the MLE is determined from the negative of the inverse of the second derivative of the log-likelihood equation using Equation F7, with respect to $r$, evaluated at the MLE. Thus, the variance of the MLE can be approximated as:

$$
\begin{equation*}
\operatorname{Var}(\hat{r}) \approx \frac{1}{\sum_{j=1}^{6} \frac{x_{j} v_{j}^{2} e^{-v j \hat{j}}}{\left(1-e^{-v} \hat{j}^{r}\right)^{2}}} \tag{F9}
\end{equation*}
$$

where $A$ is the MLE. Confidence intervals can be formed for $\ln ($ MPN ) by assuming that MPN is distributed as a lognormal distribution with variance of $\ln (M P N)$ equal to $\operatorname{Var}(A) / A^{2} .{ }^{4}$. Such confidence intervals, however, may not provide accurate coverage for 3-tube, 3-dilution MPN determinations. For the example given above, for the 3-tube, 3-dilution 2,400 MPN value (with a pattern of 333330 ), the standard error of $A$ is 1,743 and the upper $99^{\text {th }}$ confidence limit using the above approximation is estimated to be 13,000 , which is slightly less than the 15,500 limit estimated using a direct calculation. To assure an accurate calculation when estimating the distribution of levels using Equation F6, the probability distribution for the assigned pattern of positive tubes is used.

A few of the higher reported MPN values might have been based on second sets of analyses. The two results with reported MPN/ml of 24,000 were second analyses determined from a 7 ilution MPN; the reported result of $23,100 \mathrm{MPN} / \mathrm{ml}$ was a second set of analyses from an 8 dilution MPN. In all these cases, the $7^{\text {th }}$ dilution tubes were negative. As mentioned above, these second sets of analyses may provide negative biased results. Hence, it is possible that the MPN levels in the samples are greater than those implied by the pattern of results of the second set. We believe the bias is no more than 10 -fold ( $1 \log _{10}$ decrease), corresponding to at most a $90 \%$ reduction in the Salmonella cells of the sample materials that were analyzed the second time. If this assumption were true, then $7^{\text {th }}$ dilution tubes being all negative on samples that had been stored for an unknown number of days implies that it would not be likely that, from the unstored, original sample, a positive result from an $8^{\text {th }}$ dilution tube would be possible. Thus, the second sets of analyses are important for determining an upper bound of possible levels. In the analysis presented below, it was assumed that the obtained pattern 333333 on a first set of analyses, resulting in a reported MPN $>11,000$, would have resulted in no positives for $10^{\text {th }}$ dilution tubes if such dilutions were tested. In other words, the likelihood associated with a 333333 pattern is determined by adding the probabilities for the patterns, $333333 x y z$, where $0 \leq x, y \leq 3$, and $z \leq 3$.

## Estimating a distribution using Equation F4

Examining the estimate of distributions obtained with Equation F4 helps determine distributions to use in Equation F6. An unweighted analysis is performed so that the weights, $w_{k}$, are set equal to $1 /(n+1)$, where n is the number of observations for a given product type. To help determine a simple function to fit the cumulative distribution function (cdf), plots of the log-log transformation of the estimated cdf, $\rangle(x)$ derived from Equation 4, $\ln (-\ln (1-\rangle(x))$, versus $\ln (x)$ where $x$ ranges over the positive MPN values, and the linear regression lines that are given in Figure F3, for the product types and super risk categories. The linear regression lines provide reasonable good fits, suggesting fitting a Weibull distribution,

$$
\begin{equation*}
W(x \mid b, c))=1-e^{-(x / c)^{b}} \tag{F10}
\end{equation*}
$$

where $b$ is the shape parameter and $c$ is the location parameter, for the cdf for each product type ${ }^{c}$. From the linear regression, values of $b$ and $c$ are derived (see Table F12), together with the $99^{\text {th }}$ percentile of the estimated Weibull.

TABLE F12 DERIVED VALUES OF PARAMETERS $B$ AND $C$ FOR WEIBULL DISTRIBUTION USING (UNWEIGHTED) SAMPLE CUMULATIVE DENSITY FUNCTION AND LINEAR REGRESSION.

| Yolk | $4-5$ | 135 | 144 | 0.257 | 7.076 | 2696 | 4653 | 13063 |
| Yolk | All | 319 | 398 | 0.214 | 5.712 | 7207 | 13883 | 47983 |

For the whole and white egg products, the two distributions are similar, with the risk categories 1 and 2 having slightly higher estimated percentiles than the corresponding ones for the other risk categories. Combining the results from the two super risk categories provides an estimated distribution close to the individual estimated distributions. However, for the yolk product this last statement is not true. In any case, using all the data, the Weibull distribution provides a good fit for the yolk product (not shown), and thus, would be representative of the levels of Salmonella in consumed product if for the risk categories the proportions of consumed of product are the same as that of the volume produced.

[^2]

FIGURE F3 PLOT OF LOG-LOG TRANSFORMATION OF (UNWEIGHTED) CUMULATIVE DISTRIBUTION FUNCTION, (LN(-LN(1-CDF)) VERSUS LN(MPN), ESTIMATED USING EQUATION F4, BY PRODUCT TYPES AND SUPER RISK CATEGORIES, TOGETHER WITH LINEAR REGRESSION LINES. SUPER RISK CATEGORY 1 CONSISTS OF SAMPLES FROM RISK CATEGORIES 1 AND 2; SUPER RISK CATEGORY 2 CONSISTS OF SAMPLES FROM RISK CATEGORIES 3 THROUGH 5.

## ESTIMATING A DISTRIBUTION USING EQUATION F6

$G_{A}$ will be estimated for each product type and super risk category, assuming equal weights and weights proportional to production volume for the observations. If $W(r \mid b, c)$ is the assumed distribution of the levels of Salmonella spp. within the liquid product, then the likelihood of an observation (pattern of positive and negative tubes) is

$$
\mathrm{L}(\mathrm{x} \mid \mathrm{b}, \mathrm{c})=\int_{0}^{\infty} \gamma(\mathrm{x} \mid \mathrm{r}) \mathrm{dW}(\mathrm{r} \mid \mathrm{b}, \mathrm{c})
$$

where $\gamma(x \mid r)$ is the probability of obtaining the pattern $x$, given $r$. If there are $n_{x}$ measured results with the same pattern $x$, the $\log$ of the likelihood, $H(\theta)$ that is to be maximized is

$$
\begin{equation*}
H(\theta)=\sum_{x} n_{x} \ln (L(x \mid \theta) \tag{F12}
\end{equation*}
$$

where $L(x \mid \theta)$ is given in Equation F11 and $\theta=(b, c)$. The MLE estimates of $\theta$ are derived using the Newton-Raphson procedure, iterating until changes in the estimates were less than $10^{-9}$. For the weighted analysis, instead of the number of samples, the sum of the weights, $w_{k}$, of samples with MPN pattern $x$ is used.

Two functional forms for $W$ were considered: the Weibull and the lognormal. For the Weibull function, a transformation of the above function was used to simplify the calculations. Namely, the Weibull was expressed as

$$
\begin{equation*}
\mathrm{W}(\mathrm{r} \mid \mu, \mathrm{s})=1-\exp (-\exp ((\ln (\mathrm{r})-\mu) / \exp (\mathrm{s}))) \tag{F13}
\end{equation*}
$$

where $\mu$ and $s$ are parameters, so that $b=\exp (-s)$ and $c=\exp (\mu)$. Estimating $\mu$ and $s$ avoids boundary conditions for the estimates of the parameters $b$ and $c$. An estimate of the covariance matrix of $\mu$ and $s$ is derived using the inverse of the negative of the Fisher information matrix, [$\left.M^{2} H(\theta) / M \theta^{2}\right]^{-1}$, estimated at $\theta_{0}$. The unweighted MLE's, their standard errors and correlations, and estimates of the selected percentiles of the distribution are given in Table F13. Figure F4 shows plots of the sample cdf versus the estimated cdf for the different product types.

TABLE F13 MLE EStimates (UNWEIGHTEd) OF WEIBULL DISTRIBUTION PARAMETERS (EQUATION F13), WITH ESTIMATED SELECTED PERCENTILES, WITH 97.5\% UPPER CONFIDENCE BOUNDS, FOR DIFFERENT PRODUCT TYPES. FIGURE F4 UNWEIGHTED SAMPLE CUMULATIVE DISTRIBUTION FUNCTION (CDF) AND THE ESTIMATED CDF OF THE WEIBULL DISTRIBUTION, USING MLE, FROM EQUATION F6 FOR DIFFERENT PRODUCT TYPES. THE X-AXIS REPRESENTS THE NATURAL LOG OF THE MEASUREMENTS, GIVEN IN UNITS OF CFU/ML.

The estimates of the expected values and selected percentiles from Table F13 are slightly less than those from Table F12 derived using Equation F4. This is expected, insofar as the estimates from Table F12 represent the distribution of the observed results, $X$, whereas, the estimates of Table F13 represent the distribution of the underlying true levels, after accounting for the analytical error of the MPN measurement.

As a comparison, a lognormal distribution, with density function

$$
\begin{equation*}
\mathrm{f}(\mathrm{r} \mid \mu, \sigma)=\frac{\mathrm{e}^{-((\mathrm{ln}(\mathrm{r})-\mu) / \sigma)^{2}}}{\mathrm{r} \sigma \sqrt{2 \pi}} \tag{F14}
\end{equation*}
$$

where $\mu$ is the mean and $\sigma$ is the standard deviation of $\ln (r)$, was assumed and MLE estimates were calculated. The MLE estimates, their standard errors, and estimates of the $99^{\text {th }}$ percentile, are given in Table F14. Figure F5 shows plots of the sample cdf versus the estimated cdf for the different product types.

Table F14 MLE (UNWEIGHTED) OF LOGNORMAL DISTRIBUtion PARAMETERS, WITH EStimated 99th PERCENTILES FOR DIFFERENT PRODUCT TYPES.

| Type | Mean <br> $\ln (\mathbf{l e v e l} / \mathbf{m l})$ | $\boldsymbol{\operatorname { l n } ( \boldsymbol { \sigma } )}$ | 99 <br> th <br> Percentile | Upper <br> Confidence <br> Limit | Std Error <br> Mean | Std Error <br> $\boldsymbol{I n}(\boldsymbol{\sigma})$ | Correlation <br> of Mean <br> and $\boldsymbol{s}$ |
| :--- | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| White | -0.802 | 1.482 | 12515 | 35064 | 0.256 | 0.050 | -0.198 |
| Whole | 0.523 | 1.468 | 41072 | 105941 | 0.235 | 0.045 | -0.136 |
| Yolk | -0.858 | 1.669 | 97638 | 358122 | 0.324 | 0.054 | -0.240 |

From a close comparison of Figures F4 and F5, it is seen that Weibull distribution provides a better fit to the observed data. For example, the percentiles between the median and $90^{\text {th }}$ percentile of the estimated lognormal distribution are less than the corresponding sample percentiles, whereas in that range there does not appear to be any significant biases associated with those of the estimated Weibull distribution. The estimated $99^{\text {th }}$ percentiles for the two assumed distributions are quite different. For example, the estimated $99^{\text {th }}$ percentiles using the lognormal distribution are approximately 5 to 10 times higher than the estimated $99^{\text {th }}$ percentiles using the Weibull distribution.

FIGURE F5 UNWEIGHTED SAMPLE CUMULATIVE DISTRIBUTION FUNCTION (CDF) AND THE ESTIMATED CDF OF THE LOGNORMAL DISTRIBUTION, USING MLE, FROM EQUATION F6 FOR DIFFERENT PRODUCT TYPES.

## Weighted estimates of distribution

Comparison of the estimates of the parameter values of the Weibull distribution of levels, and selected percentiles for product types for weighted and unweighted data are given in Table F15.

TABLE F15 Estimates of the parameter values of Weibull distribution, comparing weighted and unweighted data.

| Type | Method | b-shape <br> (Power) <br> Parameter | c <br> Location Parameter | Expected Value | $\begin{gathered} 99^{\text {th }} \\ \text { Percentile } \end{gathered}$ | Upper 97.5\% Confidence Limit | $99.5^{\text {th }}$ <br> Percentile | Upper $97.5 \%$ Confidence Limit | $99.9^{\text {th }}$ <br> Percentile | Upper 97.5\% Confidence Limit |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| White | Unweighted | 0.239 | 3.168 | 99 | 1864 | 3564 | 3348 | 6670 | 10135 | 21949 |
| White | Weighted | 0.301 | 9.028 | 83 | 1446 | 2447 | 2304 | 4029 | 5565 | 10389 |
| Whole | Unweighted | 0.256 | 11.779 | 243 | 4545 | 8101 | 7852 | 14509 | 22091 | 43904 |
| Whole | Weighted | 0.287 | 14.027 | 160 | 2885 | 4815 | 4705 | 8099 | 11866 | 21743 |
| Yolk | Unweighted | 0.206 | 4.371 | 408 | 7210 | 15732 | 14234 | 32682 | 51541 | 131163 |
| Yolk | Weighted | 0.236 | 8.433 | 287 | 5383 | 10743 | 9740 | 20320 | 29905 | 68214 |

From Table F15 it is seen that the estimated distribution using the weighted data has lower higher percentiles that those, using the unweighted data. The above estimates (Table F15) include all the data (with the exception of one unusual MPN pattern and two results from plants with zero production volume for liquid products). However, as discussed above in the section on sample location, while there does not appear to be a systematic valve effect, it cannot be dismissed that a valve effect might have occurred on some occasions. Within particular plants this possibility might be higher than in other plants. If this were true then a reasonable candidate for which this effect had manifested itself is plant 67 that had 6 of the highest 8 MPN values. The estimates of the parameter values of a Weibull distribution without and without the results from plant 67 are given in Table F16. The estimated expected value for the yolk egg product distribution when results from plant 67 are not included is about $30 \%$ less than that when the results are not included (approximately $0.15 \log _{10}$ units). For the other type egg products the decreases are modest, about 10\%.

TABLE F16 Estimates of the parameter values of Weibull distributions, using weighted DATA, COMPARING ESTIMATES WITH AND WITHOUT RESULTS FROM PLANT 67.

## Estimates of distributions for subsets of data defined by age of eggs and liquid product.

The weighted estimated Weibull distribution with parameter estimates given in Table 15 are used in the risk assessment. However, it is of particular interest to estimate the distributions for subsets of the data defined by age of eggs and liquid product. As noted above, the age of the eggs and liquid product used seemed to affect the levels of Salmonella. For the whole and yolk liquid egg products, estimates of the distribution were made for the following subsets of data, with the number of results in parentheses for whole and yolk liquid egg product, respectively: (i) samples for which the liquid product were more than 3 hours old (262 and 229); (ii) less than or equal to 3 hours old (100 and 79); 3) eggs more than 1 day old and liquid egg product more than 3 hours old (129 and 103); 4) the other samples not satisfying the condition for (iii) (93 and 82). Table 17 gives the estimated means $\left(=c \Gamma\left(1+b^{-1}\right)\right)$, $99^{\text {th }}$ percentiles, and $97.5 \%$ upper confidence bounds of the estimated $99^{\text {th }}$ percentiles, where the upper limits were calculated assuming asymptotic normal distributions of the parameter estimates from Equation 13.

Table F17 Estimated means, $99^{\text {TH }}$ PERCENTILES, AND 97.5\% UPPER CONFIDENCE LIMIT OF THE EStimated $99{ }^{\text {TH }}$ PERCENTILES, USING WEIBULL DISTRIBUTION FOR LIQUID WHOLE AND YOLK PRODUCT USING VARIOUS SUBSETS OF DATA.

|  | Type |  |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | Whole |  |  | Yolk |  |  |
|  |  |  | 97.5\% |  |  | 97.5\% |
|  |  | 99 ${ }^{\text {th }}$ | Upper Limit of $99^{\text {th }}$ |  | 99 ${ }^{\text {th }}$ | Upper Limit of $99^{\text {th }}$ |
| Data | Mean | Percentile | Percentile | Mean | Percentile | Percentile |
| Liquid Age $\leq$ |  |  |  |  |  |  |
| 3 H | 304.8 | 4828 | 21846 | 20.0 | 295 | 1683 |
| Liquid Age > |  |  |  |  |  |  |
| 3 h | 202.7 | 3541 | 6386 | 353.4 | 6625 | 14311 |
| Egg Age $\leq 1$ d or Liquid |  |  |  |  |  |  |
| Age $\leq 3 \mathrm{~h}$ | 164.2 | 2869 | 9530 | 34.7 | 568 | 2258 |
| Egg Age >1 d and Liquid |  |  |  |  |  |  |
| Age >3 h | 264.0 | 4623 | 9710 | 337.2 | 6153 | 15206 |

The results from Table F7 show that for yolk product there is an effect of age of liquid product on the levels of Salmonella, where, the average levels for the samples with liquid product $<3$ hours is more than $1 \log _{10}$ less than the levels for the other samples. The age of the egg, however, does not seem to have a large effect on the results. For the whole egg product, the situation is not as clear: the subset with egg age being $>1$ day and liquid product age being $>3$ hours shows slightly higher levels than the levels of the other subsets.

## Assumptions used for modeling

The level or number of Salmonella cells per ml, $x$, for a given lot of liquid product is assumed to be 3 times a random variable that is distributed as a Weibull distribution, given by Equation F13, with appropriate parameters, $\mu$ and $s$, given in Table F15. Given a level $x$, the number of cells in a volume of $v \mathrm{ml}$ is assumed to be a random variable distributed as a Poisson distribution with parameter (and expected value) equal to $v x$.

The uncertainty is quantified by generating values of $\mu N$ and $s N$, where ( $\mu N, s N$ ) is distributed as a bivariate normal distribution with mean $=(\mu, s)$ and covariance matrix, given in Table F13 (as standard errors and a correlation).

## Attachment F1: Analyses of valve effect

Two analyses for evaluating the relationship of MPN with sample collection sites from a valve were performed. The first analysis evaluates the relationship of the maximum MPN within plants with the valve indicator variable. The second analysis is based on the within plant correlation of the MPN values, and on an indicator variable with respect to the sample being collected from a valve.

## First Analysis

Given $n$ samples per plant, where $n_{v}$ of them were sampled from valves, then, if there were no valve effect, the probability that the maximum MPN would be from a valve sample is $n_{v} / n=p$. Let $\delta$ be the indicator variable that the maximum MPN if from a valve sample. Then under the null hypothesis of no valve effect, the expected value of diff $=(\delta-p)$ is zero. The quantities diff were computed for all plants, and a weighted sum of them was computed, where the weight is equal to, $w=1 /(p(1-p))$. The variance of the weighted sum, assuming the null hypothesis is true, is the sum of the weights. Taking the ratio of the weighted sum of diff, to the square root of the sum of the weights yields a $z$-value, $z$, which provides a test for a significant valve effect.

This test can be expanded slightly by considering the number of samples from valves among the samples with the two highest MPN values. Assuming no valve effect, the probability of $j$ samples collected from valves being among the two samples with the highest MPN values is based on the hypergeometric distribution,

$$
\mathrm{p}_{\mathrm{j}}=\frac{\binom{\mathrm{n}_{\mathrm{v}}}{\mathrm{j}}\binom{\mathrm{n}-\mathrm{n}_{\mathrm{v}}}{2-\mathrm{j}}}{\binom{\mathrm{n}}{2}}
$$

The expected value of the number of samples collected from valves among the samples with the highest two MPN values, ${ }^{*}$, is $E(*)=2 p$, and the $\operatorname{var}(*)=(n-2) 2 p(1-p) /(n-1)$, where, as above, $p=n_{v} / n$. Thus, the weighted sum of $\operatorname{diff}_{2}=*-2 p$, with weights equal to the inverse of $\operatorname{var}(*)$, offers a test statistic, $z_{2}$, for a valve effect. In case of ties, the average of the valve indicator variable was used in the count of the number of samples from valves.

The above two tests were applied to different aggregations of data: (ii) all data; (ii) excluding data from risk category 1; (iii) for all data in risk categories 2 and 3; (iv) for all data in risk categories 4 and 5; and (v) risk category 1. $P$-values reported below are one-sided significance levels.

1. All: $z=0.66, P$-value $=0.26 ; z_{2}=0.66, P$-value $=0.25$
2. Risk categories 2-5: $z=0.80, P$-value $=0.21 ; z_{2}=0.42, P$-value $=0.34$
3. Risk categories 2-3: $z=0.24, P$-value $=0.41 ; z_{2}=0.13, P$-value $=0.45$
4. Risk categories $4-5: \mathrm{z}=0.42, P$-value $=0.34 ; z_{2}=0.25, P$-value $=0.40$
5. Risk category 1: $\mathrm{z}=0.13, P$-value $=0.45 ; \mathrm{z}_{2}=0.58, P$-value $=0.28$

## Second Analysis

Assume random variables, $x$ and $y$, measured on samples, where $x$ is the valve indicator variable (= 1 when collected from a valve, 0 otherwise), and $y$ is the MPN. To determine if there is a significant correlation between $x$ and $y$, within plants, the average of the ranks of the values of $y$ for valve samples is compared to the average rank, $(n+1) / 2$, where $n$ is the number of samples within a plant. Specifically, the statistic computed for each plant is

$$
\begin{equation*}
\mathrm{d}_{\mathrm{k}}=\left(\overline{\mathrm{m}}_{\mathrm{k}}-\frac{\mathrm{n}_{\mathrm{k}}+1}{2}\right) \delta_{\mathrm{k}} \tag{FA1}
\end{equation*}
$$

where the index $k$ specifies plant, $m_{k}$ is the number of valve samples out of $n_{k}$ samples of the plant, $\delta_{k}=m_{k} / n_{k}$ is the fraction of samples from valves, $\overline{\mathrm{m}}_{\mathrm{k}}$ is the average rank of the of the $m_{k}$ valve samples among the $n_{k}$ values of $y$ (the lowest value being assigned the lowest rank of 1 , and the next lowest a rank value of 2 , and so forth, and ties are set equal to the average rank). This statistic is symmetric about $\delta=1 / 2$. Note that $d_{k}$ is zero when $\delta_{k}=0$ or 1 , or when all the rank scores of $y$ are the same. The variance of $d_{k}$, when the null hypothesis of zero correlation is true, assuming no ties, is

$$
\begin{equation*}
\operatorname{var}\left(\mathrm{d}_{\mathrm{k}}\right)=\left(\mathrm{n}_{\mathrm{k}}+1\right) \delta_{\mathrm{k}}\left(1-\delta_{\mathrm{k}}\right) / 12 \tag{FA2}
\end{equation*}
$$

The test statistic computed is

$$
\begin{equation*}
\mathrm{T}=\sum_{\mathrm{k}=1}^{\mathrm{K}} \mathrm{n}_{\mathrm{k}} \mathrm{~d}_{\mathrm{k}} \tag{FA3}
\end{equation*}
$$

where $K$ is the number of plants. The variance of $T$ is

$$
\begin{equation*}
\operatorname{var}(\mathrm{T})=\sum_{\mathrm{k}=1}^{\mathrm{K}} \mathrm{n}_{\mathrm{k}}^{2} \operatorname{var}\left(\mathrm{~d}_{\mathrm{k}}\right) . \tag{FA4}
\end{equation*}
$$

Plants for which there were no differences in the rank values were deleted. Hence, to gauge the significance of the value of $T$ for testing whether there is a relationship (rejecting the null hypothesis of no relationship), a z-value is computed,

$$
\begin{equation*}
\mathrm{Z}=\frac{\mathrm{T}}{\sqrt{\operatorname{var}(\mathrm{~T})}} \tag{FA5}
\end{equation*}
$$

which is compared to the percentiles of the normal distribution.
The values of $z$ computed for the different aggregations of data given above for the first analysis were negative, thus were not significant. The within plant Spearman correlations were also computed, and of the 39 correlations, 18 were negative, 20 were positive, indicating, on average, no significant within plant correlation. The table in Attachment 2 presents the maximum and second highest MPN values and whether their associated samples were from valves (=1) or not (=0). If there were two highest values, then a value of 0.5 was recorded. The within plant Spearman correlations also are given.

Attachment F2: Summary Tables for FSIS Baseline Data

Table Summary of results for each plant regarding high MPN values and sample location (Valve (=1), or not (=0)). Also, the within plant Spearman correlation of the MPN with an indicator variable of sample valve location is given. All data are included.

[^0]:    ${ }^{\mathrm{a}}$ The decision to discard this result was made after some graphs were made. There was virutally no visual effect of including the sample result. The stated conclusions in the text are made for the case when the sample result was excluded, except where noted.

[^1]:    b It is coincidence that the "worst " plant was randomly assigned an ID number of 67, the highest measured number of Salmonella in an egg was $67 \mathrm{cfu} / \mathrm{ml}$, and the number of samples analyzed by laboratory 1302 during these three months was 67. The likelihood of this happening (a common number for all three events) if the queston were considered before the study would have been assumed to be extremely low.

[^2]:    ${ }^{c}$ The transformation: $\ln (-\ln (1-W(x \mid b, c)))$ is a linear function of $\ln (x)$.
